Mr. Stanley certainly did useful service, which deserves acknowledgment, in passing on from Unyanyembe to Ujiji, and announcing to Livingstone that the supplies were waiting for him at the former place. But this service has been marred by his subsequent conduct. His duty to his employers obliged him to keep Livingstone's countrymen at Zanzibar in as much ignorance as possible, and to withhold all information; and it is for his employers, not for Livingstone's countrymen, to thank and reward him. But how is it that the lonely traveller had his mind poisoned against his warmest and truest friend, who had used every means to send him help, and through whose exertions Livingstone had actually been put beyond immediate want at Kazeh? How is it that the ungrateful message was imputed to Livingstone, that he wished all relief expeditions to be turned back? How is it that one of Her Majesty's Consuls, the great enemy of slavery, is stated to have sent down to Zanzibar for slave chains? How is it that Livingstone's letters to his friends are still detained by him to whom they have been entrusted? None of these acts were obligatory, as regards duty to the New York employers. Judging him even by his own lights, the "Correspondent" has exceeded his duties to his masters, and has proportionately injured, unnecessarily, the great traveller out of whom capital was to be made. Mr. Stanley's secrecy, and refusal to give any information concerning Livingstone and his wants, to his countrymen at Zanzibar, has been most injurious to the great traveller's interests; while the system he is now pursuing of withholding Livingstone's private letters to friends, and even his despatches to the Foreign Office, is most unjustifiable.

We must repeat that the abandonment of the Relief Expedition, on the ground that its work had been anticipated, was a very serious, and may become a very fatal, mistake. The correspondent's secret proceedings ought not to have influenced the open and clearly-marked course of the Expedition in any way. Their duty was to relieve and assist Livingstone, and nothing should have turned them from it. As it is, only a party of fifty men, commanded by an Arab, has been sent up to Livingstone, with stores, arms, and other equipments entirely supplied from the funds of the English Search and Relief Expedition. But, in a letter dated June 3, unfavourable reports have been received of the character of the man who commands this party, and it may never reach its destination.

Dr. Livingstone, it is stated, intends to continue his travels for two years longer; but it has not yet transpired in what direction he will turn. He will probably endeavour to complete the examination of the great river which he believes to be the head stream of the Nile; or he may turn his steps south, as we conjectured in a former number, and solve the interesting geographical question connected with the drainage of Lake Tanganyika. He still has a vast field of discovery before him, and his countrymen will continue to watch his proceedings with warm sympathy and interest.

NICHOLSON'S INTRODUCTION TO BIOLOGY

Introduction to the Study of Biology. By H. Alleyne Nicholson, M.D., D.Sc., &c. &c., Professor of Natural History and Botany in University College, Toronto. (Blackwood, 1872.)

THIS book is an attempt to give a general view of the phenomena manifested by living beings, and to form a sort of basis for a more detailed study of some special branch of biology. It commences with an account of the differences between living and non-living matters, and with a discussion of the nature and conditions of life; then the distinctive peculiarities of animals and plants are considered, and the principles of biological classification laid down. There follow short chapters on the elementary chemistry of living beings, on the chief physiological functions, and on the varieties of the developmental process; and disquisitions on spontaneous generation, on the origin of species, and on distribution in space and time complete the volume.

In his preface the author states that his work is intended to be elementary, and useful at the same time both to the student and the general reader. This double object he can hardly be said to have succeeded in attaining. The book throughout is just one to interest the non-scientific general reader, but not one which can be recommended as fitted to lay a sound basis of biological knowledge in the mind of a student. Instead of describing typical instances minutely, and from them deducing the laws of life, the author, with few exceptions, deals throughout in generalities. Protoplasm, for example, is described, but no detailed account is given first of such a body as an amœba, or a white blood corpuscle, which would be much more fitted to leave on the mind of a beginner a clear and definite idea of the nature and properties of protoplasm than would any abstract account of its characters in general. So, again, no typical animal or plant is described in detail; but there is a chapter on the general differences between animals and plants, and, as scarcely any character of either can be mentioned to which there are not exceptions, the result of this method can only be to produce a very dim and confused state of mind in one new to the subject.

There are, however, worse faults than this in the book. There is a general retrograde tendency in it towards the point from which physiology has of late years been progressing—that of considering the actions manifested in living bodies as due to a source of energy essentially different from that of all other actions. A curious instance of this is found in the second page of the book, where among the differences between dead and living bodies, the author cites the fact that all the actions of living bodies are accompanied by a corresponding destruction of the matter by which these actions are manifested; of

course, by destruction here he can only mean the transformation of the matter into another form, which is exactly what occurs in thousands of cases in non-living sources of force—as when a steam-engine is moved by the combustion of the coal in its furnace; and instead of being a difference between dead and living bodies, is a remarkable instance of similarity, and one which, a few pages farther on, Dr. Nicholson seems entirely to forget. Again, "Dead matter is completely passive, unable to originate motion; living matter is the seat of energy, and can overcome the primary law of the inertia of matter." This point of difference is, to say the least, by no means proven. In a certain sense dead matter cannot originate motion, it can only convert some other form of force into it; but there are very good grounds for supposing that when an animal moves its limb, and so originates motion, it does exactly the same thing: at any rate, no one is justified in making the express statement that it does not; if so, indeed, where is the need for "that destruction of matter" which accompanies vital actions, or why should an animal or plant need food at all?

Protoplasm, the author states, may be regarded as a general term for all forms of albuminoid matter—an extension of the meaning of the word which is certainly not justifiable. Few would be inclined to call the boiled white of an egg, or coagulated fibrin, protoplasm. Yet upon this definition of the word Dr. Nicholson bases an argument against the theory of those who maintain that life is one of the properties of protoplasm. He represents them as asserting that life is the "result of the combined properties of the elements which form albuminous matter," and then brings forward the fact that dead albuminous matter exists, as an argument against the truth of this statement. What is really asserted is that life is a property of protoplasm, and that protoplasm is nitrogenous compound related in chemical composition to albuminous bodies; but it would be as reasonable to call starch and dextrine by the same name because one is readily converted into the other, and because they have a similar chemical composition, as to call all albuminous matters protoplasm. But even were it admitted that protoplasm, as such, can exist in a dead state, to deny that life, under other conditions, can be one of its properties, is to deny altogether the possible existence of allotropic states of any kind of matter whatsoever; and this is what Dr. Nicholson practically does. He says, moreover, that as water is a definite chemical compound, with universally the same properties, there is no need for ascribing its properties to any assumed principle of aquosity; but that, as living protoplasm has certain properties different from those of dead albuminous matter, it is best to regard *vitality* "as something superadded and foreign to the matter by which vital phenomena are manifested." But, admitting for the moment that albuminous matter and protoplasm are convertible terms, would the author assume a principle of *phosphorosity* to account for the different properties of yellow and red phosphorus.

The author falls into the very general error of stating that plants can only build up protoplasm in the light; but certain fungi will flourish in Pasteur's solution, although kept in total darkness. The difference as regards food between animals and plants is stated in a manner calculated to mislead a beginner. It is hardly correct to say that the food of plants consists of inorganic compounds; plants have the power of building up food out of these compounds, and it is this which distinguishes them from animals; the essential nutritive processes of each are the same, and consist in the breaking up of the unstable compounds thus formed; and the nutrition of plants cannot, as stated, be narrowed to the question of the modes and laws by which these unstable organic compounds are built up.

The chapters on Classification and Homology are good; in fact, throughout the book morphological questions are much more ably treated than physiological. The account given of the chemistry of living beings is very bare. Fats are the only non-nitrogenous compounds mentioned as occurring in animals. Starch is rendered conspicuous by having the only chemical formula in the book attached to it, and that on the old system of notation.

The next chapter is one on "The Elementary Structure of Living Beings," and here the author closely follows Dr. Beale, accepting his views as to "germinal matter" and "formed material." In speaking again here of protoplasm (or as he, following Beale, prefers to call it, bioplasm), the word "contractility," as applied to the cause of amœboid movements, is objected to on the curious ground that it implies an identity in kind with the contractions of a muscle, an identity which most physiologists, we think, would readily admit. The accounts of development and reproduction are much better than the earlier parts of the book. In his account of the origin of species, the author simply states the opposing views on the subject, and the chief objections to them, but expresses no opinion of his own; in fact, for some reason, he seems desirous to be regarded as having none, for in a foot-note he asks it to be remembered that a statement of each side of the case commits him to neither. "Distribution in Space" is the heading of an interesting chapter, but that on "Distribution in Time" is very imperfect, at least in a biological sense; it contains an epitome of geology, but such questions of great interest as the succession of life on the globe, or the extraordinary persistence of certain species, as Nautilus and Lingula, are entirely ignored.

The book contains a considerable number of woodcuts, some of them very good; but on the whole it is not one to be recommended as a safe guide to the acquirement of a firm foundation of biological knowledge.

OUR BOOK SHELF

Natural History of the Year. By the late B. B. Woodward, B.A. (London: S. W. Partridge.)

It does not often fall to our lot to notice a book of this description which we can so heartily commend. The design is to interest young people in the varied productions of Nature, by taking them into the fields and woods from month to month, and pointing out the numberless objects of interest that will meet the observant eye at every turn. This is all told in a pleasant manner, and withal with a religious spirit. The author was himself a keen and accurate observer of Nature; and we do not meet with those atrocious blunders with which books intended for the instruction of children too often abound in describing the most familiar things. The book is illustrated with some extremely tasteful illustrations, one for each month, and

forms altogether a most attractive gift-book for an intelligent child.

Annual Record of Science and Industry for 1871. Edited by Spencer F. Baird, with the assistance of eminent men of science. (New York: Harper and Brothers, 1872.)

THE Americans are more fortunate than ourselves in possessing a Year-Book of Science edited by a scientific man whose name is a guarantee for the accuracy and value of its contents. The various items of information are arranged under thirteen heads, viz. (1) Mathematics and Astronomy; (2) Terrestrial Physics and Meteorology; (3) Electricity, Light, Heat, and Sound; (4) Chemistry and Metallurgy; (5) Geology and Mineralogy; (6) Geography; (7) General Natural History and Zoology; (8) Botany and Horticulture; (9) Agriculture and Rural Economy; (10) Mechanics and Engineering; (11) Technology; (12) Materia Medica, Therapeutics, and Hygiene; and (13)—a very small one—Miscellaneous, with a very brief Necrology appended. To each paragraph is added the indispensable reference to the authority. Prof. Baird's position as Secretary of the Smithsonian Institution at Washington has given him unusual facility for consulting all the leading magazines, and other scientific publications of Great Britain, France, Germany, Holland, and America, of which he has availed himself to the full. An account of the discoveries made in Italy, Sweden, Russia, and other countries of Europe, some of which are daily rising into more and more importance, has been obtained only second-hand. The whole is prefixed by a general Summary of Scientific and Industrial Progress for the year 1871, occupying sixteen pages, wherein the more noteworthy incidents in each department of science are briefly chronicled. The work is the result of great labour; and, as far as we have been able to test it, presents a very fair and accurate record of the progress of science during the year. To those who desire to possess such a record for handy reference, we can confidently recommend Prof. Baird's Year-Book as the best and most complete work in the language, and decidedly preferable to anything published in this country.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Atmospheric Effect

AN atmospheric effect, which is sometimes observed in England, displayed itself here in great beauty yesterday. The western sun had been cut off from us by an intervening ridge, while the upper atmosphere was still filled with his light. There was a good deal of opalescent haze in the atmosphere, which, had the sun shone upon it uniformly, would have presented a tolerably uniform hue. But besides the haze, small detached clouds floated in the air, and behind each of them was a sheaf of shadow, drawn through the haze. The density of these shadows varied with that of the clouds which produced them, nor was the density uniform for all parts of the transverse section of the same shadow. The parallel bars of graduated shade thus produced converged, through an effect of perspective, to a point *in the east*, exactly as if the sun were going to rise there. The display of the convergent glory was strikingly beautiful.

The same effect showed itself at Oran during one of the evenings spent there by the Eclipse Expedition. I have seen it two or three times in England (always, I think, near the coast), the last occasion being in company with Mr. Hirst at Margate.

Faraday, if I remember aright, has described this effect. There was also, I believe, a question asked regarding it some months ago in NATURE. This brief account may interest the questioner.

Bel Alp, July 22 JOHN TYNDALL

Spectrum of Aurora

IN the article on the Aurora Borealis of Feb. 4, a translation of which appears in your issue of April 25, Prof. Respighi mentions having noticed the green line of the aurora when observing the zodiacal light; also, that this line was visible—more or less defined—from horizon to zenith, in every part of the heavens.

In 1867, when Angström observed the green line in the spectrum of the zodiacal light, he also detected its presence in all parts of the sky. From his own and Angström's observations, the Professor demonstrates the identity of the zodiacal light and the aurora. This appears to me, at the least, premature. Had the spectrum appeared only where the zodiacal light was perceptible to the naked eye, there would have been reason for believing it due to that light; but, be it noticed, the green line is everywhere seen as bright as in the zodiacal light itself. We have only to suppose that in both cases auroral phenomena, imperceptible to unaided vision, were present, and the spectra seen by Angström and Respighi are at once accounted for.

With all due deference to the great authorities just named, I may state that at Mr. Lockyer's request I have been observing the zodiacal light with a spectroscope since last December, and brilliant as the phenomenon has frequeently been, I have hitherto failed to detect the slightest appearance of bright lines or bands. A faint diffuse—to use Capt. Herschel's nomenclature—spectrum, about as intense as that of a bright portion of the "milky way" is all I have yet obtained.

The spectroscope used is one of Browning's 5 prism ones.

Camp Charmadi, South Canara, June 23

Kinetic Energy

IF the loss of kinetic energy in water which has flowed from lower to higher latitudes is due to friction, and represents work consumed in overcoming friction, as Mr. Croll maintains, how is the gain of kinetic energy in water which has flowed from higher to lower latitudes to be accounted for?

Mr. Croll's answer to this question will be awaited with interest. J. D. EVERETT

Belfast, July 27

Bree on Darwinism

I AM very much obliged to Mr. Alfred R. Wallace for pointing out some errors of the press, and some of hasty writing which were not corrected in the proofs, of my work upon the "Fallacies of Darwinism."

I do not think, however, he has adduced anything which justifies his virulent condemnation of a work which he has not ventured to criticise, and I do not, however, write for the purpose of making any complaint. I hope to have the opportunity of answering his remarks upon another occasion.

My object in writing is, however, to request you will give me the opportunity of pointing out that no blunder which I have made is so great as that committed by Mr. Wallace himself, when he states that Darwin's imaginary human ancestor with cocked ears and a tail should have been evolved after the incoming of catarrhine monkeys, which creatures, by what I presume some might call anticipatory retrogression of development, have actually been placed by Mr. Darwin in the human pedigree, and separated from their congeners the platyrrhine or new-world monkeys, because they had so far reached the human goal to which they were tending as to lose their tails.

Also according to Mr. Wallace the cocked-eared creature must have not only re-evolved a tail, but have gone so far backward as to lose the human-shaped, and gain the canine-like "cocked ear." C. M. BREE

Colchester, July 27

Volcanoes and Earthquakes

IT is generally admitted that an earthquake is due to the passing of a sensible wave through the earth's crust. It has also been observed that the occurrence of earthquakes is generally associated with eruptions from volcanic vents, usually in the neighbourhood, but not unfrequently at considerable distances. Now it is evident—and it has struck all observers—that there

must be some connection between the two classes of phenomena. The nature of this connection has been differently explained by different writers. But the purpose of this note is not to criticise existing theories, but to propose one, which I believe to be new, and to be capable of explaining why a sudden volcanic eruption must ordinarily be accompanied by earthquake shocks of greater or less violence (not necessarily always sensible), and why earthquakes may occur without any contemporaneous outburst.

In the preface to his "Physikalische Geologie," Bischof suggests that the phenomena observed in the laboratory should be taken as our guides to explain what happens in nature. Let us see, then, if in the laboratory we meet with any phenomena analogous to volcanoes and earthquakes.

When a reaction has to be performed in a sealed tube, and it is expected that much gas will be evolved, and consequently the pressure in the tube be much increased, it is one of the commonest precautions to draw out the tube to a capillary orifice before closing it. When this precaution has been neglected, and even although the point be allowed to blow itself out in the flame of a lamp, an explosion not unfrequently attends the attempt to open it. Let us consider the circumstances.

We have a tube whose walls are being pushed out by a very high pressure from within, which, however, it resists; but at the moment that this pressure is suddenly relieved at one point, the tube bursts. What is the cause of the explosion? It clearly cannot be the mere reduction of pressure. As long as the pressure was equally distributed over the walls of the vessel, we have seen that it was successfully resisted; as soon, however, as it was suddenly relieved at one point, a great inequality in the tension of the gas in the immediate vicinity of this point would be the result, the gas immediately at the opening assuming at once the atmospheric pressure, while that at, say, the eighth of an inch from it is at the tension of the gas in the tube. The practical effect of this sudden inequality of pressure would be to produce a tug on the mass of elastic fluid, which would cause the walls momentarily to tend to collapse, and this tendency to collapse would be transmitted through the glass as a wave. This wave would to a certain extent distort, and therefore weaken, the walls; and consequently, if the pressure inside were great enough, it would burst them; if not, the only effect would be that a shock would traverse the walls of the vessel, and the pressure would relieve itself by the orifice.

Now, suppose the vessel to be a subterraneous cavity containing an atmosphere of very great tension, and that suddenly the envelope gives way at one point, what will be the result? Just as in the case of the glass tube, the sudden relief of pressure will, in the way indicated above, cause the walls to experience a momentary collapsing impulse, which will be propagated as a wave until extinguished by the imperfect elasticity of the crust. The sudden outburst will be a volcanic eruption, and the consequent collapsing shock will be an earthquake, which either will or will not be accompanied by rending of the crust, according to the strength of the walls and the greatness of the pressure.

It is, however, not necessary that there should be a visible volcanic eruption. For, suppose two such subterraneous cavities at different pressures, separated from one another by a wall weaker than that which separates either of them from the outside of the earth; then, if the pressure in the one becomes so great as to burst the barrier between the two, the result will be an earthquake. And similarly, the pressure in the two thus united cavities may go on increasing until they burst into a third, and so on until they come to a vent, which is either open or weak enough to yield to the pressure. In this way an earthquake and an eruption may be in intimate connection with one another, although a considerable interval of time intervene between the occurrences, and the localities affected be at great distances from each other. And it is possible that some connection of this kind may have existed between the earthquake of Antioch and the eruption of Vesuvius, both having been extreme in their violence. Indeed, the whole series of disturbances, commencing with the earthquake in California and terminating with the eruption of Vesuvius, noticed by Mr. Corfield in NATURE of May 23, may possibly find an explanation under this theory.

The effect of sudden relief of pressure in weakening the walls of vessels explains many cases of explosion which otherwise appear anomalous. Thus, high-pressure boilers have been frequently observed to burst at the moment when the engineer turns on the steam.

In conclusion, the above sketched theory assumes nothing but what we know to be fact. We know that, at least in the neighbourhood of volcanoes, there must be subterraneous cavities whose atmosphere is at an exceedingly high-pressure, for we not only see it emitted from the vent, but it projects enormous masses of rock high into the air, thus testifying to the energy with which it was endowed. Further, given this high-pressure atmosphere, it is certain that, on its being suddenly relieved, it would communicate a shock to the crust, and this, on being felt outside, would be described as an earthquake. I think it is therefore clear that some earthquakes must be produced in this way. Of course this does not include the possibility of there being other causes of concussion which might produce similar effects.

Edinburgh, June 10 J. Y. BUCHANAN

On the Cohesion of Figures of Creosote, Carbolic and Cresylic Acids

WITH reference to the note by Mr. J. H. Spalding contained in NATURE of June 13, I am reminded by my friend Mr. Rodwell that some five or six years ago I showed him the cohesion figure of carbolic acid. A crystal of this acid was taken up on the end of a platinum spatula, and gently delivered to the surface of clean water contained in a clean glass; the crystal gave a few jerks, then suddenly liquified, and displayed its highly characteristic figure so well described by your correspondent. I may further remark that I showed this figure in the chemical section of the British Association, at Manchester, in September 1861, and a drawing of it is given in the plate which accompanies my paper in the *Philosophical Magazine* for October of that year. In this paper it is described as "an exaggerated form of the figure of creosote; the water seems to tear it to pieces; the crispations are amazingly active, and the disc quickly breaks up and disappears. Indeed, while a drop of creosote will endure five minutes on the surface of an ounce of distilled water in a small glass, a drop of carbolic acid will last only a few seconds on the same quantity of water. The cohesion figure is however quite characteristic of the substance, and cannot be for a moment mistaken for any other substance that I have examined."

Creosote, carbolic and cresylic acids, and newly-distilled oil of cloves, give remarkable figures of the same type, each of which is characteristic of the substance.

Mr. Spalding remarks that warm water destroys all action, by lessening, as he supposes, the adhesion of the liquids. I am sorry to have to object to this remark, but I have no doubt that Mr. Spalding was led to make it by employing unclean water or an unclean recipient. If distilled or even ordinary tap water be heated over a spirit lamp in a clean flask, and be poured into a clean vessel, the surface of the water is active at all degrees between the temperature of the air and just below boiling. On the surface of cold water a drop of creosote passes through the following changes:—(1) As soon as the drop is placed on the surface of the water the figure is formed for an instant; (2) it splits open and forms a kind of brittle arc, which (3) is shivered into a number of separate discs, each of which is a perfect cohesion figure of creosote. These figures perform their evolutions independently of each other, sailing about with rapidity, but never clashing with or disturbing each other. In the *Philosophical Magazine* for June 1867, figures are given of these different phases of the figure.

Now, if the water be heated to 100° Fah., or from that to 150°, a drop of creosote deposited on its surface produces a good active figure, but it does not split open or form the brittle arc above referred to; it sails slowly over the surface, firing off volleys of small globules in radial lines, and only when much wasted does it split into smaller systems. All this is what might be expected from the diminished surface-tension occasioned by the heat. Indeed, it is a beautiful illustration of the slight diminution of surface-tension in hot water as compared with cold. In consequence of not splitting open, the duration of the figure is greater on the surface of hot water as compared with cold.

Carbolic and cresylic acids are also very active on hot water, at all temperatures up to 210° Fah. C. TOMLINSON

Highgate, N.

Hereditary Instinct

WILL you allow me to recount to your readers what appears to me to be a striking instance of the transmission of impression in animals?

A few years ago I bought in Skye a perfectly uneducated Skye terrier. The first accomplishment which I taught him was

that of "sitting up"—an accomplishment which he had great difficulty in acquiring. This was not owing to any stupidity on his part, for when he had once passed over this *pons asinorum* of dog-performances, he proved to be a very clever animal, and learnt many other tricks with great ease. He appears, however, never to have forgotten the pains which were taken to teach him his first trick, and to have judged therefrom that there is great merit in sitting up. Not only does he rely upon this as a last resource to move me to take him out, or not to whip him, but he judges that it must soften even the heart of an india-rubber ball. Sometimes when annoyed at his playing with this, his favourite toy, I have placed it on a chimney-piece, and turned my attention elsewhere. On looking round again I have seen my dog sitting up to the india-rubber ball, evidently hoping that it would jump down and play with him again. Perhaps he looks upon this ball as "animated by a living essence" (*vide* Chap. ii. of Darwin's "Descent of Man").

My dog is now the father of a family, and one of his daughters, who has never seen her father, is in the constant habit of sitting up, although she has never been taught to do so, and has not seen others sit up. She is especially given to this performance when any other dog is being scolded. Whether this is an instance of helping a fellow animal, of which Mr. Darwin gives such curious examples, or whether the dog simply hopes to avert the passing storm from her own head, the fact appears to me patent, that this dog has inherited the impression that sitting up has some special virtue for turning away wrath.

L. HURT

Alexandra Hotel, Harrogate, July 27

RECENT OBSERVATIONS IN THE BERMUDAS

AS my late visit to these islands has placed me in possession of facts relating to their original aspect of a somewhat conclusive nature, I deem it advisable to communicate such in a brief form, instead of awaiting the time requisite for the preparation of a more elaborate paper on the subject.

On previous occasions I have always regretted my inability, from lack of time, to look more closely into their geological character in the hope of discovering some satisfactory clue to their primitive condition. I was aware that in different parts of the islands road cuttings and well borings had revealed layers of red earth at certain depths below the surface, the consistence of which was similar to that now forming the present surface soil, and it did not require much force of imagination, after personal inspection, to conceive that such layers of red earth were first formed by the decomposition of vegetable matter which grew upon former surfaces, and became covered to their respective depths by accumulated masses of drift sand, which from natural causes hardened into more or less compact sandstone. But these different layers were but a few feet beneath the surface, and so, although interesting as throwing light upon the gradual elevation of the land by drift material forming over them, yet they afforded no evidence of a contrary nature—viz., the *submergence* of the Bermuda group. Indeed, I have always been led to suppose from appearances that the whole group was the result of an upheaval of the ocean bed slightly above the water level, and a gradual elevation afterwards by means of drift matter aided by the consolidating agency of reef-building zoophytes encircling the whole with a barrier reef, and by isolated patches gradually filling up the space within. The investigations, however, which I have recently been able to make, tend I think to prove that the barrier reef encircling the islands which has hitherto been considered an atoll is merely the remnant of the more compact calcareous rock which formed the shore of a much more extensive island group than that now existing.

My views in this respect are borne out by the following facts:—The barrier reef, as far as I have inspected it, is merely ordinary calcareous rock coated with serpulæ, nullipores, &c., the reef builders only working in the sheltered waters between the reef and the shore in three to eight fathoms. About two years ago submarine blastings were carried on at the entrance of Hamilton Harbour, and at a depth of over six fathoms a cavern was broken into which contained stalactites and red earth. Again, within the last few months, I have, through the kindness of his Excellency Major-General Lefroy, C.B., F.R.S., the present Governor, been placed in possession of still more satisfactory information. During the past two years extensive submarine blastings have taken place inside an artificial harbour, situate at the western extremity of the islands, for the purpose of forming a bed of sufficient depth for the reception of the "Great Bermuda Dock," which attracted so much attention off Woolwich when launched some three or four years ago. The excavations extended to a depth of fifty-two feet below low water mark. At forty-six feet occurred a layer of red earth two feet in thickness, containing remains of cedar trees, which layer rested upon a bed of compact calcareous sandstone. Here we have the first satisfactory evidence of the submergence of an extensive deposit of soil once upon the surface, and that to the depth of forty-eight feet below the present low water level, which consequently grants an equal elevation above it in former times. Now, on carefully surveying the Bermuda chart, we find that an elevation of forty-eight feet will bring the whole space which intervenes between the present land and the barrier reef, now covered with water, above the water level. This attained, what more is required to prove the former extent of the island group before the present submergence to the present barrier reef? But having clearly ascertained beyond doubt that the Bermudas were once forty-eight feet higher than at present, will any one be bold enough to deny them a greater elevation? I have reason to believe that they once extended in a south-westerly direction—not only out to the reef, but to a greater distance. There are some rocky ledges about twenty to twenty-five miles from land in that direction, known as "The Flatts," lying in about thirty-five to forty fathoms water; and, singularly enough, in the very oldest maps of the Atlantic, copies of which I have consulted in the British Museum, "The False Bermudas" are put down about this position. Is it unreasonable to suppose that a low lying group of islets did actually exist here in former times? Again, in Smith's "History of Virginia," which gives an excellent account of the islands in the early part of the seventeenth century, it is stated among other notes upon their natural history that flocks of crows, no doubt the same species (*Corvus Americanus*) which now inhabits them, were in the habit every evening of winging their flight from the main island towards the north. This observation, which from its simplicity I should the more readily believe to be a true statement, would clearly prove the existence of land in that direction at no great distance; for the habit of this bird to leave its roosting place for distant feeding grounds during the day, to return at random, is one of its well-known characteristics.

Taking these matters into consideration, I see everything to support the supposition that the Bermudas once presented a much more extensive aspect than they do at present, and certain additional evidences which I hope to bring forward shortly in a collected form will, I conceive, tend to confirm my impression that the restricted terraqueous area lying within the limits of the outer barrier reef is merely the summit of one of a range of islands which extended in somewhat semicircular form for a distance of seventy or eighty miles, and which have suffered submergence to a depth only to be correctly ascertained by borings, which might be successfully accomplished under the auspices of the Imperial Government at a trifling expense.

J. MATTHEW JONES

SPONTANEOUS APPEARANCE OF EXOTIC FORAGE PLANTS IN FRANCE AFTER THE LATE WAR

IN a communication lately made to the Paris Academy, M. Vibraye states the fact of certain exotic forage plants having appeared in considerable numbers in the central parts of France, after the stay of the army in these localities. He gives the following account of these plants :

"Their appearance, no doubt, results from forage supplied from abroad, the seeds of which had fallen into the ground. At the present time several Mediterranean plants, (chiefly Algerian), having braved the cold of an exceptionally severe winter, are being largely propagated, forming extensive meadows, and changing soil that was formerly arid, and produced no vegetation of importance, to veritable oases. This may probably lead to the definitive introduction of a large number of plants into a more northern region than that which they appear naturally to occupy and to prefer.

"The first notion of the possibility of such plants being brought into French soil, through the fodder consumption of the army, arose in 1870. A botanist of Strasburg, M. Buchinger, wrote to M. Franchet (conservator of my collections) some days before the investment of the place that, on examining the fodder which was being given to the horses, he had found in it forty-four species of plants belonging to the Mediterranean region, and most of which were Algerian. He suggested to M. Franchet to make observations, and see whether some of these plants would not appear in the soil. The prediction was verified ; and in April 1871, M. Franchet found two exotic centauries, and communicated the fact to M. Nouel, the director of the Orleans Museum. Since then these two botanists have made minute researches on the subject, and have discovered many more such plants. This is, briefly, the history of the discovery. The places where the phenomenon has been best observed are in the Department of the Loire-et-Cher : (1) on the right bank of the Loire, near the railway ; (2) on the left bank, the country about Blois. Then, too, in the Communes of Cour, and more especially of Cheverny, which districts were successively occupied. Observations have also been made at Orleans, on the Boulevard Saint Jean, and the Isle of Arrault.

"I shall best recount these observations by giving them as they were written down in the order of date.

"On the 18th March, 1872, certain new plants, observed the previous year at Blois and Orleans, had increased considerably on arid soil, which formerly bore only some poor and stunted herbs. Each of the districts furnished about 90 to 100 species. But the species were not the same in each district, and the total number of species met with, was 157, belonging to twenty-one families, as follows :—

Ranunculaceæ	3	Compositæ	28
Resedaceæ	1	Convolvulaceæ	1
Cruciferæ	8	Borragineæ	1
Sileneæ	5	Verbasceæ	1
Alsineæ	1	Plantagineæ	1
Lineæ	1	Labiatæ	2
Malvaceæ	8	Amaranthaceæ	1
Geraniaceæ	7	Salsolaceæ	2
Leguminosæ	52	Polygoneæ	1
Umbelliferæ	4	Gramineæ	28
Dipsaceæ	1		
		Entire total	157

"The first observations could not be considered quite definitive, and there were some species which it was, perhaps, a little premature to determine ; but after deductions made on this account there remained 140 species ; a number much larger than that of the plants on the best meadow lands in France, which, according to botanists, do not furnish more than 90 to 100 species.

"It will be seen that the Leguminosæ (52 species) form about one-third of the whole, while the Gramineæ and the Compositæ form each about one-fifth (28 species). Among the Leguminosæ trefoil and lucerne predominated ; 12 kinds of trifolium were counted, and 10 or 11 of medicago ; the 28 Compositæ belonged to 21 genera, and the 28 Gramineæ to 16 different genera. Two thirds of these forage plants are annuals or biennials.

"On the 12th April a fresh examination of the Blois district showed that many of the species, and especially the medicagos, had not only persisted but been propagated from seeds. Unfortunately for the full development of this, the land was used as a pasturage for sheep, which devoured the plants in proportion to their growth, and uprooted many with their feet, the arid soil having little cohesion. At Cheverny, where I had enclosed certain spaces, several Algerian plants attained a superb growth ; among these, trefoil, melilot, phalaris, and alopecurus.

"By the 19th April it was evident that not only a large number of species had persisted, but that from being rare and poor the previous year, they had developed to a wonderful extent, notably the *Alopecurus utriculatus, Vulpia ligustica, Avena barbata, Trifolium nigrescens, Trifolium isthocarpum*, all southern and forage plants. The *Medicagos sphærocarpa* and *pentacycla* reappeared in great abundance where they had escaped the cattle, or the sickles of women in search of herbs. It was difficult to persuade these herb-gatherers to a temporary self-sacrifice with the view of ultimate advantage in respect of forage.

"On the 27th April my attention was called to the large number of annuals and biennials disseminated. The annual plants, which De Candolle called monocarpian, because they terminated their existence by a perfect and unique fructification, are invariably reproduced by the dissemination of their seeds when they have come to maturity ; the individual dies, while the species becomes perennial ; which duration, on the other hand, is temporarily acquired by the individual, when a scythe, or the grazing of cattle, retards the last and indispensable phase of the plant's existence.

"At this date, April 27, trefoil and lucerne promised to be very abundant in the Blois district. By the 1st of May an incessant appearance of new species was noticed ; and it seemed beyond a doubt that before the end of the season the four localities of Blois, Cheverny, Vendôme, and Orleans, would furnish not fewer than 200 species, of which 170 at least were peculiar to meadows and pasture lands.

"On the 3rd May a new fact presented itself. During the war a forage depôt had stood at the side of the market place of Cour Cheverny, but last year no appearance of any new plant had been discovered there, notwithstanding careful search. On the 3rd some twelve species of foreign forage plants made their appearance, and others were expected. This shows that the seeds had remained in the soil for sixteen months without alteration of their germinating properties. This is an interesting fact, and a corollary of a law of rotation observed in all natural meadows, viz., the temporary disappearance of dominant species, yielding for an indeterminate period to new types, which they by-and-by come to displace, when they meet with certain favouring atmospheric influences, not very fully understood.

"The Algerian plants withstood successfully the frost of the 12th May, which did much damage to our vines and the shoots of certain trees, especially indigenous conifers."

M. Vibraye, in closing his note, speaks of the above phenomena as being quite an event. It is not the ephemeral appearance of a few plants sparsely disseminated, raising the problematical hope of fixing in the soil a useful vegetable—it is an exodus ; the migration, not of a modest *florule*, but of a *flora*, independent and complete. It is, in a word, a treasure which the central districts of France are called on to study and to appropriate. He argues that the propagation of these plants should not be left to chance, but that human skill should be brought to bear on it.

A. B. M.

THE HURON RACE AND ITS HEAD FORM *

THE tribe of North American Indians known by the name of Hurons appears, when first brought to the knowledge of the intruding French, to have been settled in palisaded villages around Lake Simcoe, in Western Canada. They called themselves Ouandots or Wyandots. They consisted of four septs or nations; the Attignaouentans, or Nation of the Bear, the chief member of the league, the Attignenonghaes, the Ahrendarrhonons, and the Tohotaenrats. They occupied thirty-two villages when visited by the Jesuit missionaries in 1639. Brébeuf reckoned them in all in 1635 at 30,000, and they were stated in the *Relation* of 1660 at 35,000. The Hurons with other tribes dwelling at this time in Canada, were fully acquainted with agriculture, as Dr. Wilson shows, wholly independent of any European influences. The Hurons became known to the civilised world only in their decline, and immediately before their extirpation. They were then in alliance with the Adirondacks and other Algonquins, against their common Iroquois enemy. This latter is the name of a league of tribes often designated the Indians of the Five or of the Six Nations. This confederation of tribes during the seventeenth century was the great aggressive nationality of the American Continent, which subdued, exterminated, or incorporated the other tribes with which they came into contact. Cartier discovered Canada in 1535. Champlain explored and settled it subsequently. He visited the Huron country in 1615, and appears to have found the whole district between the river Ottawa and Lake Simcoe to have been almost depopulated, which is to be attributed to the implacable enmity of the Iroquois. This region, "in the latter part of the seventeenth century became the scene of the indefatigable operations of a succession of missionary fathers, some of whom divided their self-denying labours between them and their Iroquois foes, and several suffered martyrdom at the hands of the savage nations whose conversion they aimed at. Minutely detailed maps and narratives of exploration and missionary labours, record the progress of discovery in the region around the Georgian Bay, and illustrate the topography of the Huron villages so accurately, that most of their sites have been identified in recent years. Dr. J. C. Taché devoted such leisure as he could command during a period of five years, prior to 1865, to a minute exploration of the Huron country. Following in the steps of early writers whose accounts are preserved in the *Relations* of the Jesuit Fathers, communicated to the Provincial of the Order at Paris, from 1611 to 1672, he was able to determine the sites of their principal villages, and to explore their cemeteries, abounding with implements, weapons, and numerous other archæological records of native arts and habits.

The sepulchral rites of the Hurons were of a peculiar character. Their dead were primarily exposed on raised biers, as is still done by the Cowlitz, Columbia River, and other tribes; and around them were hung implements and personal ornaments of the deceased, with the tributes of affection of the survivors. In the case of death on a journey, or on the war-path, the body was temporarily interred. But the place of sepulture was carefully noted for future transfer of the bones to the general cemetery of the tribe. At intervals of ten or twelve years the great "Feast of the Dead" was celebrated by each nation of the Huron confederacy. One of these grand ceremonies, performed at Ossosane, the chief town of the Bear nation, on Nottawasaga Bay, was witnessed by the Jesuit missionaries in 1636. Skeletons were gathered from old scaffoldings, or disinterred from distant graves, by the relations of the deceased. The bones of those more recently dead were cleansed of the remaining flesh, and then wrapped carefully in skins, and adorned with prized decorations. The old wampum-belts, pipes, kettles, bows, arrows, axes, beads, and shells, which had been hung around the bier, or deposited in the grave, were anew gathered together, and the whole were brought to the appointed cemetery. There a great trench was dug, and carefully lined with beaver skins and other furs, and after a funeral-feast, with lamentations by the women, and orations by some of the chiefs in praise of the dead, the relics of mortality were cast into the trench, along with the funeral offerings. Only in cases of recent death were the corpses wrapped in furs and deposited entire; and then, amid the shrieks and wails of the mourners, the earth was thrown in, logs and stones piled over the cemetery, and with a closing funeral chant, the great "Feast of the Dead" was brought to a close.

Owing to the systematic practice of thus gathering together the remains of the Huron dead, one or more ossuaries were to be looked for in the vicinity of each village. Dr. Taché explored sixteen of them in all, containing from 600 to 1,200 skeletons in each. From the same depositories he also recovered numerous specimens of native art, and illustrations of the various customs of that people. From the same cemeteries, Dr. Taché selected upwards of eighty skulls, most of which with the accompanying relics he deposited in the museum of the Laval University, at Quebec. Another inquirer, Mr. John Langton, a writer "On the Early Discoveries of the French in North America," conceived the same idea of tracing the villages of the Hurons. He succeeded in tracing out the sites of fourteen villages, in many of which the remains of houses and stockades could still be recognised. He even succeeded in identifying St. Ignace, a village at which the principal chief and nearly 100 of the Iroquois warriors fell before the Hurons were overpowered, and the miserable remnant bound to stakes to perish in the relics of their blazing settlement. St. Ignace was finally destroyed in 1649. Some few Hurons found refuge among the Petuns, Neutres, and Eries, and shared in the subsequent fate of these tribes. The fortunes of another body of the fugitives illustrate the Indian practice of adoption into another tribe. The survivors of two Huron towns opened negotiations with their Seneca foes, and were adopted into the Seneca nation. And another band, under the conduct of the Jesuit missionaries, made their way to Quebec, then subsequently settled at Lorette, on St. Charles's river, where their lineal descendants remain, their blood mingled with that of European colonists, and speaking a French *patois*, and where they still share in certain Indian funds distributed to them by the Canadian Government.

The admixture of blood has nearly effaced the genuine characteristics of the Hurons of Lorette, although this tribe originally does not appear to have been exposed in the same degree to the adoption of prisoners of other tribes as that of the Iroquois Confederacy. Hence the remains recovered from the ancient cemeteries of the Huron country have a special value for ethnological purposes; they are the most authentic relics of the pure Hurons. As an instance of the readiness with which the aggressive Iroquois received those of other races into their tribe, Dr. Wilson speaks of an old squaw of pure white blood, reputed to be nearly a century old, who survived till recently, if she be not still living, as a member of the Mohawk tribe, of the Bay of Quinte. Her Indian name is Ste-nah, supposed to be a contraction of Christiana, and she is described as a full-blood Sko-ha-ra, or Dutchwoman. When the author last heard of her, in 1868, she was living with her granddaughter, the wife of a Mohawk chief.

The learned author is probably the solitary instance of a well-instructed British Craniologist being transferred to American soil, who has continued his favourite pursuit in the new field with perseverance. Dr. Daniel Wilson has given numerous and valuable proofs of his abiding taste for, and persistent investigation in, this fundamental branch of anthropological inquiry. In his compre-

* The Huron Race and its Head Form. By Daniel Wilson, LL.D. 3 plates.

hensive "Pre-Historic Man," which has reached a second edition, he has already paid a good deal of attention to the Huron tribe, as well as to other tribes of the North American Indians, which, in fact, constitutes one great feature of value in the work.

In this volume Dr. Wilson gave a table of the measurements of thirty-seven Huron skulls "obtained from Indian graves to the north of the water-shed between Georgian Bay and Lakes Erie and Ontario." The great purpose of the construction of this table, as of so many other investigations made by the author, was to test the truth of a doctrine which had been generally received and was in great measure endorsed by Dr. S. G. Morton, who produced the classical "Crania Americana." This doctrine, in few words, is that the American race is almost uniform in its head characters from one end of the continent to the other, and that the American typical cranium is distinguished for its shortness. To Dr. D. Wilson's persevering researches we must allow the merit of having shown that there is much variety in native American races, and that in their skulls there is considerable diversity of length. This may be very confidently asserted, without conceding to him an agreement with his assertions respecting the long skulls among the ancient Peruvians; for he evidently mistook the deformed crania of these people for the representatives of the natural form of their heads.

In the table of the measurements of thirty-seven human skulls referred to, it was seen that their length varied much. If we exclude the "Barrie skull," No. 23, which appears to be quite aberrantly short, and it is thought has been distorted by art, we find their longitudinal diameter to vary from 7·9 inches to 6 8 inches, or above an inch. The cephalic indices of these two examples, unfortunately, cannot be accurately calculated from Dr. Wilson's measurements. One of his items of measurement is "F. D." frontal diameter, which he says in this memoir "is taken from the point of junction of the frontal, parietal, and malar bones." This latter is probably an inadvertence, and should be sphenoidal bone, as the malar bone nowhere joins the frontal.

Since this table was constructed, thanks to the efforts of Dr. Taché and others, Dr. Wilson has had the opportunity of measuring many more Huron skulls. He now says: "The sight of upwards of seventy skulls, all derived from the cemeteries of a single tribe or nation, is a peculiarly interesting study to the ethnologist. But to one at all impressed with the uniform persistency of a specific ethnical type, the result is far from satisfactory." They are seen to vary materially, and especially in length. The skulls of women present a decided projection of the occiput, and here we may be permitted to allude to Dr. Wilson's plates. The first, which gives shaded profile views of the calvaria of a Huron man and woman, is excellent and very characteristic. Plate II. is lettered, "Long Huron skull, male." It is often very difficult to determine positively the sex in crania, but in this example it seems doubtful whether the plate does not exhibit the calvarium of a woman. We incline to think that it does. The long oval, vertical view is quite apparent and unquestionable. Plate III. is an undoubted instance of a "Long Huron skull, male."

Dr. Wilson, after attesting the great range of diversities in the Huron skulls he has seen, concludes in these noticeable terms: "But the specialties of the whole, in their front aspect, suggest a greater uniformity in their physiognomy than in cranial conformation. The nose is in most cases large and prominent; the superciliary ridges in the males are strongly developed; and a common ethnical character may be traced in the full-face as a whole, including the massive broad cheek-bones and superior maxilla; as well as in the indications in the greater number of a tendency towards a pointed apex, or meeting of the parietal bones at an angle at the sagittal suture." Perhaps this is as much as anyone can reasonably expect, even when divergences are to be acknowledged in the proper calvarial form. And it is difficult to conceive that these divergences are so utter and so puzzling as to prevent our seeing any constancy among them.

Dr. Wilson, in showing that some tribes of American Indians are characterised by long or dolichocephalic heads, still admits that other tribes have short or brachycephalic heads. This must be conceded, as well as that Morton's generalisation was too comprehensive and too literal. Former sweeping conclusions as to dolichocephaly and brachycephaly cannot now be sustained. It was long since seen that among the crania of any extended race of people, as the ancient Britons, there is much variation as to length, indeed that a scale might be exhibited from the shortest to the longest, in which the numerous intermediate lengths intervene to fill up the ascending degrees of the range. This truth is now more than ever apparent, since the elaborate researches among the skulls of Italian races by the distinguished anatomist, Prof. Luigi Calori, of Bologna. He has conclusively shown that there is much more dolichocephaly among the races of Italy than was previously known.

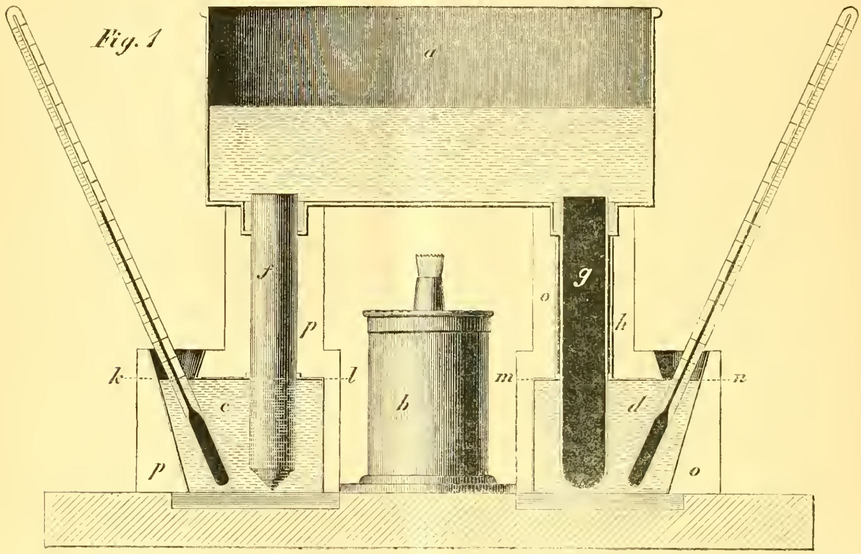
Much of the difficulty that craniologists have encountered in the study of the head-forms of different races, has had its foundation in the too rigid rules which they have assumed these forms to observe. Dr. Wilson's labours have served well to illustrate this point in reference to the American races. Were this the proper place, it would be easy to point to examples of the futile labours which have resulted from these self-imposed rules. How many learned controversies have been entertained to determine the race of a man whose only existing relic was his lower jaw? On finding that such rules cannot be fixed and defined in so absolute a manner, it has often been the case that other inquirers have lost confidence in craniology itself. This is a transition from one extreme to another. More moderate expectations from the doctrine of skull-forms would have prevented confidence in their value from being so often shaken. Larger views must be taken, but these are quite compatible with our knowledge, without any necessary leaning to the meanderings of the evolutionary hypotheses alluded to by our author.

CONDUCTIVITY OF MERCURY

IT was shown in a previous article * that solar intensity cannot be accurately ascertained by the thermoheliometer employed by Père Secchi, owing, among other causes, to the imperfect conductivity of the mercury in the bulb exposed to the sun. Meteorologists, however, do not generally accept the assumption that the conducting power of mercury is so imperfect as to affect materially the correctness of the indication of mercurial thermometers, Deschanel being quoted in support of the opinion that mercury is not an imperfect conductor. We are reminded that Prof. Everett, in a recent translation of the works of the author mentioned, assumed that the conductivity of quicksilver in the bulb of a thermometer is the same as a vessel "with thin metallic sides containing water which is stirred" (see Prof. Everett's translation of "Deschanel's Natural Philosophy," Part II., pp. 245-387). The subject is so intimately connected with the determination of solar temperature and solar energy, that it has become indispensable to settle the question by some thorough practical test. Accordingly an apparatus, represented by the following illustration (Fig. 1, p. 266) has been constructed by the writer, to ascertain the conductivity of mercury. Before entering on a description, it will be instructive to point out that the heat communicated to the bulb of a thermometer by solar radiation is transmitted to its contents chiefly by convection, hence that the altitude of the sun during the observation influences the accuracy of the

* NATURE, vol. v. pp. 344-347.

indication. This will be readily comprehended. Fig. 2 (p. 267) represents the bulb of a thermometer exposed to the rays when the sun's zenith distance is 65°; Fig. 3 representing the bulb when the zenith distance is 18° 23′, the latter being the minimum at the Observatory of the Roman College, where the thermoheliometer has been long employed for the purpose of ascertaining the intensity of solar radiation. Referring to Fig. 2, it will seen that the blank crescent *c*, whose varying thickness indicates very nearly the amount of heat imparted at each point of the spherical surface presented towards the sun, occupies a nearly vertical position. The mercury contained within the space indicated by the said crescent, having its specific gravity reduced by the radiant heat, will ascend; while the mercury on the opposite side, which retains its specific gravity, will descend; thus a circulation will be established by means of which the heat received from the sun will be gradually communicated to the entire mass of mercury in the bulb. But, when the latter is exposed to the sun's rays under a zenith distance of about 18°, as shown in Fig. 3, the heated mass of mercury contained within the crescent *a* has so slight an inclination that scarcely any circulation takes place. Consequently, if it can be shown practically that mercury is incapable of transmitting heat from particle to particle with sufficient velocity, it will be evident that thermometers and thermoheliometers, with spherical bulbs are worthless as means of measuring the intensity of solar radiation. It will be perceived that if the bulb in Fig. 3 be surrounded by an enclosure, as in the thermoheliometer, the mercury contained within the space indicated by the crescent *b* will radiate far less heat towards such enclosure than the mercury within the opposite heated crescent *a*. It will also be perceived that by increasing the size of the bulk the transmission of heat from *a* to *b* will be retarded unless the conductivity of mercury be perfect. Hence the *size* of the bulb is an element affecting the accuracy of the indication—a circumstance fatal to the employment of a spherical bulb in the thermoheliometer.



The nature of the illustrated apparatus constructed for the determination of the conductivity of mercury will be readily understood from the following description:—Fig. 1 represents a longitudinal section through the vertical plane. *a* is a boiler, with a flat bottom and semicircular ends, supported on two columns, *f* and *g*, resting on the bottom of the cisterns *c* and *d*. The column *f* is composed of wrought copper plated with silver, highly polished. The column *g* consists of a cylindrical vessel of glass open at the top, filled with mercury, and surrounded with a socket, *h*, composed of polished silver. The cisterns *c* and *d*, supported on nonconducting substances, are plated with polished silver, and provided with funnel-shaped openings at the top, through which thermometers are inserted. These cisterns, as well as the columns *f* and *g*, are surrounded with nonconducting coverings, *p*, *p*, and *o*, *o*. A lamp, *b*, is applied behind the cisterns for heating the water in the boiler. It is scarcely necessary to observe that the polished silver plating of the copper column, and the polished silver socket round the mercurial column, are intended to prevent loss of heat by radiation, while the coverings before mentioned are intended to prevent loss of heat by convection attending atmospheric currents. The inside diameter of the cylindrical vessel *g*, it should be noticed, is 0·5 in., corresponding exactly with the diameter of the copper column *f*, the top of which is on a level with that of the mercurial column. The lines *k l* and *m n* are in the same horizontal plane, their distance below the upper ends of the columns *f* and *g* being precisely two inches.

The object of the apparatus being that of comparing the conductivity of mercury to that of some other metal

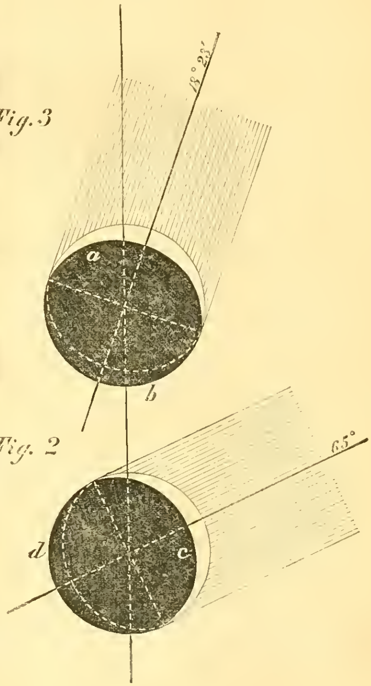
copper has been selected, as its conducting property is better known than that of any other. The leading feature of the arrangement will be comprehended by a mere glance at the illustration. An equal amount of heat being applied to each column, it is intended to show by the elevation of the temperature of the water in the cisterns *c* and *d*, what relation exists between the conductivity of mercury and copper. Regarding the application of the heat, it will be evident that an equal amount must infallibly be imparted to each column if the lamp be sufficiently powerful to keep the water in a state of continuous ebullition. Obviously the heat from the lamp, if urged, will cause a rapid upward motion of the water in the middle of the boiler, and a correspondingly rapid descending current at each end. Accordingly lateral currents varying in velocity with the strength of the flame applied under the boiler, will flow inwards over the upper ends of the columns *f* and *g*.

Several experiments have been made under varying barometric pressures and different atmospheric pressures; but the results as regards the comparative conductivity of mercury and copper have proved to be very nearly alike in all. The accompanying tables record the result of the last trial, conducted as carefully as practicable. The headings of the several columns explain so clearly the object of the tables that it will only be necessary to state that the energy inserted in the fourth column is the energy developed from the beginning of the experiment.

Referring to Table I., it will be seen that at the termination of four minutes from the commencement of the experiment, the temperature of the water in the cistern *c* had increased 29·06°, the differential temperature being then 212° − 102·56° = 109·44°. During the same period a dynamic energy represented by 2·525 thermal units had been transmitted past the line *k l*, communicated to (1) the water in the cistern; (2) the part of the copper column immersed; (3) the metal composing the cistern; (4) the immersed part of the thermometer. But, while the entire energy transmitted past the line *k l*, during the four minutes thus amounted to only 2·525 units, the rate of transmission was actually 0·850 unit per minute at the termination of the fourth minute. This apparent discrepancy was caused by the heat absorbed by that part of the column which extends above the line *k l*, the temperature at the commencement of the experiment being the same as that of the surrounding air, 73·50°. Referring to Table II., it will be seen that the energy transmitted through the mercurial column, past the line *m n*, during four minutes, was only 0·087 unit against 2·525 units for the copper column, although the differential temperature of the water in the cistern *d* was 137·50° − 109·44° = 28·06° higher than in cistern *c*. Accordingly, the conductivity of the copper composing the column *f* has proved to be $\frac{2·525}{0·087}$ = 29·06 times greater than the conductivity of the mercury of the column *g*, notwithstanding the higher differential temperature to which the latter was exposed. It will be observed that the glass, 0·02 in. thick, composing the cylindrical vessel which contains the mercury, will conduct some heat downward, tending to increase the temperature in the cistern *d*. This tendency, however, will be balanced by the loss of heat occasioned by the radiation of the glass cylinder, since the application of the polished silver socket and the non-conducting covering cannot wholly prevent the refrigerating action of the surrounding air. It is important to observe, regarding the loss of heat from the latter cause, that the cisterns, previous to trial, are charged with water of the same temperature as the atmosphere. Now, considering that the increment of temperature in the cistern *d* does not average more than 0·40° above that of the atmosphere during the trial, it will be evident that the amount of error caused by radiation will be quite inappreciable. We are therefore warranted in concluding that the conductivity of mercury, determined by the increment of temperature in cistern *d*, and by the dynamic energy transmitted past the line *m n*, cannot be far from correct. It will be asked why columns of such small diameter have been employed. The principal object has been that of presenting a sectional area in the mercurial column *g*, corresponding as nearly as possible to the size of the bulb of an ordinary thermometer. Regarding the dimensions, it will be readily admitted that the conductivity of mercury might have been ascertained with greater exactness, if columns of very large sectional area had been employed; but the trial has conclusively established the fact that mercury transmits heat from particle to particle too slowly to

Fig. 3

Fig. 2



effect a sufficiently rapid indication of mercurial thermometers provided with *spherical* bulbs; and that, when the heat is applied from above, the indication of such thermometers is wholly unreliable.

A subject of profound interest presents itself in connection with the rate of transmission of energy exhibited in the sixth column of Table I. It will be seen that although the copper column *f* is only 0·5 in. in diameter = 0·19635 sq. in. section, the rate of transmission at the termination of the fourth minute is 0·850 unit per minute. Reducing this amount to the usual standard of one square foot, it will be found that the energy developed is $\frac{144}{0·19635}$ × 0·850 = 623 thermal units per minute for a sectional area of 1 sq. foot. It will be observed that this

extraordinary amount of energy (theoretically capable of exerting $\frac{623}{42.7} = 14.5$ horse-power) is called forth by the moderate differential temperature of $212^\circ - 102.56^\circ = 109.44^\circ$ F. Now, let us compare the energy of 623 thermal units per minute to that produced by the radiation of a metallic surface coated with lamp black, and maintained at a temperature of 212°, within an enclosure of 102°. Actual trial shows that under these conditions, the radiant energy of a blackened plate composed of copper, containing 144 sq. inches, scarcely reaches 6 thermal units per minute. Our experiment has therefore established the fact, incidentally, that under the stated conditions, a plate of wrought copper two inches in thickness is capable of transmitting by conduction from one side to the other, in a given time, an amount of mechanical energy more than 100 times greater than the mechanical energy developed by the radiation of the same plate during an equal interval of time.

J. ERICSSON

NOTES

THE voluminous correspondence connected with the management of Kew Gardens, printed by order of Parliament, was issued at the close of last week. In the debate in the House of Lords on Monday, introduced by Lord Derby, the essential points of the controversy were hardly touched; and pending the debate in the House of Commons on Sir John Lubbock's motion, which was not reached on Tuesday evening, it is obviously premature to enter into the various discussions which are prompted by the contents of the Parliamentary papers.

THE choice of a foreign correspondent of the French *Académie des Sciences* has resulted in the defeat of Mr. Darwin and the election of M. Loewen, of Stockholm, who received 32 votes, against 15 given to the English naturalist. The discussion had extended over three long sittings in secret committee, the leader of the advocates of Mr. Darwin's claim being again his opponent in controversy, M. de Quatrefages, while M. Emile Blanchard led the opposition. A correspondent of *Les Mondes*, an eminent member of the Academy, in commenting on the result, states that not one of those who voted for Mr. Darwin shared his philosophical doctrines, and not one of those who opposed his candidature alleged as their motive the error or danger of his doctrines. "What has closed the door of the Academy to Mr. Darwin is that the science of those of his books which have made his chief title to fame—the 'Origin of Species,' and still more the 'Descent of Man'—is not science, but a mass of assertions and absolutely gratuitous hypotheses, often evidently fallacious. This kind of publication and these theories are a bad example, which a body that respects itself cannot encourage."

THE subject of Prof. W. K. Clifford's discourse at the ensuing meeting of the British Association will be, "The Aims and Instruments of Scientific Thought." Mr. W. Spottiswoode will deliver a lecture to working men, on "Some Properties of Light, Sunshine, Sea, and Sky."

THE Iron and Steel Institute will hold its next meeting in Glasgow, under the presidency of Mr. Henry Bessemer. The reception room will be in the Corporation Galleries, Sauchiehall Street. The general meetings will be held in the Lecture Hall, Corporation Galleries, Sauchiehall Street, as under:—Tuesday, Aug. 6, 1.30 P.M., Election of Members, Report of Council to be presented, Papers; Wednesday, Aug. 7, 10.30 A.M., Reading and Discussion of Papers; Thursday, Aug. 8, 10 30 A.M., Reading and Discussion of Papers. A room will be provided in the Corporation Galleries for the exhibition of objects of interest to the trade, either from the neighbourhood of Glasgow or elsewhere. The business proceedings will terminate about 3 o'clock on Tuesday, and it is proposed that members should devote the remainder of the day to visiting the iron and other works in the neighbourhood of Glasgow. A list of these works will be given in the detailed programme to be distributed at the meeting; and a sketch map of the district will also be ready at the same time. On Wednesday, immediately after the conclusion of the business meeting, a special train will be provided to convey the members to Coatbridge and Monkland, where the Gartsherrie, Summerlee, Langloan, Coatbridge, Malleable, and Monkland Iron Works will be inspected. On Thursday, after the conclusion of the general meeting in Glasgow, a special train will be arranged for the Motherwell district, and for the inspection of the iron works in that locality. On Thursday evening, at 7 o'clock, the members will be entertained at dinner, in the Corporation Galleries, Glasgow, by the Local Reception Committee. On Friday an excursion will be made down the Clyde, for the purpose of seeing the industrial features connected with the river. The excursion will also be prolonged to the head of Loch Long, the return being by Loch Lomond to Balloch, and thence by train to Glasgow. Luncheon will be provided at Tarbet. The following papers have been already promised:—"On the Geological Features of the Iron and Coal Districts of Scotland," by Mr. James Geikie, F.G.S., of the Geological Survey of Scotland; "On the Rise and Progress of the Iron Trade in Scotland," by Mr. Jno. Mayer, F.C.S., Glasgow; "On the Differential Clutch for Reversing Mills," by Mr. R. D. Napier, Glasgow; "On Reversing of Rolling Mills," by Mr. Graham Stevenson Airdrie; "On an improved form of Squeezer for Blooms produced in

Rotary Puddling Furnaces," by Mr. James Robertson, Glasgow; "On the Rise of Iron Steamship Building on the Clyde;" "On further Improvements in Spencer's Revolving Puddling Machine," by Mr. Adam Spencer, West Hartlepool; "On the Westward Development of the Iron Manufacture in the United States," by Mr. T. Guilford Smith, Philadelphia.

THE Annual Meeting of the Association of German Naturalists and Physicians will be held at Leipzig, from Aug. 12 to Aug. 18.

A MATHEMATICAL society of Paris has been formed, on the plan of the similar societies of London, Moscow, and Berlin, having for its object to encourage mathematical studies and increase mathematical knowledge, and to form a bond of union of those interested in the mathematical sciences. Among its original members are MM. Chasles, Serret, Ossian Bonnet, Resal, Bourget, Mannheim, Laurent, Halphen, de Polignac, Ribeaucourt, Lemoine, Laguerre, Gros, Brisse, and André. The Society proposes publishing a *Bulletin* of its Proceedings.

WE regret to learn that Prof. H. E. Roscoe is laid by from a serious accident—a kick from a horse. The injuries, however, we understand, are only such as complete rest will repair.

JUDGMENT has been given by Lord Gifford, in the Court of Session at Edinburgh, in favour of Miss Jex Blake and other lady students in their action against the Senatus Academicus, asserting their right to complete at the University their full medical curriculum, and to graduate on the same footing as male medical students. The judgment finds the ladies entitled to all the privileges of medical students, and to graduate in medicine at the University. The laws of Scotland, continues the judge, hardly as they bear against women in some respects, have never gone so far as to forbid their entering the medical profession.

WE are glad to observe that a movement which we noted in April last has succeeded in giving a well-earned reward to Mr. James Lindsay, Experimental Assistant to the Professors of Natural Philosophy in Edinburgh University for the last fifty-four years. A meeting was held in Edinburgh on the 24th, presided over by Prof. Sir R. Christison, Bart., M.D., who, in a few words, pointed out the great merit which had induced Mr. Lindsay's friends to present him with this manifestation of their respect, and gave a sketch of his long connection with the Natural Philosophy chair at the University. The subscriptions amounted in all to 235*l.*; the list of subscribers including the names of H.R.H. the Duke of Edinburgh, the Marquis of Tweeddale, the Duke of Argyll, Dr. Lyon Playfair, M.P., Mr. Carlyle, Prof. Tyndall, Prof. Sir R. Christison, Sir W. Thomson, W. M. Rankine, Tait, &c.

MR. J. LOWTHIAN BELL, of Newcastle-on-Tyne, has been elected an honorary member of the United States Mining and Engineering Institute, in recognition of his labours.

IT has been determined to erect a statue in Berlin to the memory of Albert von Graefe, the eminent oculist. The names of some of the most distinguished surgeons of Europe are on the committee.

WE understand that the Royal College of Chemistry will resume its operations at the commencement of the Autumn Term, in the new laboratories at South Kensington.

THE Museum at Thornhill, Dumfriesshire, is now open to the public on Saturdays from one o'clock. Admission will be by free tickets, which may be obtained by application at the museum, and a description will be given of some special class of objects. On other days of the week, Sunday excepted, admission will be by tickets for which the charge of sixpence will be made. To the museum will be added a small library of selected books, which may be had on loan; also a library of books for consultation at the museum. This library consists of about two thousand volumes. A few periodicals will also be added. A descriptive catalogue of the museum and a catalogue of the library are in preparation.

THE most recent publication of the Geological Survey consists of the explanation of quarter-sheet 98 S.E., illustrating the geology of the neighbourhood of Kirkby Lonsdale and Kendal, by Messrs. Aveline, Hughes, and Tiddeman. It contains the usual sketch of the physical geography of the district, and lists of the fossils of the various formations, and is illustrated by several sections.

MR. W. R. HAYWARD has in preparation a new work, which will be called "The Botanist's Pocket-Book." It is intended as a handy pocket companion for the botanist in the field, to enable him to identify on the spot the plants he may meet with in his researches. It will contain the characteristics of species and varieties, the botanical name, common name, soil, and situation, colour, growth, and time of flowering, of every plant, arranged under its own order. The volume will be published by Bell and Daldy, York Street, Covent Garden.

AN excellent compendium of our present knowledge of the sun and the phenomena of its atmosphere, from the pen of Prof. Young, has just been published by Chatfield and Co., of New Haven. This author, it is well known, has himself occupied a very prominent part in the history of more recent discoveries in regard to the sun, and the article referred to is the substance of a lecture delivered at New Haven during the past winter. This has, however, been materially modified, so as to bring the subject up to the present state of our knowledge, as rendered necessary by the rapid progress made in the science of solar physics.

IN the form of a 4to pamphlet is printed "Discussion of the anemometrical Results furnished by the Anemometer at Sandwick Manse, Orkney, 1863-1868, from the Appendix to the Quarterly Weather Report for 1871.

WE have received three papers by Prof. O. C. Marsh, on "The Discovery of Additional Remains of Pterosauria, and of the Dermal Scutes of Mosasauroid Reptiles;" "The Structure of the Skull and Limbs in Mosasauroid Reptiles," and a "Preliminary Description of Hesperornis Regalis." These have already been alluded to in our *résumé* of the contents of *Silliman's Journal.*

WE have a reprint from the *Geological Magazine* of Mr. James Geikie's valuable and interesting papers "On Changes of Climate during the Glacial Epoch." The author has made several additions and alterations, one of the most valuable additions being a summary of the general results arrived at in the memoir in a series of thirty-six short paragraphs.

THE *Notizblatt des Vereins für Erdkunde und verwandte Wissenschaften zu Darmstadt und des Mittelrheinischen Geologischen Vereins* for 1871 contains a host of valuable papers and statistical tables connected with all branches of geography—physical, political, and social, and the sciences connected therewith, especially meteorology and geology, relating to the Grand Duchy of Hesse-Darmstadt. We notice especially two very elaborately-constructed charts of the meteorological observations taken during the years 1870 and 1871.

THE *Chemical News* contains a paper by Mr. Hugo Tamm on "A Ferro-Tungstine, a New and Interesting Mineral," which Mr. Tamm desires to designate "Crookesite." This name, however, having been already appropriated, Mr. Crookes pro-

poses that, when the missing constituent is discovered, it should be called "Tammite." Mr. Tamm's analysis of the new mineral gives:—Metallic Tungsten 88·05, Metallic Iron 5·60, Metallic Manganese 0·15, Undetermined Substance 6·20. Mr. Tamm ventures upon various conjectures as to this last substance, and thinks it just possible that, after all, he may have made an analytical error, and that there may be 6·2 per cent. more of tungsten than appears in the analysis. He has, however, strong doubts on this point.

REGARDING "sea-serpents," the following note may be interesting:—The South African Museum, Cape Town, recently received a specimen of the Ribbon fish (*Gymnetrus*) fifteen feet long without the tail. It appears that this fish is known to distant inland fishermen as being forty feet long, and from its slender shape and snake-like movement is probably the "sea serpent" of late years so minutely described by navigators. From its head there is erected a plume of flexible rose-coloured spines, and from head to tail along its back there is a conspicuous mane-like fin. Its general colour is like burnished silver. The eye is large and silvery, and the profile of the head comports well with that of the horse. The specimen could not be preserved, but there are two smaller specimens in the Museum.

THE *Garden* calls attention to the great value of the Island of Jamaica as a tropical garden. Its oranges, pine-apples, bananas, limes, lime-juice, cocoa-nuts, and other such products, could not be surpassed in quality, and might be cultivated to any imaginable extent. Besides all this, the soil and climate are eminently suitable to the growth of precious drugs and plants. Bark is raised easily, the cinchona plantation being in a most satisfactory state. Then there are hemp and China grass of excellent quality, nor would any arrowroot be superior to that of Jamaica if it were but more carefully prepared for market. Here, it will be said, is a noble prospect for the colony. True, but it is a prospect only. Not until the very last returns is there shown any "tendency to the development of new industries requiring little capital and no extraordinary skill." It is the old story, "minor articles" are neglected, though they are the very articles which are wanted, and which the colonists could send. However, Jamaica is fortunate in having a Governor in Sir J. P. Grant, who can discern the true capabilities of the island, and the true place for its industry in the markets of the world.

A CORRESPONDENT of the *Madras Mail*, quoted by the *Times of India*, says that on the night of June 15 last the plain to the east, north, and north-east of Nandidroog was covered with "many thousands" of lights, which have been observed occasionally in former years. The correspondent compares the appearance to that of a large city brilliantly illuminated, and in one direction the scene, through a binocular glass, "looked like a view of part of the starry heavens, each flame being like a star." As many of the lights were from ten to fifteen miles distant from the reporter's point of view, he conjectures that each flame must have been five to six feet in length. An attempt is being made to find out the cause of the curious phenomenon, the most likely hypothesis being that the lights are "caused by the ignition of some inflammable gas escaping in jets from the surface of the earth."

WE learn from the *Field* of July 20, that Mr. Parnaby has succeeded in bringing sixty black bass fry home from America, and that they are safely deposited in the tanks at Troutdale, Keswick, and are feeding heartily, so that they may now be considered safe. He found great difficulty in collecting the fry and bringing them safely across the Atlantic on account of the intense heat. Mr. Francis considers this the second greatest feat in pisciculture, the first being the conveyance of salmon to Australia.

PROFESSOR AGASSIZ'S SOUTH AMERICA EXPEDITION*

III.

IN Mayne Harbour, on the western side of Owen's Islands, I had an opportunity of investigating two very interesting new genera of naked-eyed Acalephs. The locality naturally suggested appropriate names, and I called one after Captain Mayne, *Crossotoca Maynei*, from the festooned disposition of the ovaries, and the other after my old friend Owen, *Staurotoca Owenii*, from the cross-like figure of the ovaries. While I was collecting on board, Pourtales and Steindachner ascended the adjoining hills in search of glacial marks and land animals. The result of their excursion was most satisfactory. Pourtales found very well preserved glacial scratches and furrows upon wide greenstone dykes, which here intersected the rocks in every direction. Upon one such ledge the marks were divided into two distinct series, one running S.W. by W., the other crossing these S.S.W. Higher up on other dykes of the same character, the first series of marks occurred again, being perfectly rectilinear, in the same direction, and though in one instance interrupted, were renewed on the other side of the break on the same level with the same bearing. Still higher up on the same hillside he found also very distinct glacial furrows upon granite ridges, the furrows bearing S.W. by S., and finer lines again on greenstone dykes. The highest marks in the locality were some 500 or 600 feet above the sea level. Steindachner collected frogs and their tadpoles, and some insects and earthworms.

On approaching the Guia Narrows, the hills on Chatham Island are plainly furrowed in a north-westerly direction, and large boulders are seen all along upon the ridge of the range, while Esperanza Island appears in the south like a large rounded dome between two channels running N. and S. In wide channels we saw many whales and also small icebergs. The hills to the height of about 2,000 feet were everywhere distinctly *moutonnées*. Saumarez Island, opposite the mouth of Eyre Sound, and the island to the west of it, were particularly instructive. We followed the western channel, which is also the narrowest, and it soon became plain that wherever opposite shores with high walls approached near one another the glacial scratches and furrows, alike distinct, assumed an ascending direction, as is the case whenever a moving glacier meets an obstacle. That the south side was here also everywhere the strike side, was equally apparent from the facts that all these marks were either wanting or less distinct on the north side of the islands. Had any abrading agent advanced from the North, all appearances must have been reversed in these narrow channels; or they must have crossed them at right angles had the action come from East or West. Floating ice is out of the question where the furrows are not horizontal, and here in the narrowest part of the channel, west of Saumarez Island, there is a track where the scratches and furrows are distinctly ascending on the west side of the channel, and horizontally on the eastern side opposite, showing that the pressure of the ice-sheet must have been from S.E. to N.W.

Looking south, after passing Saumarez Island, the scenery appears totally different, from the fact that this is the lee side of the glacier action; and yet the channels have about the same width and bear the same relations to one another. In the narrowest channels the polished surfaces, with their scratches and furrows, are as well preserved and as distinct as in those of the Helle Platten at the Handeck in the valley of the Hassli in Switzerland. About Iceberg Sound all the mountains are beautifully rounded and *moutonnées*. That local glaciers, however, existed, and extended much beyond their present range, may be plainly seen in many of the inlets crossing the main channels in an east-westerly and west-easterly direction. It is true that general and local glacial phenomena are so interwoven throughout this region that it is at times difficult to appreciate their true connection; but there are also many localities where the difference is quite obvious. The most interesting of the places here have been well photographed by Dr. White, and may serve at some future time as illustrations of the fact described in this report.

In some places the various kinds of glacial marks were as plain as in the valleys of Switzerland, and I am surprised that travellers who have visited this region since the glacial phenomena have been so much discussed, have failed to notice them here. As in Switzerland, there seems to be a level above which the ice-sheet has never risen; at least there is a line above which the mountain ridges remain jagged and abrupt, while

* Reprinted from the *New York Tribune*, concluded from p. 231.

below their crusts the whole land is *moutonnée*. The abrasion by ice is so uniform and so general that I found it difficult to trace the direction of the abrading motion. There seemed to be nowhere a distinct lee and strike-side among the hills. But, as I grew more familiar with the appearance of the country, I became satisfied, and succeeded in convincing others also, that the abrading movement had taken place from the south northward—or, in other words, had been connected with the climatic condition of the Southern Hemisphere In Smyth's Channel there is no possibility of mistaking the evidence. I know no more interesting locality for the study of glacial phenomena than the vicinity of Saumarez Island. It shows in the most palpable manner that glaciers only—that is, terrestrial masses of ice moving upon solid ground—can have produced these abrasions, that floating icebergs cannot have been the cause. Their direction is such, also, that no one could suppose the adjoining cordillera to have been in any way connected with the abrasion or planing of the rock, or with its grooving and furrowing. The country has everywhere a glacier-worn aspect as far as the Gulf of Pennas. On reaching Chiloe I noticed that the rounded knolls became somewhat less marked, but yet the prominent trend of the hills continued to be in a north-southerly direction. An observer not familiar with the character of glacial denudation may sometimes be perplexed by finding the seeming lee and strike-side of the rocks in a position exactly the reverse of the general one. A critical scrutiny shows that these appearances are due to a superficial disintegration, often producing a rough side of a hill or rocky ledge where the observer of glacial phenomena would expect a smooth and polished surface. This is especially the case here, where, from the character of the stone as well as from the climate, the rock peels off and splits up very readily. One must be careful not to blinded by local appearances to the more general phenomena. At the entrance of Corner's Cove, for instance, a beautiful inlet trending east-west in Messier Channel, the rocks forming the southern and northern entrance might seem at first sight to have been ground or smoothed by a local glacier, moving out of the cove in an east-westerly direction. Seen however from a certain distance, where the local disintegration is merged in the general aspect of the exposed surfaces, the direction of the main abrasion from south-nortnward becomes as plain as daylight. You can trace rectilinear furrows upon the knolls both south and north of the entrance of the cove, following not only the same direction, but occupying the same identical level on both sides. There can be no doubt that they were continuous. Darwin has stated that the erratics, the only part of the ancient glacial phenomena observed by him in these regions, follow everywhere the course of the main channels, and he believes this to be an evidence of iceberg action. Valuable as are his results, being, indeed, almost the only connected geological observations ever made in this region, he is mistaken in his facts upon this point. Whenever we entered an inlet opening at right angles into the main channel and intersecting several parallel ridges of hills, the *roches moutonnées* and all the accompanying glacial phenomena trended in a south-northerly direction; as they did also in the main channel. Before entering the Gulf of Pennas, in Messier Channel, we passed an opening through which seven parallel ridges could be seen on the eastern side and five toward the west, all trending mainly northward, and plainly exhibiting glacier-worn surfaces.

Moreover, the Strait of Magellan itself has a main trend from east to west, and yet there is no sign throughout the whole length of any transportation of erratics from east to west, or from west to east. Dawson has made a similar mistake with reference to Switzerland. He supposes that the erratics of the Jura were deposited by icebergs sweeping up and down the great valley of Switzerland, from east to west and from west to east. He seems not to know that the older Escher von der Linth and Leopold von Bach had already clearly demonstrated the line of their transportation across the valley of Switzerland from south to northward; and that Guyot, more than twenty-five years ago, traced the different tracks of those boulders separately through the chief valleys of Switzerland northward across the very road which Dawson would have them follow.

The erratic pebbles and boulders from the eastern to the western coast of Patagonia, judging from my observations at Montevideo, in the Bay of San Mathias, in Possession Bay, at Sandy Point, in all the ports of the Straits of Magellan which we have visited, at Shell Bay, on entering Smyth's Channel, throughout Smyth's Channel itself, and upon the shores of Chiloe, have the same character. They consist of a mixture of plutonic and metamorphic rocks, among which the hardest siliceous rocks prevail. Their geological identity is further shown by the unfailing presence of a very hard, compact, epidotic rock, never absent from these erratic materials, yet never found in place, as far as I know, over the whole extent of country through which I have traced them. You will remember that I mentioned it among the loose pebbles of San Mathias Bay; nor did I lose sight of it until we left San Carlos, at the northern end of Chiloe Island, where I found it again, and as you will soon see, in still more interesting juxtaposition. This fact is of great significance, inasmuch as it shows that the drift phenomena in this region cannot have been due to the enlargement of the present glaciers, otherwise the drift would consist mainly of the rocks in place, and differ from one locality to the other. And yet their glacial origin is unmistakable, since a considerable proportion of these pebbles and boulders are polished, scratched, grooved, and furrowed, like the erratics of the United States and of Northern Europe. It is this uniformity in the character of the drift which has led me from the first to discriminate between the glaciers as they exist, and even as they once existed in their greater extension, in short, between all the phenomena connected with local glaciers, and those belonging to what I have called the glacial period, during which the two hemispheres must have been capped with a sheet of ice of enormous thickness and extent. The equatorial limit of this ice-sheet, both in the northern and southern hemisphere, is part of the problem upon which we have thus far fewest facts in our possession. In South America I have now traced the facts from the southernmost point of the continent uninterruptedly to 37° S. latitude, on the Atlantic as well as the Pacific coast. Even here at Talcahuano, large erratic boulders and *roches moutonnées* exist at the mouth of the Biobio on the hills of Hualpen.

In San Carlos de Anend, at the northern end of Chiloe Island, I have observed a fact which introduces a new element in the study of the glacial period. The ground upon which San Carlos is built is volcanic: the promontory of San Carlos consists of a volcanic breccia, the precise age of which I had no means of determining. From its mineralogical character, it must belong to the age of volcanoes proper. Now, erratic materials, small pebbles, and large boulders, among which some exhibit unmistakable glacial polish, rest in considerable quantity upon this volcanic ground. It is therefore plain that the glacial period in this part of the world, at least, has followed the older volcanic eruptions. Among these erratic materials the green epidote which I had followed so far was still to be found. The facts observed by me at San Carlos, taken in connection with Pourtales's discovery of a great many extinct craters near Possession Bay, point to the possibility of climatic changes in this region, which, should similar facts be found elsewhere, may account for the glacial period. At all events, it shows a direct connection between the glacial period and volcanic phenomena. Since finding drift upon volcanic ground at Anend, I have been watching for erratic pebbles and boulders of volcanic rocks along the coast of Chili. Their presence near the shore would prove that the glaciers of the Andes formerly reached the sea-level, after crossing the coast ranges in the temperate, and perhaps also in the tropical zone. Thus far I have failed to find anything of the kind. Darwin assumes that the erratics of western Patagonia have descended from the Andes, and he compares the outlying islands, such as Chiloe, in their relation to the Corderillas, with the chain of the Jura in its relations to the Alps. But the erratics of Chiloe have the same character as those of the Strait of Magellan and of San Mathias Bay and the two latter, and those of the two latter can hardly be referred to this source. Neither did I see any indication of very large glaciers coming down from the Andes in a westerly direction, though I have no doubt that I shall find them farther north. Evidently we are not yet sufficiently advanced in our journey from the southern extremity of the continent northward that the influences of altitude should outweigh those of latitude in the increase and decrease of those climatic conditions upon which the extension of glaciers has depended in former ages. During the waning of the glacial period, the glaciers of the Cordillera have unquestionably been much more extensive than now, and I shall not be surprised to find, upon a more careful survey, that the glacier of Snowy Bay in Smyth's Channel and those of Eyre Sound, and perhaps some of the other parts of the Cordilleras, once crossed the main channel and reached the opposite island. But I doubt that they ever reached the shores of the Pacific Ocean. It is at all events certain that the local glaciers of the present time have never had

the power in their greatest extension, or lasted long enough to obliterate or even obscure the phenomena of the glacial period. To refer the latter to an enlargement of the present glacier is simply absurd.

This leads me naturally to some remarks about the present glaciers of South America, of which we have seen great numbers during our journey. On the whole the glaciers of these southern regions recall those of Switzerland, with which I am so familiar. And yet there are marked differences also. The form of the mountains in the Straits is not favourable to the accumulation of large masses of snow, in extensive depressions and troughs like those from which the river-like glaciers of my native country descend. There are some of that character, it is true, on the highest ranges bordering Magdalena Bay and Gabriel Channel, such as Mount Sarmiento, Mount Buckland, and no doubt also Mount Darwin, though the latter were too far out of our track to be examined. Of course, as we have approached the range of the Andes with its deeper valleys, I have seen more glaciers with an Alpine character. But most of the glaciers of the Straits are dome-like, with an indented edge marking the limits where the glacial ice moved down beyond the névé. It is already known to all students of glacial phenomena that these southern ice-fields have the same general aspect, produce the same effects, and are bordered by the same loose materials, as those of other countries. But it is interesting to find that, like the glaciers of Switzerland, those of the Straits of Magellan have had a much greater extension in past times, and have gradually shrunk to their present size and relations. I have studied these facts in one of them very carefully, choosing for that purpose a glacier occupying a gorge on the northern side of the Straits. I preferred the northern side, because a glacier moving from the north southward must necessarily have encroached upon the area covered, at a still earlier time, by the Antarctic ice-sheet moving from the south northward. By the way, our party agreed, at my suggestion, to call this glacier the "Hassler Glacier," in remembrance of the Coast Survey and of the vessel in which our trip was made. It lies in what is known as Glacier Bay, so marked on the Admiralty maps, made from the combined observations of Capts. King, Fitzroy, and Mayne.

I expected to find here all the "facts" now accepted by geologists as evidence of the former greater extension of glaciers. I looked, in other words, for polished ground and furrowed surfaces, for dykes and strata on edge abraded to one level with the surrounding rocks; for moraines on a higher level and at greater distance from the ice than those at its present terminus; for erratic glacial materials of all kinds in the trough formerly occupied by the ice, and even for the peculiar scooped surfaces, called *coups de gouge*, on otherwise level slopes of rocks. I was not disappointed. All these signs are as legible about the Hassler glacier as they are in the neighbourhood of the glacier of the Aar, or that of the Rhone, and I found, besides, what is quite as characteristic, namely, a small lake shut into its basin, and kept there by an old moraine, 500 feet above the trough of the valley. There can be no doubt that this glacier once filled the whole bay down to its entrance into the main channel of the Straits, that is, three miles beyond its present termination.

Although I made a more careful examination of this glacier than of any other, we saw many local glaciers descending from the south northward, or from the north southward through similar gorges toward the main channel of the straits, and in Smyth's Channel also we passed many glaciers moving down from the W. and E. through valleys on either side of the Channel. Along our whole course we met with like evidence that all these ice fields have had a greater extension in former times. From a general survey of these appearances, it is plain that all phenomena connected with local glaciers and their former extension are independent of those produced by the more universal accumulation of ice during the glacial period proper. They form, of course, a consecutive phase—the last phase, indeed, of the waning glacial period during its passage into the present condition of things. By what combination of circumstances the glacial period was ushered in cannot be determined as yet; but after seeing the dispersion of the drift in a south-northerly direction over this part of the South American continent, and observing the relation of the local to the general glacial phenomena, I protest anew against the confusion introduced into the subject by those who imagine that what I have called the glacial period was produced by the gradual enlargement and subsequent shrinking of the glaciers now in existence.

You see that my anticipation of finding drift phenomena here independent of any local glacial action, has been realised on a greater scale than I had dared to hope. I most earnestly wish the European geologists would make a special investigation of glacial tracks upon the summit of high table lands and of mountain ranges, where, from their position, these characteristic marks cannot be traced to other ranges in the neighbourhood rising to greater heights. The true way to study general glacial phenomena is indeed to trace them over disconnected mountain surfaces, which were once entirely covered by the great ice mantle of the glacial period. Such localities I have already pointed out in New England and in Great Britain. Several appear to exist in Scandinavia also. It is most important to discriminate between the local and the general phenomena. Until this is done, we shall never understand the true relations of the facts.

Let me state that I have not noticed anything to confirm the idea that the glaciers of the northern hemisphere have alternated with those of the southern hemisphere in their greatest extension, as is assumed by those who connect with the precession of the equinoxes the difference of temperature required for the change. The abrasions of the rocks seemed to me neither more nor less fresh in one hemisphere than in the other; nor do the veins of molten rocks rising above the surrounding disintegrating rocks stand out in a more or less bold relief in either case. However astronomical causes may have been connected with the climatic conditions of the world, I see no reason for believing, from any facts I have observed, that alternations of temperature in the northern and southern hemispheres have ever been the primary and efficient clause of glacial phenomena. The more I consider these phenomena, the more am I satisfied that ice has been the great paring machine by which rocky surfaces have been fashioned. The great geological agents are not alone fire and water, as is universally admitted. Ice has had a great share in the work, and I believe this also will sooner or later be recognised with equal unanimity. After having traced what seems to me palpable evidence of an ice mantle over-spreading once the southern part of this Continent, the effect of which I have seen from Monte Video on the Atlantic to Talcahuano on the Pacific coast, the question naturally arises how far the southern extremity of Africa, as well as New Zealand and Australia, were involved in the extension. I hope I may live to see younger naturalists investigate these regions with the same object. I believe that whenever such an investigation is undertaken by a competent observer it will be found that over and above all local glacial phenomena, and still by side with them, there is also evidence of a southern circumpolar glacial agency.

You may think that I have given you too many details. I have done so purposely that no one may accuse me of basing theories on imperfect observations. I am well aware that my results will be questioned, and I shall be thought fanciful by geologists of all schools, as I have been at every step of my glacial researches. But an old hunter does not take the track of a fox for that of a wolf. I am an old hunter of glacial tracks, and I know the footprint whenever I find it.

While I was transcribing this report, Pourtales came in with the statement that he had noticed the first indications of an Andean glacier in this vicinity. I have visited the locality twice since. It is a magnificent polished surface, as well preserved as any I have ever seen upon cold glaciated ground, or under glaciers of the present day, with well marked furrows and scratches. Think of it! A characteristic surface indicating glacier action in lat. 37° S., at the level of the sea! The place is only a few feet above tide level upon the slope of a hill on which stand the ruins of a Spanish fort, near the fishermen's huts of San Vicente, in the Bay of San Vicente, which lies between Concepcion Bay and the Bay of Arauco. Whether this polished surface is the work of a glacier descending from the Andes to the sea shore or not I have not yet been able to determine. I find no volcanic pebbles or boulders in this vicinity, which, after my experience in San Carlos, I should expect all along the shore if the glaciers of the Andes had descended to the level of the ocean in this part of the country. The erratics here have the character of those observed farther south. It is true the furrows and scratches of this polished surface run mainly from east to west; but there are some crossing the main trend at angles varying from 20° to 35°, and running south-east and north-west. Moreover, the magnetic variation is 18° 3′ at Talcahuano, April 23, the true meridian bearing to the right of the magnetic. I shall soon know what to make of this, as I start to-morrow for the interior to go to Santiago and join the ship

again at Valparaiso. The trend of the glacial scratches in San Vicente reminds me of a fact I have often observed in New England near the sea shore, where the glacial furrows dip to a considerable extent eastward toward the deep ocean, while farther inland their trend is more regular and due north and south.

While in Talcahuano we have made very extensive collections of littoral marine animals, so that we now have an excellent basis for comparison with the results of the deep-sea dredgings, which Pourtales is going to make between this and Juan Fernandez. I shall make similar collections in Valparaiso, and in order to do so in the short time allowed me I take Dr. Steindachner with me.

I had almost forgotten to say that I have obtained unquestionable evidence of the cretaceous age of the coal deposits of Lota and the adjoining localities north and south, which are generally supposed to be tertiary lignites. They are overlain by sandstone containing baculites. I need not adduce other evidence to satisfy geologists of the correctness of my assertion. I have collected myself a great many specimens of these fossils in beds resting upon coal seams. L. AGASSIZ

To Prof. Benj. Peirce, Superintendent U.S. Coast Survey

ANATOMY

The Placenta of the "Tamandua" Ant-eater

To the last number of the *Annales des Sciences Naturelles* M. Alphonse Milne-Edwards contributes an important paper upon the structure of the placenta of the "Tamandua" ant-eater (*Tamandua tetradactyla*)—important, at all events, to those who, with us, reckon the *Bruta* as one of the most interesting, but, at the same time, spite of Dr. Gray's most elaborate but somewhat intricate arrangement,* least satisfactorily classified groups of the mammalian class.

M. Milne-Edwards, after mentioning his countryman Lenou's division of the ant-eaters proper into three genera—viz., the terrestrial *Myrmecophaga*, and the *Tamandua* and *Cyclothurus* with arboreal habit and correlated prehensile tail, draws attention to the fact that as yet no opportunity has been had of examining the fœtal envelopes of the great ant-eater (*M. jubata*), that the placenta of the two-toed genus *Cyclothurus* is described in the *Leçons* as a kind of concave disc, but it has not been determined to what extent the walls of the ovum are occupied by the specialised vascular tuft.

The fœtal specimen of the Tamandua examined by M. Milne-Edwards was derived from a female which had come from New Grenada. The placenta is described as situated at the end of a pretty long and cylindrical umbilical cord, in which the vessels did not take any special course. It occupies a considerable extent of the ovum, and though circular and made up of but a single lobe, is of a form too convex (*trop bombée*) to come under the category of the so-called "discoidal" placenta. It would be, in fact, more correct to term it a "placenta discoidale envahissante." It is not made up of single villosities, such as the placenta of Pachyderms, of Camels, and of Tragulines, for the vascular tufts are much crowded together, especially at the central portion, so as to give the organ at this point a spongy appearance. The edges are sharply defined, leaving that portion of the chorion smooth which corresponds to the neck of the uterus. The vascular vegetations do not, in their disposition, remind one in any degree of the reticulated fold and the honeycombed aspect described by Sharpey as occurring in the placenta of the Pangolin. Towards the centre there appeared to be *débris* of the uterine tissue, suggesting the existence of a "decidua," but on this point there is, unfortunately, no certainty. No trace of an allantois was discovered, from which it is concluded that this fœtal appendage must be at least greatly reduced in size. Owing to the long immersion of the animal in alcohol, it was impossible to dissect out the laminæ of the envelopes of the ovum, or the factors of the umbilical cord. The internal surface of the chorion is stated to have been perfectly smooth, and not to have presented any of the protuberances which have been observed on that of the Unau.

If the placenta of the Tamandua, remarks M. Milne-Edwards in conclusion, be compared with that of some other members of the groups into which the *Edentata* have been subdivided, we shall not fail to be struck with the considerable differences which seem to exist in the structure of this organ in the different members of a group considered by zoologists as constituting but a single order.

The figures given by Carus (*Tabulæ Anatomiam comparativam illustrantes*, Pars. iii., Pl. ix., fig. 15), of the placenta of the Unau, do not, in the eyes of M. Milne-Edwards, resemble that of an ant-eater, of any other kind of Edentata, or even of any Mammal.* According to Prof. Owen's description of the placenta of the "Tatou,"—a general term for the Armadilloes—this organ resembles, at least in general form, the discoid placenta of an Insectivore, while that of the Pangolin, described by Huxley "Introduction to the Classification of Animals," p. 98), after Sharpey, presents a third mode of organisation not less distinct from the preceding. The Tamandua, in fine, thinks M. Milne-Edwards, offers an arrangement which, though differing in some particulars from that existing in *Cyclothurus*, seems to be only an exaggeration.

M. Milne-Edwards concludes by putting the pertinent question —"are we to regard this diversity in the order *Edentata* as of less importance than that accorded by naturalists to like variations in the fœtal envelopes in other groups of the class Mammalia? or are we to conclude that the different zoological types included by zoologists under the name *Edentata* have less affinity between them than is generally believed, and might be represented in our system of classification by division of a higher character." M. Milne-Edwards inclines—and in this we feel also disposed to follow him—to the latter proposition, and proposes at some future time to discuss and enlarge upon the same.

J. C. G.

* "Revision of the Genera and Species of Entomophagous Edentata." Proc. Zool. Soc., April 11, 1865.

* Rapp seems to have made more out of Carus's plates than did M. Milne-Edwards, for he states (*Anatomische Untersuchungen über die Edentaten*, 2te Aufl., p. 103. Tübingen, 1852), that according to the said anatomist, the placenta in this animal is made up of several *cotyledons*, which are from half-an-inch to an inch in transverse measurement.

METEOROLOGY

On a Meteoric Iron lately found in El Dorado County, California †

FOR my knowledge of the meteoric iron of El Dorado Co., I am indebted to Mr. Alfred Stebbins, librarian of the Mercantile Library Association of San Francisco. A letter from him, dated April 26, inclosed a few grams of turnings obtained during the separation of a slice of the mass destined for the collection of the geological survey now in progress under the direction of Prof. Whitney.

The mass is described by Mr. Stebbins as having the size and shape of a man's head. It was found in a field, and, as usual, was first taken to a blacksmith's shop, where it was soon found to be an unmanageable subject for working, and hence, fortunately, found its way into scientific hands. Its surface possesses the indentations common to these bodies—the crust or coating being partially oxidised. It weighs eighty-five pounds.

I find the turnings to have a specific gravity of 7·80, which may perhaps be a trifle above what the mass possesses, as it is presumable that the turnings have suffered a slight condensation in the process of separation.

The fragments sent are free from all traces of sulphur. A single analysis upon one gram has afforded me,

Iron	88·02	per cent.
Nickel	8·88	,,
Insoluble, consisting of a mixture of Fe_2O_3 and FeO, with minute silvery particles of supposed phosphor-metals (Schreibersite)	3·50	,,

The amount of material at command was too small to search for the other metals commonly found in meteoric irons.

† By Charles Upham Shepard, Sen., Massachusetts, Professor of Natural History in Amherst College. Reprinted from the Amer. Jour. Science and Art.

SCIENTIFIC SERIALS

Le Moniteur Scientifique, April, 1872. This number commences with a translation of a paper by M. Mayer, on alcoholic fermentation, and on the nutrition of the yeast plant, and is followed by a long dissertation on scents, according to recent discoveries in chemistry and physiology, by M. Papillon. The next is a translation of a lecture by Dr. Hofmann on organic chemistry and therapeutics. The author points out the numerous discoveries which have advanced the science of

medicine, showing also clearly that to the remarkable and rapid development of this branch of chemistry during the past few years, is due the more scientific and complete system of therapeutics now obtained. He also points out in how many instances medicine has derived immense benefit from the discoveries of new compounds, which at first seemed only to possess a theoretical interest to chemists.—A paper on Anthracene and its derivatives, follows, by M. E. Kopp. It treats, in the first instance, of the formation from anthracene of dichloranthracene, and on the action of sulphuric acid on this body. This yields an acid called disulphodichloranthracenic, and which possesses in dilute aqueous solutions a most intense and beautiful fluorescence in the blue end of the spectrum. The salts of this acid, the soluble ones of which exhibit the same property, are here described. This acid, by simply heating or by the aid of oxidising agents, is converted into disulphanthraquinonic acid. Dibromanthracene may be made to yield an analogous series of compounds, which in some instances are also beautifully fluorescent. Disulphanthraquinonic acid, heated strongly with a caustic alkali, is converted into alizarin, which is identical with the colouring matter obtained from madder root. In this paper a description is given of the methods proposed by the various patentees in the matter, thus forming a tolerably complete history of this new branch of industry. Some space is also occupied with a discussion as to the state in which alizarin occurs in garancin; the balance of evidence seems to show that it is glucoside, which may be called ruberythric acid, and which by the assimilation of two equivalents of water, forms alizarin and two equivalents of glucose.—M. Blossum contributes another part of his memoir on Caoutchouc and Gutta-percha considered from a chemical standpoint. In this article he discusses the vulcanisation of caoutchouc, and the manufacture of the softened variety, giving Parkes' process for vulcanising, which consists in exposing the articles to the action of a mixture of carbonic disulphide and chloride of sulphur, after which treatment they are boiled in dilute soda solution; the same communication also deals with vulcanite and the vulcanite employed in dentistry.—Dr. Benrath has a paper on the Chemical Theory of Devitrification. The author has made numerous analyses which show reason to think that a part of devitrification is due to a separation of silica, which was previously held in solution by a silicate. The number finishes with a critical analysis by M. F. Papillon on the recent work of M. Ritter, "On the Relation between the Modifications of the Blood Corpuscles and the Modification of the Excretions," which appears to be a very valuable work.

THE *Journal of the Franklin Institute* for June contains, besides papers to which we have specially alluded, continuations of papers previously commenced, and the usual Editorial items and novelties, the Report of the Committee of Judges upon the Trial of Steam Boilers, American Institute, 1871; experiments on various coals of the Carboniferous and Cretaceous periods, an article on the gunpowder pile driver, by F. C. Prindle, C.E., with a plate; one on the great fires of 1871 in the North-west, by Prof. J. A. Lapham; and one on the utilisation of the light petroleum oils, by W. H. Wahl.

THE *Archives des Sciences physiques et naturelles* of Geneva, No. 174 for June 15, commences with an interesting article by Alph. De Candolle on the question whether modifications in vegetable species are caused by prolonged influence of climate. For this purpose he obtained from remote localities in Europe, Moscow, Edinburgh, Montpellier, and Palermo, seeds of widely-distributed plants, and sowed them in the same soil and at the same time in Geneva. Although the series of experiments was not sufficiently extensive for the conclusions to have any decisive value, the general result was that the seeds obtained from the more northern localities germinated somewhat earlier than those grown in more southern latitudes, and the plants resulting from them also came to maturity somewhat more rapidly, a difference which was more decidedly manifested in the second generation. If these results are confirmed by a more complete investigation, they will be of considerable importance in the question of acclimatisation.—The only other original articles in this number are by M. Ador on phtalyl, the radical of phtalic acid, and on the increase of intensity of voltaic induction currents, by Prof. Lemström.

IN the *Journal of Botany* for July, Dr. Braithwaite continues his series of papers, "Recent Additions to our Moss Flora," this instalment being illustrated by two plates, of *Splachnobryum Wrightii*, and several species of *Grimmia*; and the Rev. Eugene O'Meara contributes further researches on the Diatomaceæ. Two useful local lists of flowering plants are also given, by Dr. M. M. Bull, of the Island of Sark, and by Mr. J. F. Duthie, of the Islands of Malta and Gozo.

THE *Quarterly Journal of Science* for July contains four original articles. The first is a short one, entitled "The Music of Speech," by the Rev. R. W. Higgs, consisting chiefly of an epitome of "The Philosophy of the Human Voice," by Dr. James Rush, of Philadelphia, who claims to have shown that "the sentiment and the logic of our speech have a distinct mode of expression apart from the subject matter." The article is interesting; but we must protest against the introduction into our language of such barbarisms as an "orotund," compounded from *ore rotundo*, and a "vocality," to express a vocal sound. —The second article is an able advocacy of the advantages of a uniform decimal system of weights and measures, compared with our present multifarious scales.—Mr. R. A. Proctor on "The Construction of the Heavens" gives an outline of the different theories which have been started as to the constitution of the sidereal system, especially those of the two Herschels and the elder Struve, and argues in support of his view that all the nebulæ hitherto discovered, whether gaseous or stellar, exist within the limits of the sidereal system.—The last article is by Captain Oliver on "Mediæval and Modern Ordnance and Projectiles compared."—The remainder of the number is taken up with notices of scientific works and reports of progress in physical and mechanical science.

Revue Scientifique, Nos. 51-53, and 2nd series, 2nd year, Nos. 1-4.—The report of M. Claude Bernard's course of lectures at the Collège de France on experimental medicine is brought to a conclusion with the close of the volume. Further reports are given of papers read at the Rostock meeting of the Association of German naturalists and physicians. M. L. Dumont has an article on civilisation considered as accummulated force. Report of M. Milne-Edwards' lecture on the Classification of Mammalia, being the introduction to his course at the Museum of Natural History on Zoology (Mammalia and Aves).—The new volume commences with a translation of Sir John Lubbock on the Origin of the Family. Sir W. Stokes's lecture before the University of Dublin on Public Medicine in Germany is translated. Of courses of lectures in France, we have M. de Quatrefage on the origin of the Prussian race at the Museum of Natural History; M. A. Chauveau, before the Society of Medical Sciences at Lyons, on the general physiology of virus; and M. Georges Ville, at Vincennes, on Chemical Manures. No. 4 contains an interesting sketch of the history of the Observatory at Greenwich, a sequel to the history of the Paris Observatory in an earlier number. We have also the usual amount of reports of the proceedings of foreign scientific societies.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, July 1.—Prof. Westwood, president, in the chair.—Mr. Jenner Weir exhibited two examples of a rare British lepidopterous insect, *Agrotera nemoralis*, captured by him in Abbot's Wood, Sussex.—Mr. Meldola exhibited varieties of several species of British Lepidoptera, and an example of *Leucania vitellina*, taken at Brighton in 1869.—Prof. Westwood exhibited several remarkable coleopterous insects sent from Ceylon by Mr. Thwaites; also, from the same locality, banded cocoons of a species of *Ichneumonidæ* attached to threads nearly three inches long; and an illustration of the habits of some species of moth which cuts out large oval pieces from the leaves of *Citrus* and forms therewith a moveable flattened tent, beneath which it lives and undergoes its transformations.—Mr. Müller exhibited portions of the leaves of *Pteris aquilina* from Weybridge, attacked by three species of dipterous larvæ.—Mr. Dunning called attention to a letter in NATURE from Dr. Leconte concerning the parasite of the beaver on which Prof. Westwood had founded the order *Achreioptera*. Dr. Leconte considered the insect pertained to the *Coleoptera*. Prof. Westwood dissented therefrom.—Mr. Dunning also read extracts from an article in the same journal by Mr. Moseley, concerning the sound produced by the Death's-head Moth, in which the writer maintained that the noise proceeded from the proboscis, and was caused by the expiration of air.—Mr. Lewis brought to the notice of the meeting a circular addressed to entomologists (with a list of signatures appended

thereto), urging them to ignore the re-instatement of forgotten names until such time as the method of dealing with them shall be settled by common agreement.

Meteorological Society, June 19.—Mr. John Tripe, president, in the chair. At the ordinary meeting, which preceded the Anniversary Meeting, Captain Toynbee exhibited charts showing the results already obtained in the meteorological office by the discussion of the observations for a portion of the North Atlantic, comprising ten degrees square, for the first four months of the year. The district extends from the Equator to 10° N., and is bounded by the meridians of 20° and 30° W. He explained the variations in the several elements from month to month which had been rendered visible by the minute discussion to which the materials had been subjected, and pointed out the importance to navigators of the precise information as to winds, &c., now presented to them. He stated that the meteorological committee intended to distribute copies of the chart for January, in order to elicit opinions as to the proposed method of publication. At the Anniversary Meeting which followed, the Report of the Council was read. In the Report the Council stated that as the number of Fellows showed a diminution from 340 to 314, it had been deemed advisable to introduce a change into the management of the society. Accordingly a room had been taken at No. 30, Great George Street, Westminster, and an assistant secretary appointed to attend there daily. The gentleman selected is Mr. W. Marriott, formerly engaged at Greenwich Observatory, and he entered upon his duties on May 1st. It is hoped that by these means the business of the Society will be conducted in a more satisfactory manner.—The fifth volume of the Proceedings being now complete, the Council have increased the size of the publication to royal 8vo, so as to allow of the binding up of the Registrar-General's Quarterly Returns with the Proceedings of the Society. The new series will be entitled the "Quarterly Journal of the Meteorological Society," and will be edited by a committee of the council, Mr. Glaisher having resigned the editorship. The Report concluded with the usual obituary notices of deceased Fellows.—The president then delivered an address, in which he said that he would allude briefly to some facts connected with meteorology and its correlations with sickness and death. The careful daily record of meteorological observations made with standard instruments was commenced at many stations some time before the compilation of mortality returns, in the office of the Registrar-General of Births and Deaths, so that the mortality tables of the metropolis can safely be compared with the Greenwich returns, and for extra-metropolitan localities with those supplied by any of our observers. He had carefully compared the Greenwich observations for some years with those made by himself at Hackney, by Mr. Burge at Fulham, Mr. Symons at Camden Town, and Mr. Heywood in the City, and ascertained that the mean daily temperature did not vary on an average more than half a degree, although the maximum and minimum observations differed very considerably. He had therefore used the Greenwich tables in all his comparisons between the rate of death from different diseases and varying states of the weather. A number of valuable results have already been obtained as regards the course of epidemics, the influence of high and low temperatures on the public health, and, to a less extent, of different hygrometric conditions of the air. Dr. Hoskins long since (about 1855) wrote a valuable paper on the "Correlation between Meteorological, Medical, and Agricultural Science;" and he (the president) commenced a series of essays in 1848 on the influence of variations in the temperature, moisture, weight, and electricity of the atmosphere on the death-rates of scarlet fever and other epidemic diseases. The Manchester Medical Association, Dr. Ballard, and others, have written on the effects of variations of temperature on the health of the people. The whole of the writers have arrived at tolerably uniform conclusions, viz., that very cold and very hot weather induce an increase in the number of cases of disease and of deaths, and that a temperature between 55° and 65° is most beneficial to health in this country. He stated many years since, in one of his reports, that a cold wet summer always coincides with a less amount of sickness and fewer deaths than a hot dry summer. It is somewhat singular that, whilst very cold weather causes a great increase in the sickness and mortality of any given population, and especially amongst the very young and very old, the increase should extend to almost all diseases. It is true that the chief sickness and mortality are caused by affections of the lungs; but there is also a greater number of cases, although not of deaths, even from diarrhœa. Thus the rate of death, in weeks having a mean temperature of less than 35°, was nearly 45 per cent. greater than in weeks having a temperature of 60° to 65°; and in weeks having a mean temperature above 65° the average rate of death was about 30 per cent. more than in weeks having a mean ranging between 60° and 65°. The range of temperature in this country which is the best for health is so small that every one should use reasonable care when the mean is above or below the standard; at the same time we must not forget that extremes are always injurious, whatever the average may be. This is especially the case as regards diarrhœa, for the mortality from this cause, with a continuance of the mean above 65°, is at least twenty times as great as at 40° to 45°. The comparison between temperature and epidemic diseases has led to the important facts that, as regards small-pox, it produces the smallest number of deaths as soon as the daily mean reaches 62°, and has continued a short time at that degree of heat, which is usually about the end of July or early in August, and does not become so fatal again until the mean temperature has sunk for a short time below 54°, which is generally about the end of September. This is not quite invariable, as it varies somewhat in epidemic and non-epidemic years. The fatality from small-pox increases as the temperature sinks below 54°, until the middle of January, when the lowest average temperature is ordinarily reached, viz., about 35·5°. Scarlet fever, on the other hand, is at its lowest point from the middle of March to the end of the third week in April, when the daily mean varies between 41·5° and 47·5°, from which it gradually increases in fatality as the weather gets warmer, but not quite at an equal ratio, until the end of October or early in November, when the impetus apparently given to it by the warm weather has ceased, and the mortality declines. He had very carefully examined the influence of other meteorological elements on the disease, and find all of them to be almost inert as compared with that of temperature. How far the temperature, moisture, and electricity of the atmosphere are concerned in exciting diseases to become epidemic, we are unable at present to state; but the periodicity which epidemics exhibit is opposed to these being the chief causes. Thus small-pox, scarlet fever, and measles, have a very decided tendency to become epidemic in the metropolis every fourth year, whilst there is no single meteorological element or combination of elements which has so decided a periodical excess or minus of its average amount. A record of correct observations extending over many more years than we now possess, and a close comparison of these with correct returns of sickness and death in any sufficiently large area will, he does not doubt, enable statisticians to determine the precise relations which exist between the state of the public health and meteorology. There is at present, however, so little known of the varying electrical conditions of the air (at least so as to measure the changes) that it is perhaps somewhat premature to express this opinion.

BOSTON

Lyceum of Natural History, November 13, 1871.—Dr. H. Endemann read a paper "On Meat and the Methods of Preserving it," in which he described the extract of meat made according to Liebig's process, and stated that its value is overestimated, as experiments have shown that the ashes of the extract are as nutritious as the extract itself. No organic substance has been found that will produce the effects of extract. He then described the process of salting meat, and showed that the salts used, as well as any water employed subsequently to freshen the meat, remove a large part of the extractive salts, leaving it difficult of digestion. Smoking depends on the carbolic or cresylic acid contained in the smoke, by which the albumen and fibrin are coagulated, hence the meat is not readily digested. One of the best processes for preserving meat is enclosing it in air-tight cans, but this often fails on account of mechanical difficulties. He proposed to preserve meat by cutting it into slices and drying it in a hot-air chamber, at a temperature below 140° F., which may be done within two hours. This dried meat is then ground in a mill. The fibrin and albumen are not coagulated, and will take up water. The apparatus used in the preparation of the dried meat, and its applications for soup, solid dishes, and for invalids, was also described.

November 20.—Prof. B. N. Martin, vice-president, in the chair. Prof. T. Egleston exhibited five crystals of Diamond and one of red spinel, from South Africa. Two of the diamond crystals showed the cleavage parallel to the octahedron, two were curved hexoctahedra. The fifth was a cube one quarter of an inch square, weighing 0·906 grms. The cube is a twin by interpenetration, and shows the faces of the rhombic dodecahedron

on both crystals. The cube faces are all striated in the direction of the diagonals of the faces of the cube, and show, consequently, the tendency toward the octahedral form. The spinel was perfectly transparent, of a beautiful ruby colour. Its form was that of a hemitrope octahedron. —Prof. D. S. Martin exhibited specimens of a clay containing recent shells, from a deposit which had been the bed of a lagoon within quite a modern period, near the town of Lewes, Delaware. The shells are in very perfect preservation, though the epidermis is nearly gone, and the texture is becoming fragile and chalky. The principal species are *Sanguinolaria fusca*, *Nassa obsoleta*, and *Modiola plicatula*, of which the first two are now living on the beaches outside, and probably the last also. These specimens give an excellent illustration of the mode of formation of many of our fossiliferous clays and marls. The deposit may, perhaps, have value as a fertiliser. He also gave some description of the very remarkable sand-dunes or moving hills at Cape Henlopen, a mile or two east of Lewes. The sand brought down by the Delaware River accumulates at this point, and when thrown up on the beach, is taken in charge by the heavy east winds, and carried inland in a great line of drifting hills, which rises in a very long and gentle slope on the windward side, and falls off abruptly from the crest on the leeward, as is usual in wind drifts. The whole surface of the windward side is studded with the tops of dead tree trunks, the remnants of a pine forest, overwhelmed by the advance of the hill. The crest seems steadily approaching the lighthouse keeper's dwelling, and will, probably, necessitate its removal in the course of some few years. Prof. A. M. Edwards said the specimens just exhibited are of considerable interest, as they show very nicely the mode in which certain stratified rocks containing fossils are evidently formed. Under certain circumstances, say when formed in a locality like the tropics, where animal life abounded, and the mollusca especially occurred in large quantities, so that calcareous matter would accumulate, such a deposit might become, in time, converted into a limestone in which the forms of the enclosed shells and other organic remains would be preserved in a more or less perfect manner. If, on the other hand, calcium compounds were not present in abundance, but the particles of the deposit thrown down should consist of coarse and for the most part siliceous sand, sandstone, also enclosing fossils, would eventuate. But to me, the material of which the deposit exhibited consists, and which encloses the well-preserved remains of mollusca, is of more special interest, as this is the third time that such a formation has come under my observation, and I have studied one of these deposits with some care, as it proved to be, for the most part, made up of the siliceous skeletons of Diatomaceæ, to the consideration of which, both recent and fossil, I have devoted many years. All cases of marsh inversion are of interest to geologists, and the opportunities they present the microscopists of obtaining specimens for study makes them doubly attractive. The Hoboken and the Cape Henlopen specimens will be examined and reported upon hereafter.—Mr. Jas. Hyatt made some remarks on the occurrence of some plants in the vicinity of New York city. The cotton thistle, *Onopordon*, may be found at Fishkill Landing, on the Hudson River, a short distance from the railroad station, at the office of the iron works. He was able to secure flowers there for Dr. Torrey's collection. The plant has maintained itself there for several years. *Gentiana quinqueflora* abounds in South-Eastern Duchess County, and from thence he was able to furnish for Dr. Torrey's collection the only specimens from this State. *Viola rotundifolia* abounds at Weehawken, N.J., at the foot of the Palisades, west of the Ferry dock.

PARIS

Academy of Sciences, July 15.—M. de Pambour presented a further note on the reaction water wheel.—An important memoir by MM. Jamin and Richard on the cooling of gases was read.—M. A. Thenard described an apparatus for subjecting gases and vapours to the action of electricity.—M. Gaiffe described a new and cheap form of battery, consisting of a vessel in which are immersed a rod of lead and a rod of zinc, the former reaching the bottom, which is covered with a layer of aluminium; the exciting fluid in water containing 10 per cent of hydrochlorate of ammonia.—M. H. Sainte-Claire Deville communicated a note by M. J. M. Gaugain on the induction currents developed in M. Gramme's machine.—M. Faye presented a note by M. Respighi in reply to some criticisms of Father Secchi, upon his observations on the constitution of the sun.—M. J. A. Broun read a second note on the simultaneity of barometric variations between the tropics.—M. H. Tarry presented a note on the magnetic currents and solar explosions, which accompanied an aurora borealis observed on July 7. Upon this paper MM. C. Sainte-Claire Deville and Tissot made some remarks.—M. C. Sainte-Claire Deville also presented a note by M. J. Gay, describing cloud-shadows observed by him at the Grande Chartreuse, with reference to a recent balloon observation by M. Tissandier.—M. H. Sainte-Claire Deville communicated a note by M. A. Houzeau on the instantaneous oxidation of alcohol, in which the author described the conversion of alcohol into acetic acid and aldehyde by the direct action of ozonised oxygen.—M. C. Bernard presented a note by M. N. Gréhant on the quantitative determination of urea by means of Millon's test and the mercurial pump.—M. C. Dareste communicated his discovery of the presence of starch in the young of the European freshwater tortoise (*T. europæa*).—M. Des Cloizeaux read a further note upon amblygonite and montebrasite.—M. Daubrée reported upon a collection of minerals from Chili, offered by M. Domeyko to the School of Mines at Paris.—M. Sainte-Claire Deville read a paper on the absence of Combustible Gases in the emanations from the Caldeira of Furnas in St. Michael's. The same gentleman communicated an extract from a letter by M. H. de Saussure, giving an account of his observations upon the late eruption of Vesuvius in April of the present year, and made some remarks upon its contents. He also presented a note by M. Gorceix on the state of Vesuvius and of the gaseous emanations of the Phlegræan fields in the month of June, 1869.—M. Milne Edwards presented a note by M. Watelet upon the genus *Ovulites*, which the author regards as belonging to the Polyzoa. He describes a new form under the name of *Ovituba margaritula*. M. Milne Edwards also communicated a note by MM. A. Grandidier and L. Vaillant on the fossil crocodile of Amboulintsatre in Madagascar, which they regard as a new species, and name *Crocodilus robustus*.

THURSDAY, AUGUST 8, 1872

THE GOVERNMENT AND THE SOCIETY OF ANTIQUARIES

THE Government has outdone itself. Mr. Lowe and Mr. Ayrton have added another to their many claims on the esteem of their admiring fellow-countrymen, another to their many efforts to place England at the front in all matters relating to culture, and let us add another to the many indications that if science and culture are to go on in any large sense here at all, there must be some very considerable change in our present arrangements.

This time it is not a question of refusing a monument to Faraday or a search after Livingstone, of insulting a distinguished man of science at Kew, or any point relating to the investigation of any phenomena, such as the tides, which it will be recollected "My Lords," after having given their "anxious attention" to, were good enough to characterise as of an "interesting nature." This time the Government has changed its tactics altogether. Not content with hurling refusals at those societies whose duty it is to remind the Government of the claims of the sciences to which they devote themselves, the Government has singled out a society, begged it to do certain work, of course at the expense of the members, and after this work has been well and promptly done, it has turned round, and practically told the society that it is a fool for its pains. This, of course, is a *coup de maitre*, one admirably adapted to keep the societies, as well as architects, sculptors, and gardeners down, and we can well imagine that Messrs. Lowe and Ayrton have enjoyed their Bank holiday with a greater relish with this on their mind. But there is another point of view in which the transaction is less satisfactory, and to point this out it is necessary to mention some details.

We gather from the *Times* that prior to Mr. Layard's appointment as Chief Commissioner for Works and Buildings in 1868, "the office had usually been bestowed on some member of the party in power for whom there was no convenient place in the Cabinet, yet whose claims could not safely be disregarded. Sir William Molesworth had occupied the position as a distinguished champion of Radical opinions. So had Lord Morpeth as a scion of the Whigs, and Lord John Manners as a representative of the Tories. Sir Benjamin Hall succeeded to the place not so much because he represented, like his predecessors, a great political party, as that he secured for the Ministry of which he was a member the confidence of the metropolitan vestries. After Lord John Manners' second term of office the place ceased to be one of Cabinet rank; but when, after a third trial of Lord John Manners, Mr. Layard came into office with Mr. Gladstone, a new theory as to the duties of the place appears to have been initiated. Mr. Layard, setting aside his political claims, was well known to the public as a distinguished archæologist and man of letters." One of Mr. Layard's first acts was to courteously request the Society of Antiquaries to furnish him with "a list of regal and other historical tombs or monuments existing in cathedrals, churches, and other public places and buildings," such as it might be desirable to "place under the protection and supervision of the Government, with a view to their proper custody and preservation."

Thereupon the Society of Antiquaries, whose aid Mr. Layard's predecessors—whose only thoughts had been of place and party—had never required before, set to work in a most vigorous manner. They passed resolutions which were forwarded to the Government; they corresponded with their local secretaries, they appointed a numerous "Sepulchral Monuments Committee;" they divided England and Wales into districts, and made most minute inquiries; prepared a list of 531 monuments, which they considered to be included in the terms of Mr. Layard's letter; and communicated them to the Government with a report pointing out the desirability of the proposed Government action as evidenced by the demolitions which had already occurred, and stating that the work had been one of enormous labour.

By the time the report was sent in, however, Mr. Layard had left the Office of Works, and Mr. Gladstone having apparently come to the conclusion that no culture was requisite for the head of that office, Mr. Ayrton had been appointed. When the Prime Minister rewarded the important services rendered by Mr. Ayrton to his country by placing him in a position of considerable emolument, it can readily be understood that the lucre formed but a small part of the reward; and on the receipt of a letter from the Society of Antiquaries, in March, this gentleman entered upon the sweets of office with a vengeance. The Society was very quickly informed (1) that Mr. Layard's letter, on which they had acted with such alacrity and diligence, had been written "without the authority of the Treasury having been at any time obtained;" (2) "that the First Commissioner has now been informed by their Lordships that they must decline to authorise him to undertake any duties in respect to the regal and historical tombs or monuments referred to;" (3) "that the object contemplated could not apparently be accomplished without legislation;" and (4) that there was "no intention either of introducing a Bill or of laying before Parliament the report which has been made by the Sepulchral Monuments Committee."

The *Times*, in commenting upon this strange conduct, distinguishes, in reviewing Mr. Ayrton's conduct, between "the responsibilities which weighed upon him and those which encumbered his predecessor;" because "Mr. Layard, plainly owing to the enervating influence of his artistic training and literary associations, felt that in the Office of Works it was his business to encourage the fine arts, to protect the great historic monuments of the country, and to preserve from the ravages of time or ignorance those priceless memorials of the past which may be neglected by their casual owners;" while "Mr. Ayrton came into office inspired with a faith the very opposite of this, and flushed with the success which his convictions, not wholly to the satisfaction of those with whom he came into contact, had obtained at the Treasury."

But we think that the *Times* is hard upon Mr. Ayrton, inasmuch as the Lords of the Treasury are let off scot-free. Any one acquainted with the ordinary working of our political system will have a shrewd suspicion that, if it had been a question of giving a place to some little

living personage who had helped his party instead of looking after the monuments of those great men who have made England what she is, "My Lords, under the exceptional circumstances of the case," would have "been pleased to sanction the action of the First Commissioner." Moreover, it must be remembered that Mr. Layard was only First Commissioner, and that Mr. Gladstone as a Commissioner is responsible for Mr. Layard's action.

After all, however, perhaps it is well that, considering what we know of Mr. Ayrton's treatment of the living, he should have as little to do with our great dead as possible. Let their records vanish, let their sepulchral monuments disappear. What is this to the English Government? But there is a moral in all this which concerns the present. This treatment of a scientific society is the *ne plus ultra* of official Philistinism. It shows that any assistance rendered to the Government by scientific men or scientific bodies is rendered, as matters stand at present, at their peril; and until some alteration is made, any expenditure of time and energy for Government purposes should be respectfully declined.

NEW RESEARCHES IN ENTOZOA

Beiträge zur Anatomie der Plattwürmer. (Leipsic: Engelmann. 1872.)

IN the first part of this serial work, just issued, the authors—Dr. F. Sommer and Dr. L. Landois, Professors in the University of Greifswald—confine their attention to the structure of the sexually mature joints or segments of *Bothriocephalus latus.* With excellent judgment they record the results of their own investigations in the first twenty-six pages, the remainder of the *brochure* being devoted to a critical comparison of the writings of other helminthologists from the time of Eschricht down to the latest period. This method, as they remark (s. 27), not only preserves the continuity of the record of a great number of frequently repeated observations and statements, but it also has the advantage of enabling their readers to discriminate between the results obtained by themselves and those acquired by earlier and equally independent observers.

So considerable a portion of our knowledge of the structure and economy of the tapeworms is due to the researches of their own countrymen, that no surprise need be expressed at the completeness of the analysis which they afford of the writings of Siebold, Leuckart, Böttcher, Stieda, and Knoch, of St. Petersburg. Nevertheless, we may remark that, although their analysis is for the most designedly confined to the facts observed in a single species, there would have been no impropriety in noticing some of the anatomical facts given in Van Beneden's account of *Bothriocephalus punctatus;* and also, more particularly, certain facts of a similar order given in Krabbe's description of the general structure of several species of parasites belonging to the same genus. Dr. Olssen, of Lund, and other helminthologists, have likewise recorded detached observations on the structure of the Bothriocephali and their allies, some reference to which might very well have been introduced in Drs. Sommer and Landois' admirable summary.

On account of the complex character of the organisation of the proglottides of Bothriocephalus, we have hitherto been in doubt respecting many particulars connected with the intimate structure of the adult parasite. Now, happily, these are well-nigh all removed, owing principally to the investigations of Leuckart, supplemented by the present "contributions." If, in matters of biological investigation, any proof were wanting of the necessity of extending the principle of division of toil, it would be sufficient to point to Drs. Sommer and Landois' labours as affording ample proof of the value of patient research within a given limited area.

The authors commence with a description of the exterior of the proglottis, conveniently recognising at the ventral surface a clear central space which corresponds with the region occupied by the mass of the reproductive organs, and on either side of this a marginal space whose comparatively dark colour is due to the presence of numerous large corpuscles lying immediately beneath the integument. These are the yelk chambers.

Their account of the mode of termination of the ducts of the reproductive organs at the ventral surface is in harmony with the descriptions of Eschricht and Leuckart; but it is in reference to the precise nature of the connection subsisting between the *vas deferens* and the various ducts proceeding from the female reproductive organs that these contributions lend such important aid.

The male generative apparatus consists, in the first place, of a number of testicular chambers, or minute testes, individually measuring about $\frac{1}{192}''$ in diameter. Each of these is furnished with an excretory duct; all the outgoing passages uniting to form a central cistern-like reservoir; the latter emptying itself into a single tortuous *vas deferens*, or common seminal duct. Near the final outlet it expands into the well-known globular or bottle-shaped muscular organ, as previously described by Leuckart and Böttcher. Our authors ascertained that a single joint was supplied with from ten to twelve hundred of these little testes. Truly the provision made for ensuring the propagation of these intestinal worms is astonishing; for if we reckon a full-grown Bothriocephalus to consist of three thousand proglottides (an estimate decidedly below the mark), that would give us over three millions as the number of testes supplied to a (so-called) single parasite. Shakespeare was not far wrong in the remark that "evil things do fastest propagate"—a conclusion which becomes all the more striking when we make ourselves acquainted with the exceeding complexity of the female reproductive organs of the *Tæniada* and their allies.

The sexual apparatus comprises not only the vagina and uterus (which in this class of creatures form totally distinct passages, with separate outlets), but also three special sets of organs severally concerned in the production of the germ, the yelk, and the egg-shell. Moreover, each organ is itself made up of numerous parts, being, at the same time, supplied with its own proper excretory channels. All this, of course, we knew before; but in tracing out the relations subsisting between these various channels and the organs whence they proceed, and also in establishing the mode in which their final connection with the vagina and uterus is brought about, Drs. Sommer and Landois have displayed consummate ability, and have thus materially added to our knowledge.

T. SPENCER COBBOLD

OUR BOOK SHELF

Description of a Specimen of Balænoptera musculus, in the possession of the Boston Society of Natural History. By Thomas Dwight, jun., M.D. (Boston Society of Natural History.)

THE eleventh volume of the "Memoirs of the Boston Society of Natural History" contains a descriptive account, by Dr. Thomas Dwight, of the external characters and skeleton of a young razor-back whale, the skeleton of which is preserved in the Society's Museum. This animal was captured alive in October 1870, off Gloucester, Massachusetts, and its skeleton is the best preserved specimen of a large whale in any of the American museums. The animal was 48 ft. long, the flipper was 5 ft. 4 in., and the height of the dorsal fin, measured along the anterior edge, was 1 ft. 2 in. The baleen was of a very light straw colour anteriorly, whilst further back dark stripes appeared on it, until the hindmost blades were of a uniform dark slate colour. From the very careful description which Dr. Dwight has written of the skeleton, and from the figures given in illustration, there can be no question that the animal is a young example of the fin-whale, which Dr. Gray has named *Physalus antiquorum*, but which is more appropriately named *Balænoptera musculus*. In some remarks on the classification of the specimen, he refers to the tendency to variation in the forms of the bones exhibited in the skeletons of cetacea, undoubtedly belonging to the same species, and he agrees with those cetologists who have shown the danger of accepting mere individual variations in the forms of the bones of particular specimens as affording data for establishing specific or generic differences. W. T.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Bree on Darwinism

PERMIT me to state—though the statement is almost superfluous—that Mr. Wallace, in his review of Dr. Bree's work, gives with perfect correctness what I intended to express, and what I believe was expressed clearly, with respect to the probable position of man in the early part of his pedigree. As I have not seen Dr. Bree's recent work, and as his letter is unintelligible to me, I cannot even conjecture how he has so completely mistaken my meaning: but, perhaps, no one who has read Mr. Wallace's article, or who has read a work formerly published by Dr. Bree on the same subject as his recent one, will be surprised at any amount of misunderstanding on his part.

August 3 CHARLES DARWIN

Ants and Aphides

AMONG other misstatements in Dr. Bree's "Fallacies of Darwinism," so ably criticised by Mr. Wallace in NATURE of July 25, occurs the following:—"All the stories about aphides being treated as milch-cows are myths, the result of inaccurate observation" (p. 166). I can personally refute this statement, having on many occasions watched the process. Speaking of the attraction of male emperor moths by a captive female, Dr. Bree observes:—"All this was clearly, and without doubt, done by the sense of smell" (p. 209). I, in common with most other entomologists, should much value the evidence on which this very positive assertion rests; for the explanation of the attractive power of female insects has hitherto remained a mystery. R. MELDOLA

Atmospheric Effect

THE phenomenon mentioned by Prof. Tyndall as recently occurring at the Bel Alp is not infrequent at the coast. At Folkestone in the month of June last, we saw several more or less striking instances. Some years since I witnessed, while driving, on a summer's evening, between Guildford and Godalming, an equally beautiful though different effect. The evening was stormy, and the sun, still some distance above the western horizon, threw its sheaf of rays *downwards* from behind a light cloud. In the eastern horizon was a dense, dark thunder-cloud, and upon this was seen a reflection of the opposite horizon, the shadows being absorbed by the dark background, while the intervening spaces or rays shone out with a brilliancy considerably exceeding that of those in the west. The whole of the circumstances were different from those described by Prof. Tyndall, there being, as far as I can recollect, no *upward* rays from the sun, and the rays seen on the cloud being neither convergent nor divergent, but merely parallel, and apparently a complete reflection of those which shot from the sun to the horizon. Their wonderful brightness, as contrasted with the rays of which they were the image, was, no doubt, the effect of contrast upon the almost blank screen on which they were seen. This latter, however, was lighted up to a certain extent by a sort of golden haze, in which the rays shone. The whole phenomenon was one of great beauty, and was witnessed by some friends of mine at Guildford at about the same time as I saw it from a point near to Godalming. J. RAND CAPRON

Guildford, Aug. 30

The Carbonic Acid in Sea-water

IN the Deep-sea explorations undertaken of late years in England, the gases obtained from sea-water at various depths, and under different conditions, have been the subject of investigation. As coadjutor in the German expedition to the Baltic, I have been engaged in the analysis of the sea-water gases. There have occurred circumstances which I have thought it desirable to communicate to you with reference to your forthcoming future Deep-sea explorations.

I must premise that the expulsion of the sea-water gases was undertaken in a similar manner to that of the English expedition, the pans of water being boiled for a long time in vacuum, the expelled gases being collected and afterwards analysed. The result of these analyses pointed unmistakeably to a hitherto unrecognised source of error, for the prevention of which a series of supplementary experiments was necessary. The principal results of these latter can be comprised under the following heads:—

1. The complete expulsion of the oxygen and nitrogen from sea-water presents no difficulty; it is accomplished as easily as with fresh water. The proportion of oxygen to nitrogen is not sensibly different in the first and last portions of the expelled gas.

2. The carbonic acid is only partially expelled by boiling the sea-water for hours in vacuum; the proportion of carbonic acid found in the expelled gas justifies no conclusion as to the amount in the water. It is, in the first place, dependent on the length of time during which the ebullition has been continued; the portions of the sea-water gas first driven off is almost entirely free from carbonic acid, the later portions are richer in it.

3. The complete expulsion of the carbonic acid from the sea-water is attained by its distillation in a current of air free from carbonic acid. Even under this operation, the carbonic acid is detached so slowly, that only after the evaporation of a considerable amount of water carbonate of lime begins to separate; the distillation must then be continued till, at the most, a fourth of the original quantity of water remains. The carbonic acid which is passed into baryta water can be conveniently estimated by volumetric analysis.

The fact that carbonic acid is present in large proportion in sea water, not as a dissolved gas in the same sense as oxygen or nitrogen, but in a peculiar condition of closer combination, must be of great importance, not only as respects the animal and vegetable life, but also the geological relations of the sea.

I am now proposing to myself the problem to ascertain to which constituent of sea-water is due its power of close combination with carbonic acid; and to what extent the amount of carbonic acid is proportional to its saltness. Full details will be given in the Report of the German Baltic expedition. In the expedition to be sent from here to the North Sea, application of the experience hitherto obtained will be made to the estimation of carbonic acid.

Kiel, July 5 OSCAR JACOBSEN

MR. AYRTON AND DR. HOOKER

IT has been determined that this question shall not be brought on in the House of Commons at this late period of the session, as so many members are already absent that it is possible the debate might fail somewhat to represent the actual feelings of the House. At the same time it is known that had the discussion come on some weeks ago, the Government, if they had ventured to support Mr. Ayrton, would have been beaten.

Of the return moved for by Sir John Lubbock, and prepared by Mr. Ayrton, it is difficult to speak or write without expressing strong indignation. We have not what we want, and we have what no one wants. The whole object of the compilation is to leave the reader in a fog, and from this point of view the compiler deserves credit. We regret also to see the respected name of Prof. Owen dragged into the discussion on a point which has nothing whatever to do with the question under discussion, which is simply Mr. Ayrton's monstrous behaviour to a man of science. It is gratifying to see from the Treasury letter which we reprint that "My Lords" have not hesitated to hint with sufficient pointedness for an official document their opinion on the matter. It must not be forgotten that for a time Mr. Ayrton was at the Treasury, *and that he is there no longer*.

COPY OF TREASURY MINUTE, dated 24th of July, 1872.

My Lords have under their consideration the Memorandum of the First Commissioner on the rearrangement of Kew Gardens by the Office of Works, and of the changes therein.

This Memorandum embraces three subjects:—

1. The manner in which matters connected with the management of Kew Gardens have been conducted, and in doing so, refers to instances in which complaints have been made by the Director of Kew Gardens.
2. The arrangements under which this management ought to be conducted.
3. Suggestions and questions of the First Commissioner as to changes therein, and as to connecting the Kew Gardens with the Kensington Museum, which, however, the First Commissioner does not propose should be taken into consideration at present.

To the last part of the Memorandum, therefore, my Lords do not propose to refer in the present Minute.

In discussing any arrangement for the management of the establishment and gardens at Kew, it must be remembered that there is a considerable space of ground beyond the hot-houses, buildings, and ground appropriated to the cultivation of shrubs and plants for the promotion of botanical science.

Part of this ground has been used as a nursery for young trees, and the remainder has been laid out as ornamental pleasure grounds.

The establishments at Kew have always been under the superintendence of the Office of Works, subject, of course, to the superior control of the Treasury, to which department the annual estimates of expenditure are submitted for their sanction, and this control it is indispensable to maintain.

With regard to the local management at Kew, the First Commissioner's Memorandum divides it, for the purposes of administration, into four branches, Botany, Horticulture, Police, and Works.

It is unnecessary, in the present Minute, to refer to Police.

The Department of Botany the First Commissioner states to be "under the immediate direction and control of the Director of Kew Gardens;" the Department of Horticulture to be "under the immediate cultivation of the Curator, subject to the orders and control of the Director, as the responsible head."

The works are carried out by an officer of the Office of Works.

My Lords consider this statement to represent with sufficient accuracy the proper arrangement for the establishment, and that if fairly carried into execution, n the friendly and conciliatory spirit which ought to prevail amongst the different members of all public departments, no difficulty will occur.

It is essential to maintain the superior authority in all respects of the First Commissioner, *but the nature of the case makes it evident that this authority should of course be exercised with due regard to the feelings and position of the officers under him.*

The Botanical Department has been formed by the exertions of Sir W. Hooker, and of his son Dr. Hooker. It stands high in the estimation of men of science both here and abroad, and both these eminent men are entitled to the gratitude of the country for their services in this department of science.

In all matters connected with this department of the establishment, whether as regards the hot-houses, buildings, or the cultivation of shrubs and plants for botanical purposes, the opinion of Dr. Hooker should be followed, subject only to the consideration of expense. It is for him to represent to the First Commissioner what he considers necessary for the advancement of botanical science, and it is then for the First Commissioner and the Treasury to determine whether the expense necessary for the purpose shall be incurred.

No alterations in existing arrangements in the scientific branch of the department should be made without the Director's concurrence.

The actual execution of the works to be undertaken must be under the direction of the proper officer of Works, but the opinion of the Director of the Gardens should be taken as to the efficiency of what it is proposed to do, and any requisition of his for work or repairs necessary for the preservation of the valuable plants in the houses should on all occasions receive prompt attention.

With regard to those parts of the grounds which are not used for the purpose of botanical science, but as nursery grounds or pleasure grounds, it will be the office of the First Commissioner to give such directions as he may think advisable.

My Lords, however, think it desirable that even on these points he should communicate with the Director of the Gardens, through whom, as head of the establishment, all orders to the curator and to other subordinate officers should, in regular course, be conveyed.

My Lords gather from the Memorandum of the First Commissioner that, speaking generally, the business connected with Kew Gardens has been conducted in accordance with the views thus entertained by their Lordships.

My Lords do not consider that it would be conducive either to the public advantage or to the maintenance of that good and friendly feeling which they are anxious to see prevailing in every public department, if in closing this correspondence they were to go in detail into the cases where any disagreement has taken place between the First Commissioner and the Director.

But adverting to the facts contained in the Memorandum of the First Commissioner, they are not surprised that in various cases Dr. Hooker should have thought that he had just cause of complaint, though this may have grown in some instances out of arrangements for which the First Commissioner was not responsible, and in others they learn from the Memorandum of the First Commissioner that the cause of complaint has been removed.

My Lords see no reason why under these conditions there should be any serious difficulty in discharging the respective duties of the First Commissioner and of the

Director of the Gardens in a manner satisfactory to both, whoever may be the occupants of those offices, maintaining the proper authority of the First Commissioner, with due regard to the position and character of the Director of the Gardens.

Let a copy of this Minute be sent to the First Commissioner, with a request that it may be communicated to the Director of Kew Gardens.

THE ROYAL ARCHÆOLOGICAL INSTITUTE MEETING AT SOUTHAMPTON

THE annual meeting of the Royal Archæological Institute was opened in the Hartley Institution, Southampton, on Thursday last. The members of the Institute were welcomed by the Mayor and Corporation of the borough, the chair being taken by Lord Talbot de Malahide, the permanent president.

Archdeacon Jacob furnished some interesting information respecting the tomb of William Rufus. He was, he said, accessory to the removal of the tomb of William Rufus, and he had not heard the last of it. He thought, however, he was sufficiently pachydermatous not to mind this. There was William Rufus's tomb, an eyesore and a footsore, for persons dashed their feet against it to their injury, and the place was particularly wanted, by reason of the enlargement of Winchester Cathedral, for the boys to sit. The question raised was—Is that the grave of William Rufus? Is there anything in it? If there is, whose bones are they? If there are bones, are they William Rufus's? Might it not be perfectly empty, and, if so, why should it stand there an obstruction? He, then, having skilled persons about him, ventured to take up the slab, and found that the tomb had been rifled and dishonoured in every way. There were bones there thrown about and trodden. It was suggested by some that the Parliamentarians had done this, whereupon he sent for and consulted the chief science men in Winchester. They had the bones taken out and placed on the pavement, so as to see the height of the man, and, gauged by the height which Thackeray says does the work of the country, he was found to be 5ft. 8in. Having examined them microscopically, they came to the conclusion (it was not stated how) that they were the bones of William Rufus, and were quite certain the tomb had been moved again and again before. When they visited Winchester they would find where he had had it placed, and if they had not been told otherwise they would probably have believed it had always been there. Believing in the *dictum* of Bishop Andrews, who said the church was for the living and not for the dead, and knowing that King Rufus had not been a benefactor to his country, he thought it not unbecoming to move him a little further, but he was still within the sacred walls. Therefore, anticipating their judgment, he trusted they would not pitch him into the river Itchen for the so-called disturbing of the bones of William Rufus.

At three o'clock the members of the society and friends, including the Marquis of Bristol, Lord Talbot, Colonel Pinney, and many others, visited the town under the guidance of Mr. Parker, who described most of its ancient features.

The Mayor, and Mayoress, gave a *soirée* to the members of the Institute at the Hartley Institution in the evening. It proved to be a very successful affair. Over 800 invitations were issued, and a large number of these were accepted, several officers from the United States fleet being present.

The sections met on Friday. The Bishop of Winchester presided for a short time, and introduced Lord Henry Scott, who read an introductory address in the Historical Section.

Lord H. Scott confined his remarks to a history of the County of Hampshire. As to the origin of Southampton, he said there was an ancient British town called Hampton, which was probably situate higher up the Itchen, at Bitterne. The town was even now often called Hampton by the country people. In "Domesday Book" the county was called Hampton-shire and the town Hampton. It suffered severely from the incursions of the Danes. Henry I. made it a borough, and King John gave it its first charter and had a palace there. Thence sailed the expedition for Palestine, and Henry embarked for Cressy and Agincourt. Philip of Spain also landed there to meet his Queen at Winchester. It was also from thence that the great apostle of Germany, afterwards better known as St. Boniface, departed on his mission. After referring to Leyland's "History of Southampton," he came to the general history of the county. One of the most valuable historical monuments that had been left to them was the New Forest; and however much they might condemn the severe laws which were made for the protection of what were called "the King's beastes," yet they felt some gratitude that it had been preserved to their use as it was now. He then gave a sketch of the historical associations connected with the Forest. He disbelieved the old supposition that houses and churches had been destroyed by William Rufus to make the Forest, though some small holdings might have been enclosed. The connection of Tyrrel with the death of Rufus was preserved by a ford which at this day was called Tyrrel's Ford. In the Forest was Beaulieu Abbey, which was described in the charter of King John as the *bella loca regis*. It was founded by King John in 1234. It was forty years in building, and Henry III. and all his Court attended the dedication. It was the sanctuary of Perkin Warbeck for many years. His lordship observed that this part of our coast had always in our early history been exposed to invasion. Hampshire also suffered much during the civil wars, and after the Restoration Charles II. used to come down from London to enjoy holiday in it. William III. was the first after Charles II. to attempt to repair the damages which the Civil War had created in the Forest; and later, in the era of the Georges, the county had been connected with our naval victories under Nelson. Hampshire also contained the Strathfieldsaye so closely connected with the later days of the Iron Duke; and in Hampshire the poet Keble found a quiet and honourable grave.

The Rev. F. W. Baker then read a memoir of Beaulieu Abbey.—Lord Henry Scott, in moving a vote of thanks to Mr. Baker, gave the Institute an invitation to Beaulieu for the following day, and said that Mr. Baker would be in attendance to explain every point worthy of their consideration in this most interesting abbey.—The proposition having been heartily accorded, the sitting was then suspended. In the afternoon there was an excursion of the members of the Institute to Romsey and Porchester, which occupied until eight P.M. At Romsey the vicar (the Rev. E. L. Berthon) gave a discourse on the Abbey of Romsey, and showed the result of recent excavations; and at Porchester Mr. G. T. Clark lectured upon the Castle there. Saturday was devoted to the excursion to Beaulieu Abbey, and a visit to Christchurch and Rufus's Stone.

On Tuesday, the members of the institute visited Silchester (Saxon "Sil," great or best, and "castrum"), which has the largest area of any of the Roman fortifications in England. The walls at present are about 13 ft. high and 8 ft. thick. The city had four gates—north, south, east, and west—and beyond the wall was a deep ditch, and beyond the ditch a vallum 15 ft. high. The amphitheatre is situated outside the city, 150 yards from the north-east corner of the wall. The members also visited the remains of the Chapel at Basingstoke, dismantled by the Parliamentarians, and Basing House, formerly the abode of the Marquis of Winchester, by whom it was defended against the Parliamentarians. In

the evening the members held an evening session for the reading of papers.

Exeter has been fixed upon as the place of meeting next year.

THE ELECTRIC TELEGRAPH—ITS IMPROVEMENT AND CAPABILITIES

IN the beginning of the present year a Society of Telegraph Engineers was established for the general advancement of electrical and telegraphic science, intended to include not only those persons who are professionally connected with telegraphy, but those also who from their position and pursuits are enabled to render assistance in telegraphic enterprise. The institution has made a successful and promising commencement, the members at the opening meeting in February last numbering 110, the list including the historical names of Wheatstone and Cooke, the distinguished names of Thompson, Tyndall, and others scarcely less renowned for their important contributions to electrical science. The President, Mr. C. W. Siemens, D.C.L., in the course of his inaugural address, said :—

History teaches us how to read the events of the present day, and what we may reasonably look forward to even in the future ; let us, therefore, review shortly in our minds the remarkable history of the Electric Telegraph, in order that we may be better prepared to deal with questions of immediate interest.

A generation has hardly passed away since the remarkable discoveries of Oersted, Ampère, Faraday, and Weber, which laid the foundation of the electro-magnetic telegraph. The names of Steinheil, Schilling, Ronalds, Wheatstone, Cooke, and Morse furnish us with striking illustrations of the readiness with which the thinking men of different nations turn scientific discovery to practical use. While these pioneers in the field of telegraphic progress were still contending against practical difficulties, other earnest labourers entered the same field, amongst whom Werner Siemens, Bain, and Brequet should not pass unmentioned here. But so rapid has been the progress of our branch of science, that, while I am obliged to speak of these men as belonging to our early history, they are still, almost without exception, living amongst us in full enjoyment of their faculties, and, I am happy to add, members of our new society. They have the rare satisfaction to see their early day-dreams carried out upon so vast a scale that there is to-day hardly a country, however remote, that is not within a few minutes', or at all events a few hours' call, from every central point of the civilised world, that diplomatic conferences have to be held to regulate international telegraphy, and that a proposal is seriously entertained by the leading powers of the earth to place telegraphic property upon the highest, I may also say a sacred basis, by declaring it inviolable in case of war. The electric telegraph has, indeed, attained to the dignity of a commercial, a social, and an international institution of the highest importance ; it is a civiliser of the first magnitude, and we may well be proud to meet here together in furtherance of such a cause.

You will pardon me if I abstain from making special reference to the numerous claims to recognition of the fellow-labourers of the present day whom I am now addressing ; they are well known within our own circle and to the public at large, but neither my ability nor the time at my command would suffice for such a task. I will only endeavour, before concluding this address, to summarise the subject-matters which, judging from my experience, should engage our principal attention.

Problems of pure electrical science meet the telegraph engineer at every turn, the methods of testing insulated wire, of determining the position of a fault in a submarine cable under various circumstances, or of combining instruments so as to produce recorded messages by the mere fluctuation of electrical tension in a long submarine conductor, are problems worthy of the most profound physicist and mathematician. On the other hand, there is hardly a problem in electrical science that is not of practical interest to the Telegraph Engineer ; and, considering that electricity is not represented at present by a separate learned society, ranking with the Chemical or Astronomical Societies, I am of opinion that we should not exclude from our subjects questions of purely electrical science. The phenomena of electrification and polarisation, of specific induction and conduction, the laws regulating the electrical wave, the influences of rise of temperature on conduction or the potential force residing in a coil of wire of a given form, when traversed by a current, involves questions belonging just as much to pure physical science as to the daily practice of the Telegraph Engineer, and would at any rate be inseparable from our proceedings. Next in order come questions of selection of materials for conduction or insulation, of apparatus for the best utilisation of feeble currents, of apparatus for producing, alternating, and directing electrical currents, which, although still intimately connected with physical science, call into play considerations of mechanical combinations. This brings us to questions of purely mechanical import, such as the mechanical construction of instruments for recording or printing messages, of protecting and supporting insulated conductors by sea or land, or of constructing machinery for the manufacture, the laying, and the repairing of submarine cables.

These questions again lead up to the more general ones of transport of materials through difficult and inhospitable countries, of navigation, of investigations into the depth and the nature of the bottom of the seas, into the nature and effect of sea currents, and so forth, all of which belong, under certain aspects at least, to the province of the Telegraph Engineer.

I would go further, and include even statistical information respecting the nature and growth of telegraphic correspondence, without which it is impossible to adapt the construction of lines and of working instruments to the acquirements of particular cases. The invention of a telegraphic instrument, for instance, is only of practical value if it is suited to the circumstances of the particular traffic for which it is intended, and to the electrical condition of the lines which it is proposed to work, and when the early pioneers of telegraphic progress elaborated ingenious instruments for sending and recording messages automatically or for printing them in Roman type, they invariably failed, because the then-existing lines were insufficient in every way for such refinement, and the simple needle instrument seemed to suffice for all practical purposes. It was only when the exigencies of the traffic demanded a change that instruments of this nature proved to be valuable inventions.

In like manner the long underground lines that were established on the Continent at an early date had to give way to suspended line-wire, whereas the present practice and necessities undoubtedly tend toward a reversion to the former, as being less liable to interruption by accident or by atmospheric influences, and because an unlimited number of underground wires may be established between any two stations without encumbering the public thoroughfares. The best mode of insulating and protecting these underground wires with a view to reducing the inductive influence of the one upon the other, and of facilitating access to the one, for the purpose of repairs, without disturbing the others, are questions of practical interest for the present day.

The Electric Telegraph is applicable with the greatest positive advantage for the intercommunication between two points a great distance apart ; through its agency New York and Calcutta are as near to us in point of time as are the suburbs of our metropolis from one another.

It is probable, indeed, that in telegraphing from one suburb to another the message has to be oftener retransmitted than in going from the City of London to India or America, because a direct transmission from any one part of London to another would involve almost an infinite number of line-wires in all directions. For this reason there must be a limit to the applicability of the Electric Telegraphs in populous districts, and it behoves us to examine whether another agent may not be preferable in dealing with a traffic of this description. The pneumatic tube seems to be well adapted to these circumstances, and having been first applied for short distances by Latimer Clark, and subsequently modified and extended by others, it will fall within the province of our society to examine fully into this and kindred methods that may be devised for effecting rapid interchange of intelligence in towns.

THE BRITISH COAL-FIELDS

ONE distinguished geologist, at least, disbelieves in the speedy exhaustion of our coal-measures, so frequently predicted of late. At the annual meeting of the Dudley and Midland Geological and Scientific Society, Prof. Ramsay delivered an address on the existence of coal beneath the New Red and Permian strata, in the course of which he observed that for fifteen years he had been preparing to attack this subject, but it was not until he became a member of the Royal Coal Commission he had given it a really searching consideration. There could be no doubt that the various coal-fields of the Northern and Midland districts once formed one great coal-field, but had been separated by extensive denudation. Another great coal-field was formed by the now distinct fields of Devonshire, South Wales, Somersetshire, and the Forest of Dean. Between these two great divisions, the north and the south, there was no connection formed by the coal-measures, the poorer measures possibly having been deposited there, but not the rich deep ones in the carboniferous era. Referring more especially to the Midland district, he thought it highly probable that coal-measures would be found to exist between the present boundary of the South Staffordshire district and the Forest of Wyre; but it was questionable whether it would be of a workable depth. On the west side of the South Staffordshire boundary, in the direction of Bridgenorth, Shropshire, he also believed coal to exist beneath the Permian strata, at a depth of 1,500 feet, or possibly more in some places. At the north of the South Staffordshire boundary, a line drawn from Wyrley right across to the Shropshire district would, he believed, include some valuable coal-beds, a considerable part, but not all, of which would be at a workable depth. He entertained no doubt that the coal-measures were continuous between the South Staffordshire and Shropshire districts, which, although in some places disturbed by denudations, might, throughout the greater part of the area, be profitably worked. In the North Warwickshire coal-field were found, in the direction of the Staffordshire boundary, five beds of coal, which gradually amalgamated, until on nearing Coventry they formed only two measures. The shale and sandstone were split up in like manner. These features constituted most important evidence in support of the theory that the Warwickshire, Staffordshire, and Shropshire districts were united by continuous coal-measures, the peculiarities referred to in the coal, shale, and sandstone strata being identical in all three districts. In that theory Prof. Ramsay was a firm believer. From Warwickshire to the south end of the South Staffordshire boundary, there was, he believed, coal, but not profitable. Towards the northern end of the South Staffordshire boundary, however, a line drawn from Coventry would include rich and valuable coal-measures. Between Staffordshire and Leicestershire the measures were also, he believed, continuous. From Wales to the Forest of Wyre there was profitable ground; but from Wyre on to Charnwood Forest, and east of that, there were no coals of value. The speaker expressed opinions equally assuring as to the presence of coal under the area lying between the north of the South Staffordshire boundary and the mountain limestones of Derbyshire. In one part of that district—viz., north-west of Cannock Chase—Prof. Ramsay said he should not feel the slightest hesitation in recommending a search for coal; and his belief in the presence of coal at a workable depth in the neighbourhood of Uttoxeter was equally strong. Now, supposing that his calculations were only approximately correct, the result would be surprising. It would amount to this—the coal now reckoned as available in the South Staffordshire and Shropshire districts was, in round numbers, 3,201,000,000 tons. If his belief were a true one, this supply would be further augmented by 10,000,000,000 tons. In Warwickshire the proved coal-measures are estimated to yield 458,000,000 tons, and the measures he believed to exist in addition would be 2,494,000,000, or five times more than the present estimate. The Leicestershire field was calculated to possess 836,000,000 tons, and this would be supplemented to the extent of 1,790,000,000. What was the case in regard to these districts was, he believed, equally applicable to many other parts of Great Britain. The South Wales, Forest of Dean, Bristol and Somerset districts were exceptions to this rule, the coal there lying in basins caused by denudations, the surrounding measures being destroyed. In the Midland districts these small basins are not found, the whole forming one great basin. Lancashire, Derby, and the Yorkshire coal-fields were, however, subdivided by the process of denudation. Still, he had no hesitation in believing that the estuary of the Dee and the Mersey have lying between them beds of coal, although probably at too great a depth to be of practical value.

MR. TODHUNTER ON THE ARC OF THE MERIDIAN MEASURED IN LAPLAND

MR. TODHUNTER has forwarded us a reprint from the "Transactions of the Cambridge Philosophical Society," in which he discusses the observations made in connection with the measurement of the arc of the meridian in Lapland in the last century. He states that having recently had occasion to study the details of the two measurements of the arc, he has been surprised to find that the accounts of these operations, although written by very distinguished astronomers, contain numerous and serious errors. We must refer our readers to the memoir itself for a complete account of the various points raised, for it is too long for adequate notice in the space at our disposal. A curious point, however, is raised as to the effect of theory upon observation in a paragraph which we quote *in extenso*:—

"It would be a curious subject of speculation whether the theoretical opinions of persons engaged in geodetical surveys could have exercised any influence on their observations; I mean of course unconsciously, for it would be wrong to suspect any deliberate unfairness in any of the operations which I have examined. From a passage in the article 'Figure de la Terre,' by D'Alembert in the original *Encyclopédie*, it would appear that the school of Cassini originally believed that in consequence of the oblate form of the earth, the length of a degree of the meridian *would decrease* from the equator to the pole. It seems strange, perhaps, now to suppose that such an error could be seriously maintained; but there can be no doubt of it; for example, the error was vehemently maintained by Keill, a man of some reputation, who was ultimately a

Savilian professor at Oxford. See Keill's 'Examination of Dr. Burnet's Theory of the Earth,' page 140. It is certainly a remarkable coincidence that the school of Cassini starting with the erroneous theoretical notion that the degrees of the meridian *ought* to decrease from the equator to the pole arrived at the same result by observation and measurement.

"There can, I think, be no doubt that at least Maupertuis and Clairaut, who were the most eminent of the French party, held the correct Newtonian theory as to the figure of the earth; and their result was rather too decided in its confirmation of this theory. Now the geodetical angles could scarcely be influenced by the theoretical opinions of the observers; because it would not be obvious in what way the result would be affected by an error in an angle. But in measuring the base it would of course be obvious that the larger was the value obtained, the stronger was the evidence for an oblate form. Similarly in estimating the amplitude, the smaller the value obtained the stronger was the evidence for the oblate form. In these two parts of the survey then it would be necessary to be on the watch lest the conviction of what the result ought to be should influence the impression of what the observation really gives.

"It is curious that Maupertuis and his party seem to have thought at first that their success was too decided, and therefore their amplitude too small; and that on their second determination they should have made it between 3″ and 4″ larger than at first."

THE BEGINNINGS OF LIFE *

I.

AFTER a careful perusal of this important and suggestive work, a prominent feeling is one of regret that its value and popularity should be endangered owing to purely technical faults of composition and arrangement. It is so full of curious and novel facts and experiments, it contains so much excellent reasoning and acute criticism, and it opens up such new and astounding views of the nature and origin of life, that one feels it ought to and might have ranked with such standard works as the "Origin of Species" and the "Principles of Biology," if equal care had been bestowed upon it as a literary composition. But, unfortunately, it altogether lacks their powerful condensation and lucid arrangement. Its vast masses of facts are stated too diffusely, and are often so scattered as to lose the cumulative force that might have been given to them; while the arguments are broken up and weakened by a too minute classification of the subjects treated, leading to repetition and confusion rather than to clearness. Haste of composition is further indicated by the quantity of additional matter given in foot-notes that should have found a place in the text; and we often find it difficult to follow the special argument in hand, or to see the connection and relevance of much of the detailed evidence brought forward.

Notwithstanding these defects, which will undoubtedly diminish its popularity, it is a book which will make its mark, and must produce a powerful sensation.

It brings together a large body of facts, either new or hitherto almost ignored, which, unless they can be otherwise explained, prove much more than the mere production of low living organisms from dead matter; for these low forms have been seen to combine and give rise to higher forms, and these again to still higher and more complex organisms. Vegetable cells or their contents develop into various low animals; while animal as well as vegetable organisms of specialised forms and some elaboration of structure seem to be mutually transformable by processes quite unlike any of the hitherto accepted modes of multiplication or reproduction. These processes have been traced stage by stage, so that there seems no possibility of mistake; and they do not rest on the observations of Dr. Bastian alone. Facts of this nature have been repeatedly published for more than twenty years by many Continental and English naturalists, but, being so entirely opposed to current theories, have been all silently ignored, just as true facts and careful observations relating to the antiquity of man were so long ignored. Our author has, however, repeated and tested many of these observations, and finds them to be strictly accurate; and they harmonise perfectly with the views on the origin of life founded on his own experiments, and so energetically advocated by him.

Looked at merely as curiosities of science, and as an unveiling of mysteries hitherto thought to be inscrutable, these observations are of supreme interest; while their importance in connection with modern theories of development and the origin of species can hardly be overrated. Setting aside all the prejudices and dogmas of the existing schools of biology, it must be admitted that the views here presented of the perpetual origination of low forms of life now, as in all past epochs, is in perfect harmony with the doctrine of evolution, and does away with many of the physical and geological difficulties which are undoubtedly among the most serious which beset those special views of the origin of life which Mr. Darwin holds, but which are by no means necessary inferences from his theories.

The present work is essentially one that to be judged soundly cannot be judged hastily. The subject is of overwhelming importance to the future progress of scientific biology, and the facts and observations on which it is founded are so numerous and so precise, and have been tested by such a body of distinct and competent observers, that no *à priori* arguments and no authoritative dicta can have any weight against them. Observation alone can demonstrate whether they are facts or delusions. They will no doubt be fully criticised by those whose special studies render them competent to do so; but if the past history of science has any value whatever, the result cannot be doubtful. Facts observed and tested by a succession of careful and accurate observers, such as those whose evidence is adduced by Dr. Bastian, have never yet proved to be fallacies.

We now propose to lay before our readers a sketch of the more interesting matters treated of in these volumes, citing a few of the most striking of the new facts and the most important of the arguments founded upon them.

More than half of the first volume is devoted to an account of the Nature and Source of the Vital Forces and of Organisable Matters, and we have an excellent summary of modern views on the correlation of vital and physical forces, on the vital principle, on theories of organisation, and on the modes of origin of reproductive units and cells. As bearing upon subjects to be discussed further on, there is an important remark on the origin of germs or specks of living protoplasm in the fluids of the living body. These fluids, it is maintained, are not alive, and, therefore, the living germ does originate in a dead organic fluid. Even if it is held that blood and all the other secretions are alive, yet as they have been formed out of dead matter taken into the stomach there must be some point at which the particles of dead matter become transformed into living matter, and the circumstance of this occurring *within* an organism does not alter the fact of its occurrence, or render it at all more easy to conceive or explain. Why, then, should it be so absolutely incredible that specks of living protoplasm should arise in suitable fluids out of a living body? It is certain that as soon as the fact that they do so arise is established, the one will be as easy to conceive and be as credible as the other. The only other point that calls for notice in this part of the work is the discussion on the supposed "vital force," in which the views of the "vitalists" seem to be

* "The Beginnings of Life: being some account of the Nature, Modes of Origin, and Transformations of Lower Organisms." By H. Charlton Bastian, M.A., M.D., F.R.S. (2 vols. London: Macmillan and Co. 1872.)

hardly fairly stated. Dr. Bastian says:—"If the vital or directive power resident in each particle of a living being be other than a transformed physical force it must be one which—in spite of the well-known formula '*ex nihilo nihil fit*'—is capable of indefinite self-multiplication. Either such force must be continually springing into being without cause—originating itself or growing out of nothing—which is an absurdity; or else, within the ovum of any animal, there must be locked up the whole of the peculiar vital power which is afterwards to diffuse itself throughout the body," &c. But this is by no means a necessary conception of the "vital force" or "vital principle." That force or principle need not, and cannot "reside" in any particles of matter. If it exists it is cosmical, and acts *on* matter just as gravitation does. Is it any argument against the reality of gravitation that any particle of matter, however small, attracts any mass, however great; that, as Prof. De Morgan puts it, each grain of salt and pepper in a million salt-cellars and pepper-castors, individually and separately *pull*, and actually move, the sun and every fixed star? This is a *reductio ad absurdum* against the notion that the force of gravitation resides *in* matter; but it does not touch the notion of gravitation as an inscrutable cosmical force (probably the source of *all* force) acting on matter. It appears to me, therefore, that as long as consciousness, thought, and will cannot be conceived of as manifestations of the "correlated series of physical forces," we must postulate some universal "vital principle" as co-extensive with, if not superior to and the source of, the "physical forces;" and if such exists it is natural to impute to it some share in the production of these wonderful *organisms* through which alone we see consciousness manifested. In another place Dr. Bastian says that living protoplasm is believed by a large section of the physiological world "to contain no special and peculiar 'force;' but to owe its qualities entirely to the ordinary physical properties of the elements entering into its composition." It may not *contain* a peculiar force, but surely it does *manifest* some other properties than the ordinary physical properties of its elements, just as the thundercloud, when it sends out a destructive lightning flash to the earth beneath, manifests other than the "ordinary physical properties" of the oxygen and hydrogen of which it is composed. Electricity is an extra-ordinary property of matter, and *vitality* seems to me to be still more extra-ordinary. The *force* both exhibit may be correlated with other forces; but that does not account for the special *mode* in which the force is manifested in the one case more than in the other.

In the second division of his work, "Archebiosis," Dr. Bastian commences with a history of the discussion on Spontaneous Generation from the time of Aristotle to that of Pouchet and Pasteur. He then gives an outline of the evidence as to the production of low organisms in infusions. These are chiefly Bacteria and Torulæ, names which are of such frequent occurrence that we reproduce a woodcut (Fig. 1), in which they are represented, the straight objects *c* and *d* being Bacteria, while *h*, *i*, and *k* represent Torulæ; the small dots *a* are Monads, Microzymes, or plastide particles, or they may be Bacteria seen endways; while the other objects are Torula cells, or fungus germs variously combined. These are the simplest and most minute organisms; but others a little larger and more complex are shown in the next cut (Fig. 2), under the names of Vibriones, Leptothrix, Spirilla, and Mycelial filaments. These all exhibit unmistakeable signs of life, growth, and reproduction, and they appear in immense abundance in a great variety of infusions of animal and vegetable matter, however perfectly they may be shut out from the surrounding atmosphere. Most experimenters have conceived that the presence of air was necessary in order to develop organisms, and with the air it has been supposed that germs or ova have been always introduced. These germs are, however, admitted to be invisible by the highest powers of our microscopes; their very existence is therefore hypothetical, and our author shows very forcibly that Pasteur's supposed demonstration of their existence, and of their being the source of the organisms which appear in infusions, is wholly fallacious. He assumes at critical points of the argument the impossibility of his opponent's views being the true ones; and imputes his negative results to his having eliminated germs, when they can be equally well shown to be due to unfavourable conditions for development. But in order to avoid such complicated and inconclusive experiments as those carried on during the celebrated discussion between Pasteur and Pouchet, Dr. Bastian adopts a totally distinct method, which so narrows the issue as to render it possible to arrive at something like absolute certainty in the results. Instead of introducing air, purified by various chemical means, into the flasks after the infusions have been boiled, he hermetically closes their narrow necks during violent ebullition, thus producing an almost perfect vacuum above the liquid contents. After this he submits the whole flask to a heat varying from 212° to over 400° F., and then places them in favourable positions as regards light and heat. Under these rigid conditions he finds large quantities of organisms produced, which exhibit such unmistakeable signs of life as growth and multiplication. Now here the issue is reduced to its very narrowest limits, viz., what degree of heat will destroy all these low forms of life; and to determine this he adduces a series of experiments, detailed in his chapter on "The Limits of Vital Resistance to Heat." M. Pasteur found that the greatest tenacity of life was possessed by the spores of certain fungi of the family *Mucedineæ*, which germinated after being exposed to a dry heat of 248° to 257° F. for a few minutes, but half an hour's exposure to the same dry heat killed them. A Commission appointed in 1860 by the Société de Biologie found that of the lower animals, the Rotifers, "Sloths," and Anguillules found in moss, &c., were most tenacious of life, but they were all killed by a lower temperature than that above stated, so that we may fairly conclude a heat of 266° F. for thirty minutes in dry air to be the limit of vital resistance hitherto ascertained. In fluids, however, a much lower temperature suffices. Hardly any low organisms can resist 167° F., while 212° F. for even one minute is admitted by all experimenters on this subject to be fatal to all classes of organisms met with in infusions, with which alone we have now to deal. Bacteria and Vibriones, however, are killed by a much lower temperature (130°-140° F.) for ten minutes, as ascertained by a careful series of experiments; while several degrees lower was equally fatal if prolonged for four hours. It has been objected that the flasks being only partially filled, some germs or organisms may escape the liquid and survive on the sides of the glass; but as they must be exposed to almost pure steam of the same temperature as the water, and as the heat actually employed was often greater than any such organism can withstand, even in dry air, the objection cannot be held to be valid.

What, now, are we say to such experiments as the following:—Prof. Jeffries Wyman found Vibrios and Bacteriums moving with great rapidity in mutton juice which had been exposed in a hermetically-sealed flask to a heat of 120·6° C. for five minutes. Prof. Mantegazza found living Bacteria in a decoction of lettuce which had been similarly exposed for 30 minutes to 284° F. Prof. Cantoni, of Pavia, heated a solution of yolk of egg in a hermetically-sealed flask up to 242° F., and found in it after two days a large number of Vibrios. Dr. Bastian himself exposed a strong infusion of turnip in a hermetically-sealed flask to a temperature of 270°-275° F. for twenty minutes. After two months the contents were examined, and found to contain numbers of organisms, of which the annexed cut (Fig. 3) represents a specimen. Again, a solution of ammonic tartrate and sodic phos-

phate in distilled water was heated to a temperature of 295°-307° F. for four hours. It was at first colourless and clear, and being carefully watched was found after some days to become slightly flocculent; a small speck then appeared, which grew for several days till it could be seen with the naked eye. On being opened and examined, the

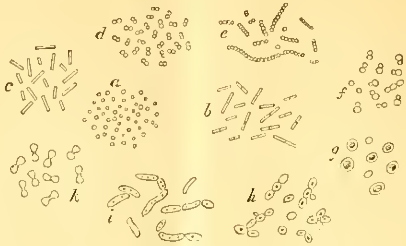

FIG. 1.—SOME OF THE MOST COMMON PRIMORDIAL FORMS OF LIFE: BACTERIA, TORULÆ, &c. (× 800)

speck was found to be the remarkable fungus represented in Fig. 4.

Besides this class of experiments, others have been made with the same infusion heated to different temperatures, by which it has been ascertained that for each substance there is a different maximum, if heated beyond which no

organisms appear. The juice of meat, for instance, produced Vibrios if heated to 112° C., but none if heated to 114° C. Cows' milk produces them, if heated to 113·5 C., but remains unproductive if heated to 114·5 C.; while a decoction of pumpkin produces them at 110° C., and not at 112° C. Prof. Cantoni naturally asks why, if the Vibrios

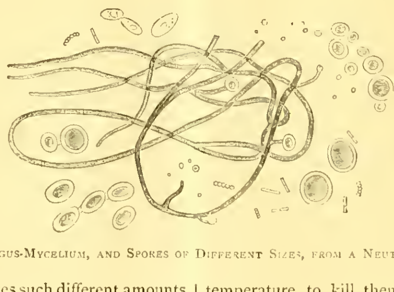

FIG. 3.—BACTERIA, TORULÆ, FUNGUS-MYCELIUM, AND SPORES OF DIFFERENT SIZES, FROM A NEUTRALISED TURNIP INFUSION (× 800).

are produced from germs, it requires such different amounts of heat to kill them in different solutions; and why these hypothetical germs should require such a vastly higher temperature to kill them than suffices to destroy their parents? A large number of comparative experiments made by Dr. Bastian further shows that the presence or

absence of Bacteria and other low organisms in infusions often bears little or no relation to the facilities for the admission of germs from the atmosphere, but seems to depend on a variety of special conditions only to be learnt by long practice. The temperature at which the infusion was made, its quantity, the presence of dense or rarefied air in the flask, a few degrees more or less of temperature of the room where the flasks are kept, and a variety of other circumstances, so affect the results, that in some cases organisms refuse to appear when there is every facility for the hypothetical germs to gain admission; while, as we have seen, they are often plentifully produced when every possible precaution is taken to keep them out and to destroy them. The only way of escaping from the results of such a series of experiments as that here recorded is by asserting that, although the *organisms* which are produced in the flasks are killed by a temperature much below that to which the flasks have been subjected, the *germs* from which they have been produced are not so killed. We are asked, therefore, to accept as facts three pure suppositions: first, that such excessively minute and simple organisms as Bacteria, whose only mode of multiplication is by fission or gemmation, have germs which possess different physical properties from themselves; secondly, that these germs, as well as many others, are omnipresent in the atmosphere; and, thirdly, that they are not injured by an exposure for four hours to vapour heated to over 300° F.; and, finally, we are to accept all these suppositions as facts in order to avoid admitting that specks of living protoplasm are originated *de novo* in some fluids just as specks of crystalline matter originate in other fluids, and although some organisms can be seen to make their appearance in fluids independently of all pre-existing visible germs, just as crystals do.

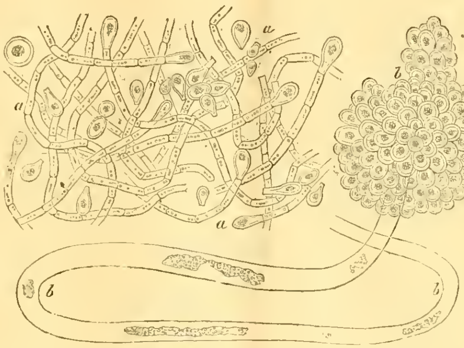

FIG. 4.—FUNGUS FOUND IN A SOLUTION OF AMMONIC TARTRATE AND SODIC PHOSPHATE (× 600).

It must, we think, be admitted that in the portion of his work we have now been considering, Dr. Bastian has fairly met and fully answered all the objections that were made to his earlier experiments. He has, moreover, shown the fallacy of many of the arguments of M. Pasteur and his supporters; and, by a series of careful and well-devised experiments, the results of which agree with those arrived at by a large number of other workers both in this country and on the Continent, has proved the *de novo* origin of various living organisms in air-tight flasks. This alone is a great step gained; but it is, as we propose to show in our next article, only the stepping-stone to more important observations and more startling facts.

DR. LIVINGSTONE

THE despatches and private correspondence of Dr. Livingstone, after a long detention, have at last been delivered, and we are now able to give extracts from the explorer's reports which throw further light on his discoveries. He appears to have ascertained, by a journey round the south-eastern side of Tanganyika, that that lake has no outlet. He has also explored the drainage to the eastward for nearly 600 miles. We learn also that his present object is to examine the hills to the south-west of Lake Bangweolo, where he had been told that there are four fountains, which he confusedly connects with the sources of the Nile, as described by Herodotus. There is marvellous heroism in this persistency, and it is sad to reflect that the grand old traveller is doomed to disappointment. But there can scarcely be any doubt that these rivers to the eastward of Tanganyika have no connection with the Nile. Apart from other considerations, Livingstone's own observations show that his Lualaba, where he saw it, was only at the same height above the sea as Gondokoro, and the error of his instrument would increase rather than diminish the height. This makes it impossible that his discoveries can be connected with the Nile. Doubtless the mass of waters is lost in some inland swamp.

The measures for Dr. Livingstone's relief were conducted with zeal and good faith, and he is now well supplied from stores sent up by Dr. Kirk and by his son. Mr. Stanley has also done excellent service in pushing on to Ujiji, in accompanying Livingstone to Unyanyembe, and in bringing home the letters and despatches. The President of the Geographical Society, in the name of the council, has promptly and cordially acknowledged this service, and the perseverance and energy with which it has been performed, in a letter addressed to Mr. Stanley as soon as the despatches were received. There was no delay or hesitation in giving him the credit that was his due; and equal promptitude has been shown by the Secretary of State for Foreign Affairs, whose letter has already been published. But the American correspondent's subsequent conduct, though doubtless agreeable to his employers, deserves no thanks from the countrymen of Livingstone. The ungenerous attack upon Dr. Kirk is sufficiently refuted by the evidence of Dr. Livingstone's own son, whose letters will, we trust, dispell the delusions with which his father's mind had been filled. Even now we can scarcely believe that Mr. Stanley is justified in his assertion that Dr. Livingstone, the great enemy of slavery, commissioned him to send up sets of slave chains to be used by Her

Majesty's Consul! The statement of Lieutenant Henn, which induced him to abandon the Relief Expedition, that Dr. Livingstone desired all such parties to be turned back, led directly to the miserable alternative of sending up supplies in charge of a native; while Mr. Stanley's secresy and concealment of all particulars respecting Livingstone's wants and intentions while at Zanzibar was unnecessary and injurious. These proceedings, the objects of which are transparently obvious, necessarily detract from the warmth of our gratitude to the man who has certainly done no small service in accompanying Livingstone to Unyanyembe, and in bringing home his letters and journal.

The supplies at Unyanyembe, and those procured from the funds of the Relief Expedition, and sent on by his son, will doubtless have enabled Livingstone to continue his exploration, and, though the disappointment to which his notions about the Nile sources must inevitably lead is to be regretted, there can be no doubt that his contemplated further discoveries will lead to valuable results, and we sincerely trust that the brave old traveller will, after one more difficult journey, live to be cordially welcomed home, and to see some good fruits from his truly heroic perseverance. We now proceed to give some extracts from his despatches.

Dr. Livingstone, in the following passage, describes his march from the ridge overhanging the western shore of Tanganyika to the great river Lualaba:—

"In going west of Bambarre, in order to embark on the Lualaba, I went down the Luamo, a river from 100 yards to 200 yards broad, which rises in the mountains opposite Ujiji, and flows across the great bend of the Lualaba. When near its confluence I found myself among people who had lately been maltreated by the slaves, and they naturally looked on me as of the same tribe as their persecutors. Africans are not generally unreasonable, though smarting under wrongs, if you can fairly make them understand your claim to innocence, and do not appear as having your 'back up.' The women here were particularly outspoken in asserting our identity with the cruel strangers. On calling to one vociferous lady, who gave me the head trader's name, to look at my colour and see if it were the same as his, she replied, with a bitter little laugh, 'Then you must be his father!' The worst the men did was to turn out in force, armed with their large spears and wooden shields, and show us out of their districts. Glad that no collision took place, we returned to Bambarre, and then, with our friend Muhamad, struck away due north, he to buy ivory, and I to reach another part of Lualaba and buy a canoe. The country is extremely beautiful, but difficult to travel over. The mountains of light grey granite stand like islands in new red sandstone, and mountain and valley are all clad in a mantle of different shades of green. The vegetation is indescribably rank. Through the grass—if grass it can be called, which is over half an inch in diameter in the stalk, and from 10 to 12 feet hight—nothing but elephants can walk. The leaves of this megatherium grass are armed with minute spikes, which, as we worm our way along elephant walks, rub disagreeebly on the side of the face where the gun is held, and the hand is made sore by fending it off the other side for hours. The rains were fairly set in by November, and in the mornings, or after a shower, these leaves were loaded with moisture, which wet us to the bone. The valleys are deeply undulating, and in each innumerable dells have to be crossed. There may be only a thread of water at the bottom, but the mud, mire, or (*Scottice*) 'glaur' is grievous; 30 or 40 yards of the path on each side of the stream are worked by the feet of passengers into an adhesive compound. By placing a foot on each side of the narrow way one may waddle a little distance along, but the rank crop of grasses, gingers, and bushes cannot spare the few inches of soil required for the side of the foot, and down he comes into the slough. The path often runs along the bed of the rivulet for 60 or more yards, as if he who first cut it out went that distance seeking for a part of the forest less dense for his axe. In other cases the Muale palm, from which here, as in Madagascar, grass cloth is woven, and called by the same name, 'lamba,' has taken possession of the valley. The leaf stalks, as thick as a strong man's arm, fall off and block up all passage, save by a path made and mixed up by the feet of elephants and buffaloes; the slough therein is groan-compelling and deep. Every now and then the traders, with rueful faces, stand panting; the sweat trickles down my face, and I suppose that I look as grim as they, though I try to cheer them with the hope that good prices will reward them at the coast for ivory obtained with so much toil. In some cases the subsoil has given way beneath the elephant's enormous weight; the deep hole is filled with mud, and one, taking it all to be about calf deep, steps in to the top of the thigh, and flaps on to a seat soft enough, but not luxurious; a merry laugh relaxes the facial muscles, though I have no other reason for it than that it is better to laugh than to cry.

"Between each district of Manyema large belts of the primeval forest still stand. Into these the sun, though vertical, cannot penetrate except by sending down at midday thin pencils of rays into the gloom. The rain-water stands for months in stagnant pools made by the feet of elephants; and the dead leaves decay on the damp soil, and make the water of the numerous rivulets of the colour of strong tea. The climbing plants, from the size of whipcord to that of a man-o'-war's hawsers, are so numerous that the ancient path is the only passage. When one of the giant trees falls across the road it forms a wall breast high to be climbed over, and the mass of tangled ropes brought down makes cutting a path around it a work of time which travellers never undertake."

In another despatch we have a more general review of the results of his explorations, as follows:—"I have ascertained that the watershed of the Nile is a broad upland between 10° and 12° south latitude, and from 4,000 feet to 5,000 ft. above the level of the sea. Mountains stand on it at various points, which, though not apparently very high, are between 6,000 feet and 7,000 feet of actual altitude. The watershed is over 700 miles in length, from west to east. The springs that rise on it are almost innumerable—that is, it would take a large part of a man's life to count them. A bird's-eye view of some parts of the watershed would resemble the frost vegetation on window-panes. They all begin in an ooze at the head of a slightly depressed valley. A few hundred yards down, the quantity of water from oozing earthen sponge forms a brisk perennial burn or brook a few feet broad and deep enough to require a bridge. These are the ultimate or primary sources of the great rivers that flow to the north in the great Nile valley. The primaries unite and form streams in general larger than the Isis at Oxford or Avon at Hamilton, and may be called secondary sources. They never dry, but unite again into four large lines of drainage, the head waters or mains of the river of Egypt. These four are each called by the natives Lualaba, which, if not too pedantic, may be spoken of as lacustrine rivers, extant specimens of those which, in pre-historic times, abounded in Africa, and which in the south are still called by Bechuanas 'Melapo,' in the north, by Arabs, 'Wadys;' both words meaning the same thing—river-bed in which no water ever now flows. Two of the four great rivers mentioned fall into the central Lualaba, or Webb's Lake River, and then we have but two main lines of drainage as depicted nearly by Ptolemy. The prevailing winds on the watershed are from the south-east. This is easily observed by the direction of the branches, and the humidity of the climate is apparent in the number of lichens, which make the upland forest look like the mangrove swamps on the coast. In passing over 60 miles of latitude, I waded

32 primary sources from calf to waist deep, and requiring from 20 minutes to an hour and a quarter to cross stream and sponge; this would give about one source to every two miles. A Suaheli friend, in passing along part of the Lake Bangweolo during six days, counted 23 from thigh to waist deep. This lake is on the watershed, for the village which I observed on its north-west shore was a few seconds into 11° south, and its southern shores and springs and rivulets are certainly in 12° south. I tried to cross it in order to measure the breadth accurately. The first stage to an inhabited island was about 24 miles. From the highest point here the tops of the trees, evidently lifted by the mirage, could be seen on the second stage and the third stage; the mainland was said to be as far as this beyond it. But my canoe men had stolen the canoe, and got a hint that the real owners were in pursuit, and got into a flurry to return home. 'They would come back for me in a few days truly,' but I had only my coverlet left to hire another craft, if they should leave me in this wide expanse of water, and being 4,000 feet above the sea, it was very cold, so I returned. The length of this lake is, at a very moderate estimate, 150 miles. It gives forth a large body of water in the Luapula; yet lakes are in no sense sources, for no large river begins in a lake, but this and others serve an important purpose in the phenomena of the Nile. It is one large lake, and unlike the Okara, which, according to Suaheli, who travelled long in our company, is three or four lakes run into one huge Victoria Nyanza, gives out a large river which, on departing out of Moero, is still larger. These men had spent many years east of Okara, and could scarcely be mistaken in saying that of the three or four lakes there only one, the Okara, gives out its waters to the north. The 'White Nile' of Speke, less by a full half than the Shire out of Nyassa (for it is only 80 or 90 yards broad), can scarcely be named in comparison with the central or Webb's Lualaba, of from 2,000 to 6,000 yards, in relation to the phenomena of the Nile. The structure and economy of the watershed answer very much the same end as the great lacustrine rivers, but I cannot at present copy a lost despatch which explained that. The mountains on the watershed are probably what Ptolemy, for reasons now unknown, called the Mountains of the Moon. From their bases I found that the springs of the Nile do unquestionably arise. This is just what Ptolemy put down, and is true geography. We must accept the fountains, and nobody but Philistines will reject the mountains, though we cannot conjecture the reason for the name. Mounts Kenia and Kilmanjaro are said to be snow-capped, but they are so far from the sources and send no water to any part of the Nile, they could never have been meant by the correct ancient explorers, from whom Ptolemy and his predecessors gleaned their true geography, so different from the trash that passes current in modern times. Before leaving the subject of the watershed, I may add that I know about 600 miles of it, but am not yet satisfied, for, unfortunately, the seventh hundred is the most interesting of the whole. I have a very strong impression that in the last hundred miles the fountains of the Nile mentioned to Herodotus by the Secretary of Minerva in the city of Sais do arise, not like all the rest, from oozing earthen sponges, but from an earthen mound, and half the water flows northward to Egypt, the other half south to Inner Ethiopia. These fountains, at no great distance off, become large rivers, though at the mound they are not more than ten miles apart. That is, one fountain rising on the north-east of the mound becomes Bartle Frere's Lualaba, and it flows into one of the lakes proper, Kamolondo, of the central line of drainage; Webb's Lualaba, the second fountain rising on the north-west, becomes (Sir Paraffin) Young's Lualaba, which, passing through Lake Lincoln and becoming Loeki or Lomame, and joining the central line too, goes north to Egypt. The third fountain on the south-west, Palmerston's, becomes the Liambia or Upper Zambesi; while the fourth, Oswell's, fountain becomes the Kafue, and falls into Zambesi in Inner Ethiopia. More time has been spent in the exploration than I ever anticipated."

He then sums up the results of his work as follows:—"The Geographical results of four arduous trips in different directions in the Manyema country are briefly as follows:— The great river, Webb's Lualaba, in the centre of the Nile valley, makes a great bend to the west, soon after leaving Lake Moero, of at least 180 miles; then turning to the north for some distance, it makes another large sweep west of about 120 miles, in the course of which about 30 miles of southing are made; it then draws round to north-east, receives the Lomame, or Loeki, a large river which flows through Lake Lincoln. After the union a large lake is formed, with many inhabited islands in it, but this has still to be explored. It is the fourth large lake in the central line of drainage, and cannot be Lake Albert; for, assuming Speke's longitude of Ujiji to be pretty correct, and my reckoning not enormously wrong, the great central lacustrine river is about 5° west of Upper and Lower Tanganyika. In my attempts to penetrate further and further I had but little hope of ultimate success, for the great amount of westing led to a continual effort to suspend the judgment, lest, after all, I might be exploring the Congo instead of the Nile, and it was only after the two great western drains fell into the central main, and left but the two great lacustrine rivers of Ptolemy, that I felt pretty sure of being on the right track. The great bends west probably form one side of the rivers above that geographical loop, the other side Upper Tanganyika and the Lake River Albert. A waterfall is reported to exist between Tanganyika and Albert Nyanza, but I could not go to it; nor have I seen the connecting link between the two—the upper side of the loop—though I believe it exists."

His despatches conclude with the following account of his future intentions:—"Geographers will be interested to know the plan I propose to follow. I shall at present avoid Ujiji, and go about south-west from this to Fipa, which is east of and near the south end of Tanganyika; then round the same south end, only touching it again at Pambette, thence resuming the south-west course to cross the Chambeze and proceed along the southern shores of Lake Bangweolo, which being in latitude 12° south, the course will be due west to the ancient fountains of Herodotus. From them it is about ten days north to Katanga, the copper mines of which have been worked for ages. The malachite ore is described as so abundant, it can only be mentioned by the coalheavers' phrase, 'practically inexhaustible.' About ten days north-east of Katanga very extensive underground rock excavations deserve attention as very ancient, the natives ascribing their formation to the Deity alone. They are remarkable for all having water laid on in running streams, and the inhabitants of large districts can all take refuge in them in case of invasion. Returning from them to Katanga, 12 days N.N.W. take to the southern end of Lake Lincoln. I wish to go down through it to the Lomame, and into Webb's Lualaba and home. I was mistaken in the information that a waterfall existed between Tanganyika and Albert Nyanza. Tanganyika is of no interest, except in a very remote degree in connection with the sources of the Nile. But what if I am mistaken, too, about the ancient fountain? Then we shall see! I know the rivers they are said to form—two north and two south—and in battling down the central line of drainage, the enormous amount of westing it made caused me at times to feel as if running my head against a stone wall. It might after all be the Congo, and who would care to run the risk of being put into a cannibal pot and be converted into black man for anything less than the grand old Nile? But when I found that Lualaba forsook its westing, and received

through Lake Kamolondo Bartle Frere's great river, and that afterwards farther down it takes in Young's great stream through Lake Lincoln, I ventured to think that I was on the right track. Two great rivers arise somewhere on the western end of the watershed, and flow north—to Egypt (?). Two other large rivers rise in the same quarter and flow south, as the Zambesi, or Liambai, and the Kafue, into Inner Ethiopia. Yet I speak with diffidence, for I have no affinity with an untravelled would-be geographer who used to swear to the fancies he collected from slaves till he became blue in the face. I know about six hundred miles of the watershed pretty fairly. I turn to the seventh hundred miles with pleasure and hope. I want no companion now, though discovery means hard work. Some can make what they call theoretical discoveries by dreaming. I should like to offer a prize for an explanation of the correlation of the structure and economy of the watershed with the structure and economy of the great lacustrine rivers in the production of the phenomena of the Nile. The prize cannot be undervalued by competitors even who have only dreamed of what has given me very great trouble, though they may have hit on the division of labour in dreaming, and each discovered one or two hundred miles. In the actual discovery so far, I went two years and six months without once tasting tea, coffee, or sugar; and, except at Ujiji, have fed on buffaloes, rhinoceros, elephants, hippopotami, and cattle of that sort; and have come to believe that English roast beef and plum pudding must be the real genuine theobroma, the food of the gods, and I offer to all successful competitors a glorious feast of beefsteaks and stout. No competition will be allowed after I have published my own explanation, on pain of immediate execution without benefit of clergy! I send home my journal by Mr. Stanley, sealed, to my daughter Agnes. It is one of Letts' large folio diaries, and is full except a few (five) pages reserved for altitudes which I cannot at present copy. It contains a few private memoranda for my family alone, and I adopt this course in order to secure it from risk in my concluding trip."

NOTES

We are in a storm of Congresses. Scarcely has the British Archæological Institute finished its work at Southampton before the British Archæological Association, the Iron and Steel Institute, and the British Medical Association have thrown Wolverhampton, Glasgow, and Birmingham respectively into unwonted excitement; while by this time next week the British Association will be in full swing at Brighton. With regard to this latter Congress, we are happy to announce that admirable arrangements for the reception of visitors are being made, and that a large and satisfactory meeting, under the presidency of Dr. Carpenter, may be anticipated.

At the moment of going to press we hear that a M. Delaunay, "director of the Astronomical Observatory" (*sic*), has been drowned by the upsetting of a boat at Cherbourg. We sincerely trust this does not refer to the distinguished director of the Observatory of Paris. But the telegram is ominous.

The French Association for the Advancement of Science will hold its first annual meeting at Bordeaux, from the 5th to the 12th of September. The Administrative Council, consisting of MM. Claude Bernard, Broca, Delaunay, A. d'Eichthal, De Quatrefages, Wurtz, Cornu, secretary of the Association, Masson, treasurer, and Gariel, secretary of the Council, have issued a circular inviting many of our most eminent men of science to be present; and, as the new French society is based upon an old English one, it will be both graceful and useful that as many shall attend as possible. We have also received the first publication of the society, containing a *compte rendu* of the inauguration meeting of the society, held in April in Paris, and the statutes of the society, which have already appeared in NATURE nearly in their final form. We wish the society every success; its object is essentially decentralisation. Would we in England were in a position to decentralise!

Dr. Cobbold, F.R.S., has been appointed to a Professorship of Helminthology at the Royal Veterinary College. During the ensuing winter months he will give a course of lectures on the Parasites and Parasitic Diseases of our domesticated animals.

Dr. Brown-Séquard has resigned the Chair of Comparative and Experimental Pathology in connection with the Faculty of Medicine in Paris, which he has occupied several years. M. Vulpian has applied for the Chair.

Dr. Gerhart, of Jena, has been appointed successor to Dr. Bamberger as Professor of Clinical Medicine at Würzburg.

We regret to learn that Mr. M. C. Webster, the acting collector at Trichinopoli, to whose exertions the Eclipse Expedition owed so much, has been ordered home without delay for two years on sick certificate.

One of the most recent applications of science to practical purposes, which, according to most people is the only part of science which is worth anything, is sufficiently curious. In the "Mors Electrique" of M. Sidot, we have electricity employed in a manner to combine the study of electricity with a ride or drive into the country in company with a restive horse. Nothing is more simple. In the carriage, or even in the saddle, we have a pile *système hermétique Trouvé*, and a small induction coil, along the reins the magic wires are laid, and on either side the animal's lower jaw we have a *couronne métallique*. These are the data. The inventor is under the impression that when the quadruped's motion becomes too rapid it will be instantly brought to zero by the passage of the spark through the aforesaid jaw, but we do not learn that he has tried it. We would suggest that in a cavalry charge it would be most effective. This should be tried at the forthcoming manœuvres. In war the principle might be extended. The horses might be armed unicorn-wise, with blunderbusses and Abel's fuzes, the *couronne métallique* being of course removed from the lower jaw to the novel weapon. Probably in this way the functions of the riders might be abolished altogether; this would bring about a great saving in the army estimates, and in this way cause the Government to think that there may be something in science after all.

No. 6 of the Illustrated Catalogue of the Museum of Comparative Zoology at Harvard College, just come to hand, contains the supplement to the Ophiuridæ and Astrophytidæ by Theodore Lyman, with two plates, in which figures are given of the most important of the singular deep-sea Ophiurans brought up by the dredgings off the coast of Florida, and described in Bulletin No. 10, vol. i. of the Catalogue.

Our common sparrow, as most of our readers are aware, has been for some time naturalised in the New York parks and elsewhere in the United States, for the purpose of keeping in check a plague of caterpillars, in which office it is doing yeoman service We regret to learn by a paragraph in *The New York Industrial Monthly* that our compatriots are in danger of extermination by a race of feathered rowdies, also bent upon turning the balance of creation their own way. The sparrow's enemy is the great northern shrike; and the *Industrial Monthly* states that one of these "butcher-birds," which eat only the brains of their victims, recently killed a sparrow "by squeezing its head into a crotch made by the fork of two branches, each about half an inch thick."

THE Paris Academy of Sciences has submitted the names of MM. Loewy and Wolf to the Minister of Public Instruction to fill the vacancy in the Bureau des Longitudes, occasioned by the death of M. Langier.

M. FOLIE has recently called the attention of the Royal Academy of Sciences of Belgium to the question of the density of the earth. He criticises some points in Sir George Airy's discussion of his observations, which gave the value 6·566, and states his opinion that 6·439 is nearer the mark.

IN the *Canadian Journal* for July, Prof. H. Alleyne Nicholson discusses the Contemporaneity of Strata and the Doctrine of Geological Continuity with the view of demonstrating "that groups of strata presenting the same fossils, if widely removed from one another in point of distance, can only exceptionally be 'contemporaneous' in the strict sense of the term. On the contrary," he contends, "in so far as we can judge from the known facts of the present distribution of living beings, the recurrence of exactly the same fossils in beds far removed from one another, is *prima facie* evidence that the strata are *not* exactly contemporaneous; but that they succeed one another in point of time, though by no long interval, geologically speaking." Dr. Nicholson concludes "that it is not correct to say that we are living in the Cretaceous period in any other sense than one might say we are living in the Silurian period; with this difference only, that the Cretaceous period is much nearer to us in point of time than the Silurian, and that we can thus trace a relationship between certain living types and certain Cretaceous forms, such as we cannot hope to establish in the case of Silurian forms." Farther, "the conditions present in the deep Atlantic cannot be exactly similar to those of the Cretaceous seas; for the *Cephalopoda* of the chalk seem to have no representatives in the abyssal mud of the Atlantic, while this class was well represented in the Carboniferous times; so that there is, if anything, a closer genetic connection between the chalk and the Carboniferous limestone than between the chalk and the Atlantic 'ooze.'"

THE principal articles in the Transactions of the Royal Microscopical Society for August are the conclusion of Dr. L. S. Beale's paper on the Nerves of Capillary Vessels and their probable action in Health and Disease, a discussion of the vexed question of the Nomenclature of Objectives, by Dr. J. J. Woodward, of the U. S. Army, and a useful paper, by Dr. R. H. Ward, on Our Present Medical and Students' Microscopes.

THE July number of the Proceedings of the Geologists' Association contains a paper, by Mr. Henry Woodward, on Relics of the Carboniferous and other old Land Surfaces, and an essay, by Mr. M. Hawkins Johnson, towards a solution of the chalk-flint enigma.

THERE are only two papers in the recent issue of the Transactions of the Institution of Engineers and Shipbuilders in Scotland, one on the Manufacture of Cast Steel, by Mr. B. D. Healey, the other, by Mr. Alexander Morton, on the Expansion of Water. The former is copiously illustrated.

OTHER things besides history have a tendency to repeat themselves. Vice-Consul Green, in his report concerning the Tunisian fisheries, states that a large portion of the fish supply of the capital of that African state comes from the Bisuta Lake, a distance exceeding forty miles, on pack animals, and, consequently, frequently arrives in an unmarketable state. It is calculated that if proper and expeditious conveyance could be obtained, the supply of the fishery would be sufficient to augment its yearly value by 15,000*l.* or 20,000*l.* But owing to the present fish farmer being able, without any considerable outlay in guards and assistance from preservative enactments, to secure a handsome return from the fisheries conceded to him, great waste and destruction of fish exist.

THE Proceedings of the Asiatic Society of Bengal for May consist mainly of the third instalment of Dr. F. Stoliczka's Notes on the Reptilian and Amphibian Fauna of Kachh or Cutch.

ACCORDING to Dr. Henry Seueur, the twenty-eight weeks' siege of Paris cost upwards of 50,000 lives to the civil population. He ascertains that 300,000 Parisians left Paris by rail before the investment; but 190,000 regular troops and 170,000 refugees from the suburbs entered the city; so that the population of Paris, on the whole, was raised from 1,890,000 to about 2,000,000, the excess consisting chiefly of men between twenty and forty years of age. The mean mortality of the four preceding years and of the following year for these twenty-eight weeks was 24,928; that for the twenty-eight weeks of 1870-71 was 77,231—an excess of 52,303. The mortality fell unevenly on persons of various ages. Between fifteen and twenty-five, it was multiplied sixfold. The general mortality was tripled. The mortality was least among men from forty to sixty; they took no part in active service, and had comparatively greater facilities for resisting cold and privation. The diseases which contributed chiefly to the immense mortality were six—small-pox, bronchitis, pneumonia, typhoid fever, diarrhœa, and dysentery.

THE seventh annual meeting of the Quekett Microscopical Club took place on the 26th ult., when Dr. L. S. Beale, F.R.S., the retiring president, delivered his valedictory address. The club now numbers about 550 members. Dr. R. Braithwaite, F.L.S., is the president for 1872-3. The four vice-presidents are Dr. L. S. Beale, F.R.S., Mr. Arthur E. Durham, Mr. Henry Lee, and Dr. Matthews. The following gentlemen have been re-elected to serve during the ensuing year:—As treasurer, Mr. Robert Hardwicke, F.L.S.; as secretary, Mr. T. Charters White; and as secretary for foreign correspondence, Mr. M. C Cooke, M.A.

THE *British Medical Journal* thinks "it cannot be doubted that one moral will be finally drawn from the difficulties of the southern districts of London as to their water-supply. An adequate supply of drinking water to a crowded part of a great city is of as great importance as a supply of fresh air; and it may reasonably be doubted whether any pains or penalties will suffice to protect a great population from the shortcomings of companies who undertake to furnish a water-supply on purely commercial grounds, and who neither have nor can be expected to have any benevolent interest in the health and comfort of their customers. The water companies of the metropolis hold in their hands the lives of a very large mass of people; and very slight *lâches*, as in the case of the East London epidemic of cholera, suffice to slay hundreds of helpless and perfectly innocent water-drinkers." The *Journal* holds out to "the consideration of all classes of statesmen and of electors, whether the water-supply of great cities, such as London, should be left to the tender mercies of companies, whose opinion as to the importance of 'living organisms' and 'previous sewage contamination' are notoriously sceptical, and are much influenced by the annual arguments presented by the auditors." The Lambeth Water Company, it remarks, "is alike a terror to drunkards and teetotallers; it adds a fresh terror to adulteration, and another curse to the list of these that afflict great cities."

WE have received Part iv. of the fourth edition of Yarrell's "British Birds," edited by Prof. Newton, and in course of publication by Van Voorst. The birds described in this part are chiefly of the families *Turdidæ* and *Silvidæ*.

AT the recent half-yearly meeting of the Grand Trunk Railway Company of Canada, in respect to the rails being exposed to severe cold for a great length of time, the President said that from 3,500 to 4,000 rails on the line break every winter! But he found comfort in the fact that, in about 110 miles of steel

track, only eight or ten rails have broken. This would seem to indicate that Bessemer rails are suitable for cold climates.

CAPTAIN MAJENDIE, in his report of the Stowmarket explosion, says that he resisted as long as possible the suggestion that the catastrophe was due to foul play on the part of some one who wilfully added acid to properly purified and manufactured gun-cotton. Step by step, however, his examination established the theory of foul play as the correct one; and in face of the evidence no other verdict than that given by the jury was possible. He thinks the balance of probability leads to the belief that whoever added the acid was unaware of the terrible consequences it would produce.

THE pupils of the Trade School at Keighley, in Yorkshire, established by the Schools Inquiry Commissioners for the higher education of the children of the artisan classes of that town, have distinguished themselves in the recent examinations. The results are as follows:—Acoustics, Light and Heat: Nine first-class, thirteen second-class.—Theoretical Mechanics: Three first-class, thirteen second-class.—Physical Geography: Twelve first-class, twenty-two second-class.—Steam and the Steam Engine: Three first-class, twenty-five second-class.—Applied Mechanics: Four first-class, twenty-five second-class.—Building Construction: Two first-class, eight second-class.—Animal Physiology:—Two first-class, thirty-one second-class.—Machine Drawing: Nine first-class, twenty-three second-class.—Inorganic Chemistry: Eight first-class, fifteen second-class. (Six second-class by students from Cullingworth.)—Laboratory Practice: Six first-class, four second-class.—Mathematics: Three first-class, twelve second-class. In all, sixty-one first-class passes, and one hundred and ninety-one second-class passes. The Keighley School of Art is attended by about one hundred young men of the town. The examiners at South Kensington have passed the drawings of eighteen of them in the elementary section, and of five in the advanced section, while the works of three—Annie Preston, Thomas Ramsden, and J. Midgley—have been laid out for national competition.

THE fruit crop of 1872 (says the *Gardeners' Magazine*) s probably the smallest that the most experienced and observant cultivator can call to remembrance. It is certainly but little better than no crop at all, and in many fruit-growing districts will not pay for gathering, and, therefore, perhaps, will be lost entirely. The imports of fruit from the Continent have been very much below the average hitherto this year; and the fact suggests itself that our neighbours across the Channel are in much the same plight as ourselves as respects this season's product of fruit. Usually in seasons notable for short supplies of fruit, some kinds are sufficiently plentiful to compensate in part for the general deficiency, but the present is an exceptional season in that respect, for the failure is complete. There can be no mystery about the cause of this general barrenness. The trees made a good growth last year, and the wood was sufficiently ripened. Hence there was a good show of bloom when vegetation was roused into activity by the genial weather which occurred in the month of February. The crop was ruined by the second winter that distinguished the month of March and greater part of the month of April.

IT is estimated that the whole available stock of the famous "Torbane Hill mineral" does not now exceed 50,000 tons, for the extraction of which a pit is about to be sunk. A trustworthy authority states the quantity already worked at about 1,800,000 tons.

IN a communication from Natal, Mr. G. K. Blanche states that Mr. B. Bouwer had seen, in a stone cave in Namaqua-land, about twelve days from Lake Ngami, pictures of all sorts of animals, drawn by Bushmen, in which the unicorn was distinctly delineated. Mr. Bouwer added that an old Bushman at Ghanze told him that he had many years ago seen the animal, that it was very fierce, but that it had now gone away. He had heard, besides, other Bushmen speak in similar terms, of the reputed fabulous beast. Mr. Blanche concludes:—"My opinion is, that the unicorn existed recently in Africa, and that it is *not proved* to be extinct now, but that the probability of its being in existence now is not very great." He rests this conclusion on the general accuracy of such rude sketches by savages in other parts of the world besides Africa, asking, if the unicorn never did exist, why should drawings of it be made in Namaqua-land, Natal, the Transvaal Republic and Cape Colony, possessing the same general and one particular characteristic.

FRANK CLOWES, Esq., B.Sc., London, F.C.S., has been appointed Science Master at Queenwood College, Hants.

THE *American Naturalist* for July contains a pretty exhaustive account of the Wyandotte Cave and its fauna, by Prof. E. D. Cope. The animals catalogued are fifteen in number, but as this collection was the result of only two days' exploration, Prof. Cope considers that the Wyandotte is richer in life than the better known Mammoth Cave, which has yielded only seventeen species after frequent examination. He describes a curious parasite—a Lernæan—on the blind fish of the cave. The representatives in the Wyandotte of two of the blind genera in the Mammoth Cave are furnished with eyes.

IN his paper on the Wyandotte Cave, in the July number of the *American Naturalist*, Prof. Cope incidentally remarks:—"I believe that wild animals betake themselves to caves to die, and that this habit accounts in large part for the great collections of skeletons found in the cave deposits of the world. After much experience in woodcraft, I may say that I never found the bones of a wild animal which had not died by the hand of man lying exposed in the forest."

THE small white butterfly (*Pieris rapæ*) which has quite recently become naturalised in North America, is likely to spread over the more temperate parts of that continent, to the serious detriment of farmers and gardeners. In a paper on the subject in the *Canadian Entomologist*, Mr. G. J. Bowles, of Montreal, states that the insect has already spread over the province of Quebec and the New England States, and is estimated to have destroyed 500,000 dols. worth of cabbages last year in the vicinity of New York alone. Mr. Bowles communicates some interesting facts in the life history of the immigrant butterfly. "The species," he says, "in its new habitat, has to pass through extremes of temperature to which it has not been accustomed in England, from which country it was most probably introduced; and while the increased summer heat of Canada appears to have made it more prolific, by augmenting the number of broods, the greater cold of winter has balanced the account by killing off, while in the chrysalis state, the surplus which otherwise would have rendered the insect an intolerable pest. The 'compensating' principle in the laws of nature," he adds, "is thus in useful operation with regard to *P. rapæ*; and as the power of cold decreases in effectiveness through the butterfly becoming acclimatised (which will probably happen in course of time), no doubt other agencies will arise, in the shape of new parasitic enemies, to keep the species within due bounds."

MR. H. HAUPT, C.E., in an article in *Van Nostrand's Engineering Magazine* (N.Y.), proposes a system of narrow gauge wooden railways in rural districts and sparsely-settled localities in America, which he describes at some length, and asserts can be constructed more cheaply than ordinary country roads, and upon which transportation can be conducted at less expense than on ordinary railroads. The system, he adds, has been tested to a limited extent, and found to answer admirably.

A SUPPLEMENT to the fifth annual report of the United States' Geological Survey has just been published. It consists of an enumeration, with descriptions by M. Lesquereux, of tertiary fossil plants collected by Dr. F. V. Hayden in 1870, from which some important climatic and other conclusions are drawn.

IT is stated that a plan has been submitted to the Spanish Government for a tunnel under the Straits of Gibraltar, which might be connected with the shortest route to India. The length to be traversed would be 13,800 metres, while that of the contemplated Dover and Calais tunnel is stated as 32,000.

THE late thunderstorms have done considerable damage to the Postal Telegraphs of the United Kingdom. Demagnetisation of needles, and in a large number of instances the fusing and complete destructions of the instrument coils, show that the want of an efficient lightning protector is still much felt.

CORK trees are being extensively introduced into Southern California.

FORMS OF SOLAR PROTUBERANCES *

PROFESSOR TACCHINI gave a full account of some of the work recently done by the Italian Society of Spectroscopists, which will be read with interest. At the beginning of his discourse he dealt specially with the observations on the solar protuberances, made with the view of throwing light on the question, whether the strata below the sun's chromosphere are solid, liquid, or gaseous. If we suppose that the protuberances have the form of jets, that is to say, narrow at the base and spreading out like a fan, as in the jets of gas which issue from terrestrial volcanoes, and if, moreover, instead of being composed of one element or a small number of elements, they are composed, from base to summit, of numerous materials, then it will appear probable that they are produced by eruptions taking place through a strongly resisting medium; and consequently that there must be already formed, on the surface of the sun, a crust solid enough to resist, for the most part, the powerful tension of the internal incandescent gases, which, breaking through this crust at certain points, give rise to violent eruptions, constituting the phenomenon of the solar protuberances. On the other hand, if all or most of the protuberances have a wide base and taper upwards like a pyramid, if their composition is simple, perhaps of the same materials as the chromosphere—a complex composition occurring only in a few of them, and at the base or at a small height above it—then the protuberances, properly so called, must be regarded, not as true eruptions, but as alterations of the chromosphere in those parts, where, through special circumstances, the composition of the subjacent strata becomes modified, either by an outflow of the internal constituents of the solar sphere—in which case the phenomenon is brought about by internal causes—or by disturbances arising in particular zones in consequence of movements developed in the sun's atmosphere, in which case the protuberances are produced by external causes; in other cases both these causes may concur in the production of the phenomena in question.

These considerations are sufficient to show the great importance of establishing the general character of the solar protuberances, and for this purpose, and to avoid certain sources of error, Prof. Tacchini invited P. Secchi, at Rome, and Prof. Lorenzoni, at Padua, to join with him in making contemporaneous observations of the solar protuberances. The proposal was favourably received, and it was agreed that from the 1st to the 13th of July, 1871, observations of the entire limb of the sun should be made from 7 to 10 o'clock.

The spectroscope employed by Tacchini at Palermo is formed of three direct vision prisms, constructed by Tauber, of Leipzig; that of P. Secchi is an instrument with angular vision, somewhat inferior in power to the Palermo instrument; and that of Prof. Lorenzoni is a direct-vision spectroscope which was used in Sicily in the observation of the total eclipse of 1870.

A comparison of the observations made at Rome and at Palermo led to the following results:—

1. All the masses are found indiscriminately in the drawings made at Rome and at Palermo; the most remarkable peculiarities of the chromosphere are likewise reproduced in both.

2. The principal characters of the forms of the protuberances are identical in the two sets of drawings; the direction and position of the plumes, the luminous masses, and frequently the regions of the chromosphere where the flames have a peculiar appearance, are perfectly identical.

3. The heights of the protuberances are for the most part the same, notwithstanding the diversity of the methods employed for measuring them.

4. The differences in the two sets of delineations are of two kinds: the first arising from the mode of drawing, the second from the greater distinctness of vision at Palermo. Other differences are real, being due to the rapid changes taking place in the protuberances.

At Padua the observations were limited to the delineation of individual protuberances; these were found to be the same in form and altitude as those seen at Rome and Palermo, thus affording proof that at the three stations, with different means of observation, the objects seen were identical, and removing any doubt that might previously have existed as to the power of the spectroscope to afford accurate results respecting the chromosphere and the forms of the protuberances.

Tacchini next proceeded to consider the general form of the protuberances. By observations with the spectroscope, continued from March 1871 to February 1872, he found that out of 2,903 protuberances, only 234, or about 8 per cent., have the form of a tree or of a fan, that is to say, are narrow at the base and spread out towards the upper part, as if they were produced by volcanic eruptions, whereas the remaining 92 per cent. have a broad base and taper upwards like a pyramid, seem, therefore, to be due rather to a simple throwing up of the substance of the chromosphere. He, therefore, regards the general form of the protuberances as inconsistent with the existence of a solid crust on the surface of the sun. This is entirely in accordance with the English work.

When the chromosphere is observed with large instruments—and under peculiarly favourable conditions—it does not present the appearance of a continuous level stratum, as should be the case if it were solid, pasty, or liquid, but often appears to be formed of a continuous series of very distinct flames.* It looks indeed like a general conflagration, more or less developed, which is incessantly renewed with greater or less force, and with especial violence in particular parts, where it gives rise to the protuberances. In small instruments, on the contrary, the chromosphere appears smooth, excepting certain parts where the flames rise to an unusual height. In like manner the details of the protuberances, and especially their outlines, as observed with small instruments, are not comparable with those made with large telescopes, which must necessarily afford a higher degree of definition.

Tacchini next described certain observations which tend to show that the so-called jets, projected upwards from the chromosphere, have their counterpart in a descent of matter from above, in a kind of solar rain, when a mass or cloud of luminous hydrogen suspended in the sun's atmosphere throws off filaments on both sides, which gradually descend and unite at the sun's edge, thereby forming a protuberance which exhibits the arborescent or fan-like form usually attributed to an eruptive jet. This is a new point of great interest.

The theory which attributes the solar protuberances to violent eruptions forcing their way through a solid crust, or a liquid of great resisting power, may, Tacchini remarks, appear to derive some support from the chemical composition of the protuberances. If the masses which project above the chromosphere were found to contain many materials different from those which compose the chromosphere itself, there would be good reason for regarding them as projected from the interior of the sun. And, in fact, some of the protuberances have a somewhat complex chemical composition, the bright lines observed in their spectra often corresponding to magnesium, iron, sodium, titanium, calcium, barium, nickel, chromium, copper, together with eight other lines which may belong to as many different substances; in all therefore eighteen elements, besides hydrogen and the element provisionally named Helium, which is never absent, and represents the constant material of the entire chromosphere. On August 27 last in a single protuberance nine different substances, represented by a brilliant spectrum of twenty-four bright lines, nine of which belonged to iron were seen.

* "On the Forms of the Solar Protuberances and the Regions of Magnesium and Iron on the Surface of the Sun." By P. Tacchini (Public Conference held on Feb. 18, 1872, in the Royal University of Palermo).

* See Lockyer, Proc. R.S. vol. xvii. 1870, p. 354.

But is this rich composition common to all the protuberances, or limited to a certain number? and do these materials extend throughout the protuberance, or are they confined to a limited portion of it?

Tacchini's observations show that the varied composition in question is limited to a very small height; in other words, to the mere base of the protuberance, whereas the higher portions are composed exclusively of hydrogen and the element D_3. Now, if the protuberances were the result of violent eruptions, the substances ejected with such force could not fail to attain a considerable height above the base of the protuberance, which is contrary to observation. Moreover, it is not all the protuberances that give a mixed spectrum; that is to say, they are not all formed of numerous materials, as they should be, at least in the majority of cases if they were produced by violent eruptions. According to Tacchini's observations, only 10 out of 100* protuberances give a mixed spectrum, the remaining 90 giving spectra which exhibit only the hydrogen lines and the line D_3. He also finds that in all the spectra which he has observed, either of protuberances near the sun's edge, or of clouds and filaments of greater height, the hydrogen lines never occurred alone, but always accompanied by the line D_3. In one case only were the hydrogen lines and D_3 accompanied by other bright lines in the distinctly higher portions of the protuberances. This was observed on December 19, 1871, on a magnificent protuberance resembling a great conflagration, the central part of which exhibited two red lines.

If the protuberances were formed of materials violently ejected from the interior of the sun, it would follow that at every point of the sun's edge where a mixed spectrum occurs, that is to say, where there is evidence of the presence of numerous materials, there also the corresponding protuberance should exist; but observation shows the contrary.

From his first examination of the protuberances, indeed, Tacchini had been led to conclude that the bright protuberances alone afforded certain indication of a rich variety of materials; but observing afterwards some parts of the sun's edge which, though free from protuberances, nevertheless had a peculiar structure, inasmuch as they were formed of a series of flames higher and brighter than usual, he was led to examine the spectrum of these portions more attentively; and he found indeed that there also, in addition to the lines of hydrogen and D_3, lines appeared corresponding to many other substances. A very careful examination of the sun's edge was accordingly made in August and September 1871, the result of which was to show that in very extensive tracts of the edge, amounting to $\frac{1}{6}$ of the whole, the entire chromosphere was invaded by the vapours of various metals, although these same parts of the edge were not covered by protuberances, an observation before made by Lockyer.†

These tracts continued to show themselves more or less extensively for many days afterwards in the same part of the sun's limb, representing in their aggregate vast regions of the surface where the hydrogen of the chromosphere was mixed with many other substances which commonly exist at the base of the chromosphere. Thus on the 28th of August and 17th of September, 1871, throughout an area of 60°, from the position 30° to 90°, the edge gave a mixed spectrum, although the constituent substances were not found to be present in the same number at all points of this arc; the greater number indeed were found at the middle of the arc, while at the ends they were reduced to magnesium, hydrogen and D_3 of the chromosphere, so far as this last-mentioned line may be regarded as belonging to a peculiar substance. This order in the number of substances on the portions of the edge which give a mixed spectrum, has been observed so frequently, that the regions of the sun corresponding to the aggregate of these successive tracts may be regarded as isolated portions of the solar surface, in the centre of which there is found a large number of different substances, this number diminishing towards the edge of each of these regions, where it reaches its minimum; and if we leave out of consideration the materials of the chromosphere which are common to the whole surface of the sun, we may say that at the borders of these regions there remains nothing but magnesium. In these tracts or regions, indeed, though the composition might be different in different parts, magnesium was never absent; for this reason Tacchini designates these portions of the surface as *magnesium regions*.

Instead then of special points marked by eruptions, we find on the sun's surface large regions exhibiting throughout a complex spectrum, but not covered by protuberances; and this affords the strongest argument for not regarding the protuberances as a phenomenon of true eruption. We cannot therefore admit the existence of a solid or highly resisting liquid stratum, but rather a purely gaseous envelope, such as may permit of the ready mixing of the internal materials with those of the chromosphere on a vast scale, thereby giving rise to the regions above designated as regions of magnesium.

This view, however, does not absolutely exclude the occurrence of eruptive phenomena; for if these materials show themselves in the chromosphere at certain determinate points, they must have issued or been ejected from the centre towards the circumference. Tacchini, however, thinks that he has proved that these eruptions are not violent, and do not take place through a strongly resisting medium.

Contemporaneously with the determination of the angles of position of the protuberances, and of the portions of the chromosphere which exhibited a mixed spectrum, similar determinations were made of the positions of the faculæ and regions of faculæ visible or near the edge. A comparison of the two series of determinations thus made showed the coincidence of the magnesium regions with the regions of the faculæ. The positions of the protuberances on the other hand did not coincide with either.

The limits of the regions of magnesium and of the faculæ, on either side of the sun's equator, were found to be as follows:—

Regions of Magnesium, August 1871	+ 60° − 27
September	+ 60° − 32
Regions of the Faculæ, August	+ 43° − 32
September	+ 64° − 32

Considering now the magnesium regions above described, and the intensity of the phenomena there exhibited, it is clear that at any given epoch, the luminous intensity of the solar disc may vary considerably, and exhibit great differences as compared with that of the general envelope. At such times the solar atmosphere will not be uniformly illuminated, but will include a number of cones, varying in extent and brightness according to the different magnesium regions existing on the sun; and Tacchini suggests that in the case of total eclipses of the sun, during which the solar atmosphere becomes visible to us in the form of an aureola, this aureola which is differently illuminated in different parts, and therefore presents the appearance of plumes perpendicular or oblique to the edge of the moon, may arise from the cones embracing a large extent of surface corresponding to that of the magnesium regions.

Whilst Tacchini was studying the magnesium regions, Lorenzoni obtained evidence that the temperature of the sun's surface is least at the poles. The regions occupied by the metallic vapours corresponding to a certain line, which probably belong to the spectrum of iron, are called by Tacchini iron regions; they do not coincide with the regions of magnesium and of the faculæ, or with those of the protuberances, which are more limited.

Since the vapours of iron are diffused in the chromosphere on so vast a scale, and the magnesium regions also are so large as has been previously shown, Tacchini asks is it possible to admit the existence of a state of solidity or viscosity in those envelopes, or a temperature so low as some persons suppose? He regards such a view as totally inadmissible, and considers that all the observations above detailed point to the conclusion that the time is yet very distant when the sun will approach to those transformations which have reduced the earth to its actual state; and that the sun is still an entirely gaseous mass, relatively hotter at the centre, and cooler in the superficial strata, which we distinguish by the names of photosphere and chromosphere.

* Tacchini's observations divide prominences as Lockyer has divided them.

† Proc. R.S. vol. xviii. p. 75 1879

ASTRONOMY

On the Meteors of April 30-May 1*

PROF. SCHIAPARELLI, in his list of meteoric showers whose radiant-points are derived from observations made in Italy within the last few years, describes one as occurring on April 30 and May 1, the apparent position of whose radiant is in the Northern

* From *Silliman's Journal* for July, 1872.

Crown, R.A. 237°, N.P.D. 55°. The same shower has also been recognised by Robert P. Greg, F.R.S., of Manchester, England. This meteor-stream, it is now proposed to show, is probably derived from one much more conspicuous in ancient times.

In Quetelet's "Physique du Globe," pp. 290-297, we find meteoric displays of the following dates. In each case the corresponding day for 1870 is also given,* in order to exhibit the close agreement of the epochs.

1. A.D.	401,	April 9;	corresponding to	April	29,	for 1870
2. ,,	538	,, 6	,,	,,	25	,,
3. ,,	839	,, 17	,,	May	1	,,
4. ,,	927	,, 17	,,	April	30	,,
5. ,,	934	,, 18	,,	May	1	,,
6. ,,	1009	,, 16	,,	April	28	,,

The epochs of 927 and 934 suggest as probable the short period of seven years. It is found accordingly that the entire interval of 608 years—from 401 to 1009—is equal to 89 mean periods of 6·8315 years each. With this approximate value the six dates are all represented as follows:—

From A.D. 401	to A.D. 538	we have	20	periods of	6·85	years
,, 538	,, 839	,,	44	,,	6·84	,,
,, 839	,, 927	,,	13	,,	6·77	,,
,, 927	,, 934	,,	1	,,	7·00	,,
,, 934	,, 1009	,,	11	,,	6·82	,,

This period corresponds closely to those of several comets whose aphelion distances are somewhat greater than the mean distance of Jupiter. So long as the cluster occupied but a small arc of the orbit, the displays would evidently be separated by considerable intervals. The two *consecutive* showers in the tenth century indicate, however, an extensive diffusion of the cluster at that epoch; so that the preceding part passed the node April 30, 927, and the following part, May 1, 934; the interval being somewhat more than one complete period. The comparative paucity of meteors in modern times may be partially explained by the fact that the ring has been subject to frequent perturbations by Jupiter.

It is not impossible that this meteor-stream was connected in its origin with the comet which passed its perihelion on April 29, B.C. 136.

DANIEL KIRKWOOD

* Making proper allowance for the precession of the equinoxes.

SOCIETIES AND ACADEMIES

LONDON

Geologists' Association.—The excursion to Ludlow and the Longmynds on July 22 and five following days, the concluding and most important field meeting of the season, was under the direction of Prof. Morris, F.G.S., Mr. R. Lightbody, F.G.S., and the Rev. J. D. La Touche, B.A. After the members had assembled in Ludlow Castle the Upper Ludlow rocks on the right bank of the Teme were examined, and Mr. Lightbody gave his reasons for considering the Aymestry Limestone to be represented at a point near the old bridge, although *Pentamerus Knightii* is not found here. The Upper Ludlow contains *Chonetes lata* in great abundance, and scarcely a fragment of the rock was picked up without this species being seen on the surface. From the high ground by the river side the valley of the Teme may be advantageously seen. The river here flows through a gorge in the Upper Ludlow rocks, with the castle and town of Ludlow picturesquely situated on the left bank; while the "Old Red" country extends beyond to the Clee Hills, the igneous summits of which commandingly rise to the east, surrounded by the coal measures. The well-known section in Ludford Lane, showing the "bone-bed," was next visited. This bone-bed, or "gingerbread," as it is sometimes called from its appearance, is in places not more than a quarter of an inch thick, and is found only after careful search. The fragments of the remains of fish, of which it is partly made up, were until comparatively recently the oldest fish remains known. The following day (Tuesday) was devoted to an examination of sections of the Aymestry Limestone, Lower Ludlow, and Wenlock rocks, occurring in the course of a route of about twenty miles. The journey was performed by means of carriages, but abundant occupation was given for the hammers of the party at the various exposures of the richly fossiliferous rocks above named. Graptolites from the Lower Ludlow were obtained in abundance, and fine specimens of *Phacops longicaudatus* were found in the Wenlock, exposed in the bed of the Teme, near Burrington; while *Pentamerus Knightii* was seen in great profusion in the Aymestry Limestone of Ruacktree. Near Comus Wood (so called from being the scene of Milton's "Comus") a very extensive view is obtained of the "Old Red" district of Herefordshire, with the Malverns distinctly seen in the distance. In the evening the members were entertained at a *soirée* given by H. Salway, Esq., of "The Cliff," Ludlow. During Wednesday the Upper Ludlow rocks in the valley of the Teme were subjected to further examination, and the party proceeded as far as Downton, where the uppermost members of the series are seen at the Tin Mills section. At one point on the road to Downton the physiography of the district to the north of Ludlow is well seen, and here Prof. Morris pointed out the principal features of the extensive landscape, and showed how entirely due they were to their geological structure, and that the coal measures of the Clee Hills had been preserved by the old volcanic outbursts which had formed the central masses of hard "Dhu-stone" composing the summits and caves of these lofty hills. On Thursday the party ascended the Longmynds at their southern extremity, where masses of quartzose conglomerate of Cambrian age protrude from the surface. The Rev. Mr. La Touche described the topography and the geology of the district seen from the elevated ground on which his hearers were assembled, and, subsequently, Dr. Hicks explained the order of the succession of the Cambrian and Lower Silurian rocks of St. David's, which he had been re-examining during the previous fortnight, and which he considers to have representatives in some of the beds of the Longmynds. The Llandovery conglomerates lying on the uplifted beds of the Cambrians at an angle of 22° were found to be exposed on the eastern slope of the hill, and the "Pentamerus limestone," with its characteristic *Pentamerus oblongus*, was also seen. The party then proceeded to the quarries of Caradoc sandstone in the Onney valley, at one of which Prof. Morris gave a general description of the Silurian system and the extension in England of its various members. Friday was occupied by a journey in carriages to the mining district of Shelve, and by an inspection of the very interesting hill-country between that place and Church Stretton. Quarries in the Cambrian rocks at the south end of the Longmynds and in Llandovery beds near Norbury occasioned stoppages, and afterwards a visit was paid to Linley Hall, the residence of Mr. Jasper Marc, who courteously invited the party to inspect his fine model of the South Shropshire mining districts, the famous pig of lead of Roman age, with the name of the Emperor Hadrian upon it, found near Shelve, and specimens of the mineral products of the locality of extraordinary size and beauty. The members were then entertained at luncheon, after which they left Linley Hall and traversed a long, narrow, and very beautiful valley in the park, and terminating at the Stiper Stones. At a little distance from the park enclosure a mass of felspathic ash in Lower Llandeilo rocks is quarried for road metal, and the Llandeilo beds thus laid bare were eagerly and most successfully searched for fossils. After a brief visit to the White Grit Mine, the carriages were finally left, and the party commenced the ascent of the Stiper Stone ridge, from the summit of which is seen a fine panorama of the Welsh mountains, with the old volcanic Corndon in the foreground, and Cadir Idris and Plynlimmon in the extreme distance. The extraordinary masses of obtruding hard white quartzite rocks called the Stiper Stones were objects of great interest to the party, some of the members of which were not satisfied with the evidence of their being the equivalents of the Lingula flags. The Longmynds ridge, extending for nearly fifteen miles, bounds the view to the east, and this range had now to be crossed. The intervening valley affords several sections, at one of which was seen what was considered by Murchison to be the junction of the Silurians with the Cambrians. Near the summit of the Longmynds a very fine exposure of Cambrian conglomerates occurs; and further along the edges of the vertical green and purple shales and slates are seen beneath the feet as the mountain road is traversed. On the eastern side of the range the rocks are well exposed, and the indenting gorges numerous and picturesque. Caer Caradoc stands boldly out at a little distance to the north-east, with the Wenlock and Aymestry limestone ridges beyond, and bounding a valley of great beauty and extent, terminated northwards by the volcano-like cone of the Wrekin, at the foot of which the Severn flows through a deep gorge. The morning of the concluding day, Saturday, was given to an examination of the Upper Ludlow rocks, the "Bone-bed," and the Downton sandstone in the neighbourhood of Morton

Camp and Ovibury; and the week's proceedings concluded with a visit to Stokesay Castle, in which the Rev. James Parker gave an interesting account of the curious old pile. Thanks were most warmly accorded to the Rev. Mr. La Touche and to Prof. Morris for their able conduct of the excursion, and the members then took their departure from the Craven Arms Station, congratulating each other on the very interesting, instructive, and successful character of the visit of the Geologists' Association to Shropshire.

KENT

East Kent Natural History Society, August 1.—A communication was made by Mr. Gulliver, F.R.S., in relation to the shark (*Lamnia Cornubica*) taken last November off Rye. As this is the first description of this important skeleton of this huge fish, which may now be seen at the College of Surgeons, we give it at some length. This shark is the Porbeagle of many authors and the Beaumaris Shark of Pennant. Every anatomist knows more or less how an ordinary natural skeleton is made; but as this of the Porbeagle is an extraordinary one, it is well worth while to note some of the means employed in its preparation. In the first instance careful measurements were made of the different appendages, and kept for guidance in regulating their due position, since in the drying there would be much distortion or displacement which could only be corrected by a constant reference to their state in the fresh fish. Then came the question, how to get out the brain; and this it was found could be easily done through a natural opening—a sort of fontanelle—more than an inch in diameter, in the upper and front part of the skull. Next, it was foreseen that, in such a large fish, there would be great shrinking in its length from the contraction by drying of the intervertebral substances, as had happened to the skeleton of this shark at Haslar; and this fault was prevented by the insertion between the bodies of the vertebræ of temporary wedges or plugs of wood. And as the skull and orbits, being cartilaginous, would shrink and curl into a shapeless and ugly mass, unless means could be devised to preserve their form, all these parts were supported by plaster casts, while the foramina were kept open by wooden plugs. In this state six weeks were passed in the drying, although this was often hastened by artificial heat. The plugs and plaster being removed, the skeleton parts were left in their natural form and position, as now so admirably preserved for the instruction of anatomists. The eyes, too, are shown *in situ* without the least shrinking. The spine has been strengthened by a strong cane introduced along the neural canal, and remaining permanently there, but not visible without curious inspection. It is remarkable that there is but little fatty matter in the skeleton. Among the manifold parts of the skeleton are seen, in their natural position, the five pairs of Branchial Arches; the Hyoid Arch with its three pieces on each side, and the Branchiostegous Rays; the Scapular and Pelvic Arches; and, as appendages of the pelvis, the pair of osseous Claspers, each of two pieces and a curious Spine of hard bone, particularly noticed by Prof. Flower, at the free end. The Vertebræ, of which the number has not hitherto been recorded in this species, are, as counted by Prof. Flower and Mr. Gulliver, no less than 152, of which 60 belong to the tail. These caudal vertebræ turn abruptly upwards at an angle of about forty degrees from the straight vertebral column of the trunk, and run straight along the upper border of the superior lobe of this caudal fin. The frame-work of this fin-lobe is chiefly formed of the caudal vertebræ, with their broad and flat inferior spinous processes; the lower lobe of the caudal fin is composed of a densely-packed layer or plate of parallel rays proceeding from above downwards, and apparently of fibro-cartilaginous texture. The vertebral column has no ribs. The Rays of the front Dorsal Fin are distantly jointed; the joints like those of soft-finned bony fishes, but much further apart in each ray; and this is so remarkable in the Pectoral Fins of this fish as to remind us of the digital phalanges of mammalia. Of course, every ichthyologist well knows that the caudal fins of the Plagiostomes are unequal (heterocercal); but it is not so familiarly known that the caudal vertebræ in several of these fishes, and also in some other fishes, pursue a different course. Indeed, the disposition of the caudal vertebræ of osseous and cartilaginous fishes, both in adults and in the different stages of development, affords, as Agassiz and Huxley have recognised, a very interesting subject for more research than has yet been devoted to this branch of ichthyology. Meanwhile we have in this skeleton of the Porbeagle a noble contribution to the osteology of the Selachians.

PARIS

Academy of Sciences, July 22.—A paper was read by Prof. Cayley on the conditions enabling a family of given surfaces to form part of an orthogonal system.—M. A. de Caligny communicated a note on a liquid vein formed in part by a current, and in part by the blows of the waves against two convergent breakwaters.—A note on the vibrations of cords under the influence of a diapason by M. E. Gripon was read.—M. F. Lucas communicated the results of experiments made by him in the Seine during the siege of Paris for the purpose of ascertaining how far the waters of the river would convey sounds which might be employed for telegraphic purposes. He found that the sounds produced by heavy bells were not transmitted more than 1,500 to 1,800 metres.—M. W. de Fonvielle described a new example of the danger caused by large masses of metal during thunderstorms.—M. Le Verrier read a memoir on the masses of the planets and the parallax or the sun, in which he indicated that in the present day the exact determination of these and some collateral matters had become a necessity, and dwelt especially upon the desirableness of a new direct measurement of the velocity of light. Upon this subject MM. Fizeau and d'Abbadie made some remarks.—M. Boussingault communicated a note on the determination of iron in the blood of an invertebrate animal. The animal employed was the common garden slug; its blood contains only 0·00069 per cent. of iron.—A note was read by M. P. Thenard on a new process for the quantitative determina- of ozone, and a second by the same author on the action of permanganate of potash or oxygenated water in the midst of a freezing mixture.—M. Sace presented a memoir on a new process for the preservation of alimentary substances by means of acetate of soda.—M. Berthelot communicated a note on the constitution of acid salts in solution; and MM. P. Champion and H. Pellet a note on the theory of the explosion of detonating compounds.—M. A. Boillot described a process for the preparation of ozone by means of a new mode of production of the electrical effluvia.—M. C. Bernard communicated a further note by M. Oré on M. Liebreich's endeavour to demonstrate that strychnine is an antidote to chloral.—M. C. Robin presented a note by M. Rabuteau on the physiological properties of quinic acid, and on the reduction of perchloride of iron in the organisms; and M. C. Sainte-Claire Deville communicated a letter from M. Diego Franco on the late eruption of Vesuvius.

CONTENTS

THURSDAY, AUGUST 15, 1872

THE BRITISH ASSOCIATION

THE recurrence of our annual Congress of Science naturally leads us to reflect on the position which the British Association occupies in our social economy, and on the part it is qualified and, perhaps, destined to play. Whilst other scientific societies occupy themselves in giving publicity to results and speculations, and in rewarding with their medals successful labours, the British Association alone systematically undertakes to distribute the greater part of its income, about 2,000*l.* per annum, in grants to enable men of science to conduct scientific investigations, and to institute inquiries with a view to possible future action. Stated briefly, this constitutes the broad distinction between the British Association and other scientific societies. As a publishing society it cannot vie with some other bodies, as, for instance, with the Royal Society. The great bulk of the papers it receives are published in abstract and but few *in extenso*; and it allows a greater latitude than other societies with regard to the reception of subjects which have been elsewhere made public, thus constituting its proceedings, to a great extent, a *résumé* of the year's work—a characteristic quite in keeping with its practice of meeting but once a year.

It is distinguished also by the wide range of subjects admissible in its various sections, by the facility with which membership is granted, by its attractiveness to foreign men of science, and, above all, by the tendency which its practice of meeting each year in a different town has to disseminate Science throughout the kingdom.

All these characteristics combine to make the British Association a truly national body. And the feeling that it is so has always made its leaders more ready to interest themselves in large national objects connected with Science, than, as members of other societies, the same men have elsewhere shown themselves to be. The British Association has thus always exhibited more self-assertion, and, in its communications with Government, more boldness, than other societies. In other scientific circles there is a disposition to regard any assistance given by the State as a favour to Science, and a timid reluctance to point out plainly cases in which the aid of the State is really necessary. The total Solar Eclipse of 1871 is a case in point. The Astronomical Society had not the heart to place before the Government a clear statemen of what was required. The duty of doing this, which obviously devolved on that Society, being thus neglected by it, was at once, without a moment's hesitation, successfully performed by the British Association, to the great benefit of knowledge.

But a more striking and far more important example of the wise vigour which has generally characterised its counsels, is afforded by the steps it took to obtain a thorough inquiry through a Royal Commission into the whole condition of scientific action and administration in England. Whether that inquiry leads to immediate reform and expansion of our scientific institutions, as it is generally expected it will, or not, the inquiry itself has already been productive of incalculable good. It will probably be found, when the evidence is published, that our "system" at present consists of a mass of inconsistencies, and deficiencies, of the existence of which not even those who originated the movement could have had any clear idea, much less any reliable proof. The utter absence of any guiding principle in the dealings of successive Governments with Science, and of any system for administering such imperfect and dislocated institutions as we possess, which we are convinced the inquiry must also establish, will so startle all thinking men, whether scientific or not, that sooner or later reform must come, although the causes of this state of things are not far to seek.

Another good result of the inquiry is that it has forced the large body of men of Science who have been examined to turn their attention from that too rapt contemplation each of his own labours to which English philosophers are addicted, towards the great fields which others are cultivating; and by forcing them to regard Science as a whole, to recognise and duly appreciate the individual value and the interdependence of its several parts. The change in scientific thought which has taken place in the course of the two years during which the Royal Commission has been sitting, is quite perceptible to those whose attention is turned to the subject.

But no change of thought is perceptible in the Ministry of the day. It is perfectly clear that now, as ever, any aid given to Science is a mere question of pressure. Sometimes it is yielded with apparent promptitude to the external force of numbers, importunity, or probable popularity. At other times it is as stubbornly refused. An example of each is of recent occurrence. Aid was given to expeditions to observe the two last total Solar Eclipses, in the shape of several thousand pounds, and the use of ships. The aid of 150*l.* was refused to the British Association for completing tidal investigations, on which that body had spent 600*l.* As it is impossible to refer these two acts to one and the same guiding principle, we must assume that different motives prompted each, and that, as no properly instructed mind could consider Eclipse Observations many times more important to a great naval and maritime country than Tidal Researches, compliance with the one demand cannot be set off against refusal of the other in assessing the real regard for Science to be credited to the Government.

These two well-marked cases, the miserable Hooker-Ayrton wrangle, the treatment of the Society of Antiquaries recorded in our last number, and the declaration of Mr. Gladstone at the Royal Society's anniversary dinner that Science must suffer if aided, or as he expressed himself, if "interfered with," by the State, are all indications that the Government do not yet know that it is possible to draw a boundary line separating the regions of scientific activity which should be occupied respectively by individuals or private bodies and by the State. And the truth does not yet seem to have dawned on them that the prolonged neglect of those scientific objects which State resources alone can attain is a positive dereliction of duty, the effect of which in overweighting England in the race of European civilisation is already perceptible.

Our immediate object in drawing attention to the unsettled and phlegmatic views of the Government with

respect to Science is to raise the question whether the British Association cannot reinforce the healthy tone of thought they have brought about through the Royal Commission obtained by their influence. We believe that this question will be raised in a more formal manner at Brighton; but as it was first suggested in these columns,* we may, without impropriety, give it our advocacy.

It is thought by many that the perplexed and perplexing way in which the relative functions of individual and of State action in Science are now confounded, has its origin in a great measure in neglect of classification on the part of private persons and private bodies. And the opinion is spreading widely that the British Association itself has not sufficiently discriminated, in distributing its funds, between objects which individuals are perfectly able to compass, and which they should be encouraged to undertake, and those which the State alone can successfully grapple with, and which, by reason of their evident importance to the community at large, the State is therefore bound, as a matter of duty, effectively to provide for.

We shall not here attempt to indicate the tests by which these two classes of scientific objects may be distinguished. If the principle be but admitted that a distinction does exist, the necessary rules for enforcing it may safely be left to the wisdom of the Association to draw up. Its experience is very wide, and its records will supply ample materials for ascertaining what are the purposes which, with the best intentions, it has been unable to attain, and on which its grants have been virtually wasted. These will afford data sufficient for the construction of a code of rules applicable to almost every case that can come before it.

The next question is, how should these tests be applied? We are satisfied that the time has arrived when the Association may with perfect propriety, and with the certainty of the most beneficial consequences, decline to allot any portion of its funds to purposes which should by rights be undertaken by Government. We are far from counselling this step as a retaliation for such refusals of State help as that respecting, for instance, the tides. Any such feeling would be quite unworthy of such a body as the British Association. Its grounds for doing as is proposed would be perfectly clear, and entirely free from any suspicion of antagonism or irritability. First, many of the objects which the Association has attempted to attain have been distinctly proved to be too large for its resources, and to require official machinery which it cannot command. The question of Sewage is a marked example of this class. But the fact that the Association has taken up such a subject leads to the mistaken belief that it is properly provided for; and it is not till some years have elapsed that the truth breaks upon us that the time and money expended upon it have been almost wholly wasted, and that the question remains pretty much in its original condition—not appreciably advanced. The attempt to deal with such problems with insufficient means results, therefore, in delusion and delay. Secondly, to deal with all classes of scientific questions without discrimination, perpetuates and deepens the obscurity which prevails in England as to the duties of the State. No one has yet been bold enough to maintain that the State should do nothing whatever for Science, and that what is at present done should be discontinued; but scarcely any one seems to have a clear idea of the principles on which such duties should be defined, and on which expansion should proceed. If once such a definition is arrived at, the main difficulty will have been overcome. If it is once settled by competent authorities that certain inquiries, or experiments, or observations, should, by reason of their expensiveness, of their value to the community, or of the length of time they must occupy, be undertaken by Government, the first step will have been taken towards that organisation of State Science which it is clear must not be much longer delayed.

Now, there can be no more practical mode of arriving at such a definition than that of firmly refusing to apply private funds to public purposes, as here proposed. There will at first be some difficulty in effecting the necessary classification, and it will be well not to apply it at the outset too rigorously; but by degrees the difficulty will vanish, and it will be as easy to say what subjects devolve on the State as it now is to say what subjects appertain to particular sections of the Association.

Another great advantage which will ensue will be the amount of funds thus set free for assisting those objects which can be effectually attained by individual enterprise, the number of which is very great. It is well known, and much to be lamented, that many of these invaluable undertakings are starved for want of those very funds which are now spent in the vain endeavour to do the State's work.

The subjects which the Association may thus pronounce to be not within its province should not be lost sight of. An enumeration of them should be submitted annually to Government, and the resulting action taken on them by Government should be regularly reported to the Association and published. The effect of this would be to assist the Government in arriving at some measure of the scientific work which must be done by them, if done at all. This will soon be shown to be enormous in extent and variety. Attention will next be called to the machinery existing for such purposes. The first question will be, If such and such investigations are to be undertaken, which department shall be made responsible for them? And this must bring out prominently the absurdity of our present arrangements, whereby the various scientific institutions of the State are scattered amongst the various departments, and must lead to what is the fundamental requisite—concentration of all such institutions under one department responsible for the whole.

Nothing that the Association can do would, in our opinion, conduce so directly to this desired end as the classification of the applications made to them for funds in aid. The object is one in strict keeping with its traditions, and quite worthy of its ambition, destined as it is to be the High Court of Appeal in Science, and the prime mover in all that concerns material and philosophical progress. In the present day no considerable measure is undertaken by the State except in obedience to an impulse from without. This will clearly be the case with respect to Science. The first impulse has been given already by the British Association. We foresee that the issue will depend materially on the persistent firmness with which its first efforts are followed up by that powerful and useful body. Success must crown them at last, and sooner perhaps than some at present anticipate.

THE BEGINNINGS OF LIFE *

II.

LEADING on to the newer and more important observations in the latter portion of the work, we have a sketch of the relation of crystals and organisms, in which a variety of curious and suggestive facts are adduced, tending to show that there is a striking analogy, if nothing more, in their mode of origin. The influence of changed conditions is shown to produce very similar results to both, and the views of Mr. G. H. Lewes—that organisms are not always united by the link of a common heritage, but that many may owe their similarity to having originated under the influence of uniform organic laws acting under uniform conditions—is quoted with approval. Just as similar crystals are produced in similar liquids under like conditions, so may low organisms of similar or identical structure be produced; and just as the fragments of a crystal will, under favourable conditions, form each an entire and perfect crystal, so do low organisms multiply by fission, each part becoming a perfect whole. The difference between crystals and organisms is said to be less radical than has been supposed, and is mainly due to the much greater complexity and instability of the molecules which go to build up the latter. Crystals are statical; organisms, dynamical aggregations of molecules. Specks of new living matter soon aggregate into certain definite forms just as crystals do, but being much more complex and unstable, they are liable to much greater variations and successive modifications. The excessive variability and instability of low forms of life is dwelt upon as an anomaly on the ordinary theory, when viewed in connection with their supposed wonderful stability for immense periods of time. It is generally believed that every one of the lower animals is a descendant of other low forms which lived in ages far anterior to the Silurian epoch. Many of the foraminifera.

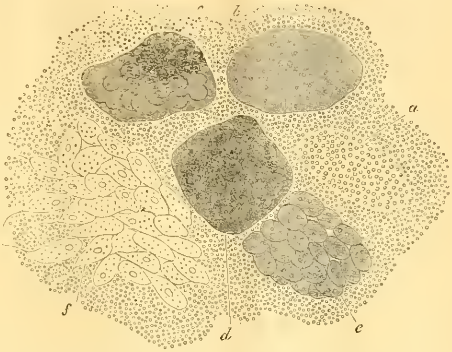

FIG. 1—SEGMENTATION OF EMBRYONAL AREAS INTO MONADS—(× 1,670).

a. First stage of differentiation. *b.* Second stage; area almost homogeneous and refractive. *c.* First traces of segmentation. *d.* Segmentation more complete; units highly refractive *e.* Units less refractive; forming tailless corpuscles. *f.* Fully developed Monads derived from such corpuscles.

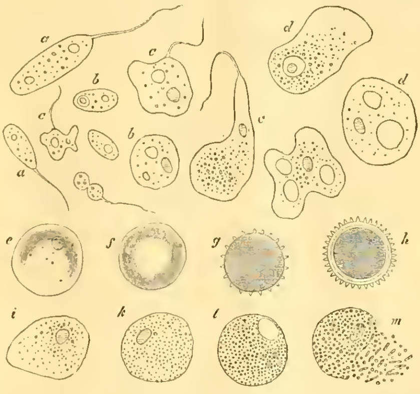

FIG. 2.—PHASES IN THE LIFE-HISTORY OF MONADS AND AMŒBÆ—(× 1,670).

a, a. Monads in different stages of growth. *b, b.* Similar Monads which have lost or retracted their flagella. *c, c.* Monads about to be transformed into Amœbæ. *d, d.* Resulting Amœbæ in active and motionless stages. *e, f, g, h.* Stages by which motionless Amœbæ become encysted. *i, k, l, m.* Stages by which other Amœbæ become resolved into Bacteria.

* "The Beginnings of Life: being some account of the Nature, Modes of Origin, and Transformations of Lower Organisms." By H. Charlton Bastian, M.A., M.D., F.R.S. (2 vols. London: Macmillan and Co. 1872.)

for example, have hardly undergone any essential change, the same forms and varieties recurring at very distant geological periods. If, however, living matter does continually come into existence, the lowest forms will probably have been very similar in all ages; and it is only as these forms developed into more complex organisms that the varying conditions of the different periods will have led to the development of specialised groups.

The nature and mode of development of the low organisms found in infusions is next elaborately discussed, with the following result:—"No other conclusion remains for us, but that the several organisms are products of the direct developmental unfolding of new-born specks of living matter. And yet among these forms we see Bacteria, Vibriones, Leptothrix, and Torulæ; Fungus filaments, with and without fructification; Protamœbæ and flagellated Monads; Pediastreæ and Algoid filaments. All these are therefore proved with the greatest certainty to be interchangeable forms, which may be assumed on different occasions by newly evolved specks of living matter." Evidence is also adduced of the changes in other low forms. Green corpuscles thrown off from a single Lichen have been seen by Dr. Hicks to assume the forms and mode of growth characteristic of no less than twenty-three supposed species of Algæ; while gonidia from an Alga or from a Moss were developed into Lichens, Algæ, or Mosses, according to the conditions under which they were placed, while they may sometimes give birth even to active Monads.

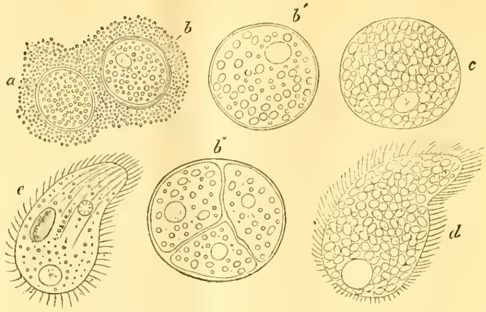

FIG. 3.—MODE OF ORIGIN OF PARAMECIA—(× 800).

a. First stage of differentiation. *b.* Later stage, in which vacuole has appeared. *b*¹. Similar stage of much larger embryo. *b*². Another embryo which has segmented into four (only three parts visible). *c.* Later stage; embryo filled with large particles, and revolving within its cyst. *d. Paramecium* after it emerges from its cyst. *e. Nassula*-like form into which many afterwards passed.

Having clearly proved that Bacteria and other low organisms, which form a pellicle on the surface of infusions and other liquids, are produced *de novo* in such infusions, the third part of the work, entitled "Heterogenesis," is devoted to a history of the microscopical examination of the changes which take place in this pellicle, and of all that is at present known of the transformations of the various classes of organisms to which it gives birth. To make this part of the subject clearly intelligible, it will be necessary to reproduce a considerable number of the woodcuts by which these changes are illustrated. One of the most simple series of changes—this transformation of motionless corpuscles into ordinary Amœbæ—was closely watched by Dr. Bastian, and seen with the most perfect distinctness in thousands of instances. Fig. 4 shows the stages by which the more highly organised Monads are developed. The first step was an increase of the amount of gelatinous matter between the corpuscles or Bacteria, which gradually became less defined, and at last scarcely visible in the protoplasmic mass, in which segmentation then began to take place, and continued till it separated into active Monads. After a time, however, these again began to change into Amœbæ, and these latter, passing through a motionless and encysted stage, became resolved into Bacteria (Fig. 5). The whole

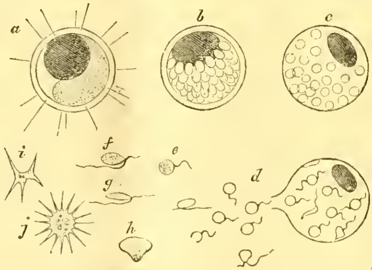

FIG. 4.—HETEROGENETIC ORIGIN OF MONADS FROM NITELLA (CARTER)—(× 350).

a. Contents of new-formed cyst separating into Protoplasm and dark brown refuse matter. *b, c, d.* Segmentation of the Protoplasm into Monads, which afterwards escape from the ruptured cyst. *e, f, g.* Different forms of the Monads. *h, i, j.* Forms of Amœbæ and Actinophrys which the Monads subsequently assume.

series of these changes occupied about ten days. In other cases similar corpuscles developed into fungi; while in some instances in the same pellicle the change into Amœbæ on the one hand, and into Fungus germs on the other, went on simultaneously. It was soon discovered that the temperature at which the infusion was made was of great importance. If it had been heated to 212° F. no development beyond Bacteria occurred; if at 149°—158° F. Fungus germs arose; while an infusion in all other respects similar, but prepared at a temperature of 120°—130° F. gave rise to actively-moving Monads.

A step further takes us to the "spontaneous eggs" of Pouchet, which are seen to be formed in the pellicle, and afterwards give birth to Paramecia—highly organised ciliated Infusoria. These never appear except in infusions made with cold water, and Dr. Bastian assures us that he

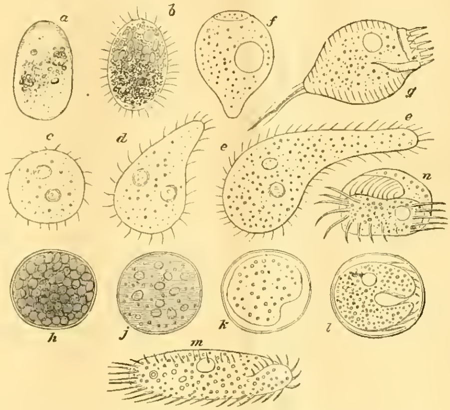

FIG. 5.—MODES OF ORIGIN AND DEVELOPMENT OF CILIATED INFUSORIA—(× 600).

a. A transforming Euglena with red "eye speck" still visible. *b* A similar body, having many of its chlorophyll corpuscles still green, fringed with almost motionless cilia. *c.* A completely decolourised sphere derived from a transformed Euglena, provided with a few partly motionless cilia. *d, e.* More advanced forms of a similar embryo developing into a Dileptus (?). *f.* Vorticella, soon after its emergence from a cyst of Euglena origin, which subsequently develops into a striated variety (*g*). *h.* A large Chlorococcus-vesicle whose contents gradually undergo decolourisation (*j*), and at last become converted into an animalised mass (*k*), which gradually shapes itself into the form of an Oxytricha (*l*); this after a time ruptures its cyst and soon takes on the characteristics shown at *m*. *n.* A form of Plæsconia derived from an embryo produced within other apparently similar Chlorococcus-vesicles.

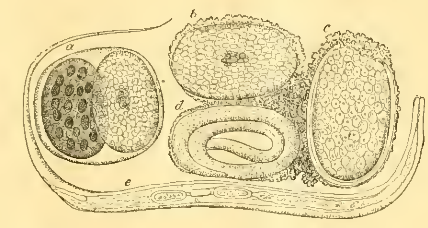

FIG. 6.—ORIGIN OF NEMATOIDS FROM EUGLENÆ (GROS).

a. A large Euglena which after encystment has undergone fission, whilst one of the halves has become decolourised. *b.* An Euglena which has become converted into a decolourised embryonic mass, leaving only a small coloured remainder. *c.* Another decolourised mass, which, after undergoing certain changes, becomes converted into a young Nematoid, as at (*d*). *e.* A female specimen of the developed Nematoid three weeks old, in whose ovaries two partially developed ova are seen.

has verified Pouchet's observations in all essential particulars, as represented in Fig. 6; and the still more complex Vorticellæ have been seen to arise in a similar manner. Now the germs of Ciliated Infusoria are comparatively very large and easily recognisable; they have never, or very rarely, been discovered in the atmosphere; and no competent observer could overlook them; so that it is almost impossible not to accept the fact of the origin of these organisms in the manner here described.

The course of the argument is at this point interrupted by a chapter on the Atmospheric Germ Theory, which, though exceedingly interesting and well written, is quite out of place here; and we then come to some curious observations on the production of organisms within the closed cells of various plants. M. Trecul, a distinguished French botanist, has watched the formation of Amylobacters, low organism allied to Bacteria, and minute Fungi within the closed cells of living plants. In *Ficus carica* he discovered fungoid organisms within the completely closed cells of the medullary tissue, which, he believes, "negatives all ideas as to the introduction of germs from without." Minute crystalline tetrahedrons in cells of the bark of common elder and other plants were actually seen to be transformed into Amylobacters. The transformation of milk globules and a film of diluted cream-cheese into Fungus germs has also been closely watched by several

observers, and has convinced them that these organisms have not arisen from accidentally introduced spores, but by a true heterogenetic transformation of the substance examined. Dr. Lionel Beale has discovered lowly vegetable organisms "in the interior of the cells of animals, and in the very centre of cells with walls so thick and strong that it seems almost impossible that such soft bodies could have made their way through the surrounding medium." Many other observers have even watched the transformation of the contents of healthy epithelial cells into Bacteria and Vibriones; and well-developed Fungi have been found within the uninjured eggs of birds and serpents. Now, all these facts, and a vast number of others detailed by Dr. Bastian, are claimed to be in complete harmony with the facts he has already established by his experiments with hermetically closed flasks, and with the theory of Archebiosis, while they have always offered immense difficulties to the advocates of Homogenesis, and have never been explained but by means of pure assumptions of a most improbable character.

We next come to the consideration of true Heterogenesis among lower organisms. Dr. Braxton Hicks has observed the production of Amœbæ by the transformation of the chlorophyll and protoplasmic contents of the cells of Moss radicles. Mr. H. J. Carter has closely followed the changes occurring in the cells of Nitella, one of the Characeæ, resulting in the formation of Monads and Amœbæ, as represented in Fig. 1. A vast number of observations of a similar character by many different observers are detailed, showing that the chlorophyll vesicles of Algæ are sometimes metamorphosed even into Pedias treæ, Desmids, and Diatoms.

But we must pass on to still more remarkable facts. The cell contents of Confervæ give rise to Euglenæ and Astasiæ, beautiful green organisms which abound in stagnant water, and these undergo transformations into a variety of higher or lower organisms, such as Diatoms, Amœbæ, and Ciliated Infusoria, the latter process being represented in Fig. 2. But Ciliated Infusoria themselves undergo transformation into various forms of lower animals, among others into Rotifers. The low Euglenæ are also transformed into either Rotifers, Tardigrades, or Nematoids, and the latter even grew into well-developed males and females (Fig. 3). Still more extraordinary, if possible, is the transformation of the minute Algoid Chlorococcus into the large, complex, and well-known Rotifer, *Hydatina senta*. Concerning the reality of these transformations, astounding as they are, Dr. Bastian assures us he entertains not the slightest doubt, having traced them through all their stages. The extreme prevalence and almost universal distribution of certain common forms of Rotifers, Tardigrades, and Nematoids, whose germs or ova are unusually large, and have been proved not to be universally present in the atmosphere, is inexplicable to those who disbelieve in the occurrence of heterogenetic transformation. Not only is it said to be proved that such transformations occur among Algæ, Fungi, Lichens, and Mosses, in every group of animals belonging to the class Scolecida, and in some of the lowest Annelida, but also in some of the lowest Arthropoda. In concluding this part of his subject, our author remarks :—"The fact that animals with such distinct and specific organs should arise in this definite manner from the reproductive products of a plant, will doubtless seem to many to flavour more of fable than of fact. After the observations which have been detailed, however, we must accept the occurrence of such phenomena as established facts, just as we are compelled, and are now quite accustomed, unhesitatingly to believe in the reality of other equally inexplicable phenomena. When we are able really to explain the reason of the processes by which one minute vesicular mass of fatty and albuminoid particles develops into a man, another into a fish, and another into an insect, we may then, with a little more show of reason, think of rejecting other more or less similar facts because they are incomprehensible."

Passing now from facts and observations of which we have only been able to indicate the character and extent by a few examples, Dr. Bastian proceeds to discuss the nature of "individuals" and "species" by the aid of the new light these researches have thrown upon them. He adopts the definition of an "individual" given by Herbert Spencer as being any organised mass "having a structure which enables it continually to adjust its internal relations to external relations, so as to maintain the equilibrium of its functions," and would define species to be any assemblage of individuals which are enabled for many generations to reproduce their like. But between these two he believes we must now establish a third category, for which he proposes the term "Ephemeromorphs," to include all those various forms which, although they sometimes produce their like, are shown to be interchangeable, and which, occasionally or regularly, arise from, or give birth to, forms quite distinct from themselves. All groups in which there is no differentiation of sexes are probably Ephemeromorphs, and the phenomenon of "alternate generations" in sexual animals is thought to be a recurrence to a partially Heterogenetic mode of reproduction.

The facts of Heterogenesis, if established, will undoubtedly largely modify our views as to the universality of the action of "Natural Selection." They seem to show that among the lower organisms, unknown laws of "polarity" akin to those which influence the production of crystals, but of infinitely greater complexity, directly cause the development of a vast variety of forms; while conditions of existence to a great extent determine the special forms that shall arise in each individual case. For such creatures "laws of heredity" hardly exist, and if so, Natural Selection can have little or no power. If we consider the enormous variety of forms that have been here shown to arise by Heterogenesis, it becomes evident that the field of action for Natural Selection becomes thereby considerably reduced. Again, the experiments detailed by Dr. Bastian prove the overwhelming importance of external conditions in determining the form that shall be assumed by many of the lower organisms, just the reverse of what has been found to obtain among the higher animals. And, what is still more important, the varying conditions do not act by producing changes in the adult organism which may be transmitted to their offspring, but actually so modify the developing germs as from a similar starting point to produce organisms which would rank as of distinct species, genera, or even families. The change produced seems to be quite incommensurate with the modified conditions which lead to it, and we are thus forced to accept some form of belief in innate tendencies or laws of progressive development, dependent on the polarities, forms of equilibrium, and attractive or repulsive properties of the complex physiological units of which organisms are built up. Such views are generally repudiated by modern thinkers; but Dr. Bastian believes they are necessitated by the facts now brought forward, and that they are really not only in harmony with, but almost necessary deductions from, the principles of the philosophy of evolution.

The phenomena of Heterogenesis also lead us to conclusions as to the rate of change in time of lower organisms exactly the reverse of those generally held. From having mainly studied the higher forms of life, and from having ascertained that the complex actions and reactions of such organisms on each other have been more efficient in producing specific changes than mere variability or the influence of changed conditions, Mr. Darwin has been led to the conclusion that the rate of change of the early forms of life, which had far less complex actions and reactions among themselves, must have been exceedingly slow.

This has almost the appearance of a paradox, in view of the admitted fact of the extreme variability and instability of these lower forms; yet it has been generally accepted as a sound inference from the law of natural selection, and has greatly increased the difficulty that has been felt as to the enormous time required for the development of all forms of life from the supposed primordial germs. But if the facts of Archebiosis and Heterogenesis are true, and all the lower forms of life are continually being produced *de novo*, under the influence of unknown laws of development, then we may fairly conclude that, when once the earth had arrived at conditions favourable to the production of living organic matter, the process of development would be rapid, and an immense variety of low forms of animals and vegetables would soon people it. It is a fair inference, too, that if such complex organisms as Ciliated Infusoria, Rotifers, Nematoids, and even simple Acari, can be developed independently of the slowly modifying influence of natural selection, the same laws of development will continue to act a subordinate part much higher in the scale, and, by assisting natural selection in its work, may have enabled a much more rapid progress to be made.

It is very strongly argued by Dr. Bastian that the conception of an origin of living organisms at a single remote epoch in past time, and the lineal descent of all existing organisms from those primal forms, is one quite opposed to the uniformitarian and the evolutional philosophy, and in the highest degree difficult to accept. It is almost inconceivable that Bacteria, Moulds, Monads, Amœbæ, and a thousand other minute and simple organisms, should still exist so universally over the earth, and under such an infinite variety of simple forms, if all were descended from ancestors which could hardly have been more simple in the almost infinitely remote past, and which throughout all that time had been subject to those same causes of change and advance in complexity of organisation which have resulted in the varied forms of all the higher animals. Whatever laws and conditions led to the production of the earliest organisms, they are hardly likely to have been of so exceptional a nature as never to have occurred since. It does not seem probable that the very existence of life upon the earth depended on so rare and improbable a set of conditions that, having once occurred, they should never occur again in the whole period between some remote pre-Laurentian epoch and the present day. If, therefore, there is good evidence of the continued *de novo* production of lower forms of life, and of the direct transformation of these into various higher and more complex organisms, such a view will have many *a priori* considerations in its favour, and will tend to bring the whole series of life-phenomena into greater harmony with those of inorganic nature, without in any way diminishing the mysterious grandeur that surrounds them.

But if these views should be established, we shall have to form an entirely new conception of the genealogical history of the various existing organisms. We shall no longer have one "tree of life," but a vast number of such trees, all having their roots in a similar substratum of the lowest organisms, evolved at various periods of the earth's history, but differing greatly in their subsequent development. It is probable that by far the greater number of these "trees of life" have become extinct at various periods of their growth, and that all existing living things belong to portions of but a few "trees," some of which may be comparatively recent, while others may have their roots far back in the past, anterior to the earliest epochs of which geology affords us a record. But notwithstanding this diversity and separateness of origin, through the whole life-history of our globe the progress of organisation seems to have been essentially similar; which is readily explicable on the ground that living things, both as regards their origin and subsequent differentiation or development, are the immediate products of natural laws or material properties, which are probably the same now as they have ever been. Similar types of form may, therefore, again and again have arisen; and Dr. Bastian remarks, that even "the vertebrate grade of organisation *may* have been attained by ultimate branches of different trees of life." It remains to be seen how far this conception will throw light on obscure and difficult questions of biological classification, and on those facts of geological succession which are most difficult to reconcile with the usual view of all organisms whatever having originated from a single almost infinitely remote source.

It will now be seen, even from the very imperfect sketch of its subject-matter, how many questions of the highest scientific importance rise out of the facts adduced in Dr. Bastian's work. It is not too much to say that, if its main conclusions are established, it will create a revolution in organic philosophy of equal importance with that which was effected by Mr. Darwin, whose observations and most important theories will, however, remain unaffected by it. That gentleman has himself remarked that "analogy is a deceitful guide," and it is only by analogy that he extends the laws he has established for the higher animals and plants to those lower forms with which Dr. Bastian deals; and the establishment of facts proving that they come under a different category will even relieve the theory of natural selection from some of its greatest difficulties, and neutralise some of the most serious objections that have been brought against it. The whole question, however, is primarily one of facts, and, however it may be ultimately decided, every lover of science must admire the courage and energy with which Dr. Bastian has taken up an unpopular subject, the skill and patience with which he has experimented, the labour which he has bestowed in collecting the records of widely scattered and almost forgotten observations, and the logical force as well as the philosophical spirit with which he has worked out his conclusions. It is a book that cannot be ignored, and must inevitably lead to renewed discussions and repeated observations, and through these to the establishment of truth.

ALFRED R. WALLACE

NOTES

THE Lords of the Committee of Council on Education having decided to transfer the instruction in Physics, Chemistry, and Natural History from the Royal School of Mines in Jermyn Street, and the College of Chemistry in Oxford Street, to the new buildings in Exhibition Road, South Kensington, notice has been given that in future the following courses of lectures and practical laboratory instruction will be given at South Kensington at the date specified:—Chemistry by Prof. Frankland, D.C.L., F.R.S. A course of forty lectures on Inorganic Chemistry commencing 21st of October, 1872. A course of thirty lectures on Organic Chemistry commencing 13th of January, 1873. Laboratory instruction consisting of an elementary and an advanced course commencing on 1st of October. Biology by Prof. Huxley, LL.D., F.R.S., a course of eighty lectures on Biology (or Natural History, including Palæontology) with laboratory instruction, commencing the 7th of October, 1872. Physics by Prof. Frederick Guthrie. The course will consist of lectures, with laboratory work on the subject of the lectures, divided as follows:—Twelve lectures on Molecular Physics, Sound, &c., commencing 24th of February, 1873; fifteen lectures on Heat, commencing on 24th of March; fifteen lectures on Light, commencing on 12th of April; twenty lectures on Electricity and Magnetism, commencing on 19th of May. Each course will be complete in itself, and may be taken separately.

THE Trustees of the British Museum have nominated Dr. Albert Günther, F.R.S., to the post of "Assistant Keeper" in the Zoological Department, vacant by the decease of the late Mr. G. R. Gray. It need hardly be said that no fitter appointment could have been made. The vacancy occasioned by Dr. Günther's promotion is, we understand, to be filled by Mr. R. B. Sharpe, F.Z.S., late Librarian to the Zoological Society, a young and rising Ornithologist, to whom the care of the National Collections of Birds will be entrusted.

IT is with great regret that we find there is too much truth in the report that the eminent astronomer and physicist M. Delaunay, Director of the Paris Observatory, has met his death by the upsetting of a boat while in an excursion on the Coast of Normandy. We hope in a future number to give a biography of this distinguished man. His loss is an irreparable one, not only to France, but to Science throughout the world.

THE meeting of the British Association for 1873 will be held at Bradford, under the presidency of Mr. J. P. Joule, D.C.L., F.R.S. At the present meeting the Association loses, with great regret, the services of one of its permanent officers, Dr. Thomas Thomson, one of the general secretaries, who will be succeeded by Dr. Michael Foster, F.R.S.

WE have to record the death of Sir Andrew Smith, K.C.B., Director-General of the Army Medical Department from 1851 to 1858, at his residence in Alexander Square, Brompton, at the at the age of 75. Sir Andrew Smith is well and favourably known to zoologists by his "Illustrations of the Zoology of South Africa." His complete and accurate knowledge of the various tribes of Southern Africa rendered his opinion of great value to successive Governments, and it was upon his representation and advice that the district of Natal was constituted a colony.

ALTHOUGH we can quite sympathise with those feelings which induced Mr. Fawcett to bring on the Ayrton-Hooker question in the House of Commons at all hazards, we consider that it is extremely unfortunate that Sir John Lubbock's determination to postpone it till next session—when the true opinion of the House, if necessary, would have been elicited—was not carried out. As it is, Mr. Ayrton has had an opportunity of exhibiting himself in his true character, which, however, was pretty well known before; and Mr. Gladstone has had an opportunity of again learning from the public press, in no hesitating tone, what is thought of his *protégé*; but the case itself has not progressed since the time we last referred to it.

IN his annual address as president of the Pharmaceutical Society, delivered at Brighton on Tuesday morning, Mr. H. B. Brady advocated the application of a portion of the surplus funds of the Society to the encouragement of scientific training. He enunciated the very sound proposition that beyond an investment sufficient to guarantee the means of carrying out the examining and governing functions entrusted to the Society by Government, there can be no excuse for the accumulation of wealth. Constantly recurring investments represent good left undone, opportunities unaccepted. Nor in this hoarding of money instead of science is the Pharmaceutical Society true to the spirit of its founders. The Society was formed to do in a collective capacity what could not be done by individuals. "It has seemed to me," he continued, "that the most substantial aid which could be rendered in the direction alluded to would be the setting apart of a number of free benches in the Society's laboratory for students who, having passed the Major examination with credit, might desire to continue their studies. These should even be endowed with a small annual income, under certain conditions, if found necessary. The only primary stipulation should be that, possessing the requisite preliminary knowledge, the recipient should be ready to work for the advancement of pharmacy under the direction of the professor. The effect of half-a-dozen or a dozen men so trained, sent out annually from Bloomsbury Square, would be to make a British school of pharmacy the like of which has never existed; and were this carried out, the most serious difficulties in the way of provincial education would resolve themselves in a few years." Should the Pharmaceutical Society follow this admirable advice of its president, it will place itself distinctly in the van of our learned societies, and will furnish an example which might be well followed by some of the others with their too abundant invested property.

A MONUMENT in honour of Jahn, the founder of the German Turnvereine, was unveiled on Saturday on the Haasenheide, near Berlin, amid enthusiastic acclamations. When shall we, as a nation, delight to honour in a similar manner the physical benefactors of mankind?

THE French Academy has elected M. Loewy, Titular Astronomer to the National Observatory, to a seat at the Bureau de Longitudes, vacant by the death of M. Laugier.

ONE of the biennial posts for practical work at the Laboratory of Cryptogamic Botany at Pavia is now open. There is attached to it a honorarium of 700 francs.

LORD NORTHBROOK has shown his appreciation of the value of scientific research by offering a gold medal for competition by the students of the Calcutta Medical College for the best essay on the exciting causes of fever, with special reference to the calamity which has for a long time devastated the Burdwan district in India, and the measures, sanitary or other, to be adopted for their remedy and prevention.

A METEOROLOGICAL Congress is being held at Leipzig from the 14th to the 16th inst. inclusive.

THE establishment of the College of Physical Science at Newcastle-on-Tyne has been followed by the formation of a similar scheme for another of our industrial centres, Birmingham, the necessary endowments being, on this occasion, given by the munificence of a single private individual, Mr. Josiah Mason, to whom Birmingham already owes so much in various ways. Being deeply convinced (Mr. Mason says, in his trust-deed) from long and varied experience in different branches of manufacture, of the necessity for and benefit of thorough systematic scientific instruction specially adapted to the practical, mechanical, and artistic requirements of the manufactures and industrial pursuits of the Midland district, and particularly of the boroughs of Birmingham and Kidderminster, he has determined to devote a portion of his remaining property to the foundation of an institution wherein such systematic scientific instruction may be given. With this object he assigns certain freehold and leasehold property situate in various parts of the town, which may be roughly estimated worth not less than 100,000*l.*, to a body of trustees in trust for the purposes of the college. Out of the net income a sum not exceeding one-tenth may be set apart annually for providing scholarships, exhibitions, and other prizes, premiums, or gratuities, for the pupils, the remainder going to the general support of the college, the payment of professors, &c. Instruction is to be provided by means of classes in mathematics, physics, chemistry, the natural sciences (especially geology and mineralogy, with their application to mines and metallurgy), botany, zoology, physiology, the English, French, and German languages, mechanical drawing, and architecture. In addition to these means of instruction, the trustees may arrange for popular or unsystematic teaching by means of additional lectures or classes upon any subjects comprised in the regular curriculum. While no person is to be admitted to the benefit of the institution who is not for the time being wholly or principally dependent for a livelihood upon his own skill or labour, or upon the support of his parents, or upon some other person or persons, the poorer classes of the community are not to be considered as having any exclusive right to the benefit of the institution. An excellent site

for the new college has already been secured in the immediate vicinity of the Birmingham Town-hall, and now that the list of trustees is completed, the college may be expected to assume form very shortly.

THE announcement, a year or two ago, of the purchase by an American of the celebrated Hay collection of Egyptian antiquities, at the time on exhibition at the Crystal Palace in London, created quite a sensation, in view of its intrinsic value and the desire which had been manifested to procure it for the British Museum. In the increasing rarity of objects of this kind, resulting from the great demand on the part of national museums throughout the world, it is believed quite unlikely that such a collection will again be brought together. Its richness in mummies, objects in bronze, marble, alabaster, &c., together with those of smaller size usually found in Egyptian tombs and elsewhere, is very great. While this collection does not embrace many statues or immense sarcophagi, it is believed to be equal to any in the completeness of its series of the smaller objects of religious and domestic Egyptian antiquity, and not inferior to the best collections of Paris, London, Berlin, or Leyden. It was purchased by Mr. Samuel A. Way, of Boston, and removed to that city, and offered to the Museum of Fine Arts, under certain conditions, which the directors did not think best to accept. At the death of Mr. Way, however, it passed into the possession of Mr. Charles Granville Way, himself an artist of merit, who has in turn offered it to the same establishment without condition other than it is to be kept in a room by itself, and to be called the Way Collection. This stipulation, we learn from *Harper's Weekly*, was gladly agreed to, and the collection accepted by the trustees, and its treasures will doubtless before long be opened to the public.

Harper's Weekly states that among some collections of specimens of natural history and ethnology lately presented by Governor W. M. F. Arny, of New Mexico, to the Smithsonian Institution, were some mastodon remains, which were submitted by Prof. Henry to Prof. Leidy for examination. These were found to indicate the existence of a very remarkable species of mastodon (*M. obscurus*), very different from the common *M. americanus*, and previously known only by a few fragments from California and a tooth found many years ago in the Miocene formation of Maryland. One peculiarity of this species consists in the existence of enamel on the tusks of the upper jaw, which does not occur in the more modern *M. americanus*. It also had tusks in the lower jaw, projecting from the prolongation of the jaw, as in the adult of the Miocene *Mastodon angustidens* of Europe, and known only in the young animal of *M. americanus*. The specimen referred to will be figured by Prof. Leidy in his forthcoming report to Dr. Hayden on the vertebrate fossils of the Western Territories.

THE second part of "Mycological Illustrations of New and Rare Fungi," edited by W. W. Saunders, F.R.S., with illustrations by Mr. Worthington Smith, will be ready in a few days. Although more than a twelvemonth has elapsed since the publication of the first part, it is hoped that in future the parts will be issued more regularly at about quarterly intervals.

WE have just received the "Monthly Record of Results of Observations in Meteorology, Terrestrial Magnetism, &c., taken at the Melbourne Observatory during March, 1872; together with Abstracts from Meteorological Observations obtained at various localities in Victoria, under the superintendence of Robert L. J. Ellery, Government Astronomer." Prefixed is a useful table of the averages and extremes of different meteorological elements at Melbourne and other localities for a number of years; and the tables which follow, showing the daily registrations for the month of March, seem sufficiently minute in detail and drawn up with great care.

THE BRITISH ASSOCIATION MEETING AT BRIGHTON

FROM Edinburgh to Brighton is a great leap, and the change is not merely one of clime and latitude. Two towns could hardly be found presenting a greater contrast. We exchange an ancient seat of learning for a modern watering place, the narrow streets and lofty houses of the Old Town for the palatial dwellings of the Steyne, Arthur's Seat for the New Chain Pier, the memory of Scott for that of the Prince Regent. So far the migration has little to recommend it; but then we have the set-off of being within easy reach of London; the British Association has, in fact, never before held its meetings so near the capital, and the present may be looked on as an experimental trial of a metropolitan meeting.

The list of officers of the meeting, and of the sections, has already been announced. The following is the diary of proceedings for each day:—

Wednesday, August 14—General Committee in the Town Hall, at 1 P.M.; Committees of Sections, at 2 P.M.; Inaugural Address by the President, in the Dome, at 8 P.M. Thursday, August 15—Committees of Sections, at 10 A.M.; Sections, at 11 A.M.; *soirée* in the Dome, Corn Exchange and Museum, at 8 P.M. Friday, August 16—Committees of Sections, at 10 A.M.; Sections, at 11 A.M.; discourse in the Dome by Prof. P. Martin Duncan, F.R.S., on the Metamorphoses of Insects, at half-past 8 P.M. Saturday, August 17—Committees of Sections, at 10 A.M.; Sections, at 11 A.M. Excursions: lecture to working men by Wm. Spottiswoode, LL.D., F.R.S., on Sunshine, Sea, and Sky, in the Dome, at 8 P.M. Monday, August 19—Committees of Sections, at 10 A.M.; Sections, at 11 A.M.; General Committee in the Town Hall, at 3 P.M.; discourse in the Dome by Prof. W. K. Clifford, on the Aims and Instruments of Scientific Thought, at half-past 8 P.M. Tuesday, August 20—Committees of Sections, at 10 A.M.; Sections, at 11 A.M.; *soirée* in the Dome, Corn Exchange and Museum, at 8 P.M. Wednesday, August 21—General Committee in the Town Hall, at 1 P.M.; concluding General Meeting in the Dome, at half-past 2 P.M. Thursday, August 22—Excursions.

The reception room will be in the New Museum and Library, Pavilion, and the following will be the rooms for meetings of Sections:—A, Mathematical and Physical Science, Albion Room; B, Chemical Science, Lecture Room, New Museum; C, Geology, Town Hall; D, Biology, Pavilion; E, Geography, Concert Hall, Middle Street; F, Economic Science and Statistics, Old Ship Assembly Rooms; G, Mechanical Science, Friends' Meeting House, Ship Street.

An Exhibition of objects of interest and works of art will be on view, during the meeting, in the Corn Exchange, New Museum and Library, and the following Excursions have been arranged:—Saturday afternoon, August 17—(1) To Glynde Station, for Glynde Place, the Chalk Pits, and Mount Caburn; to Glynde Station, for Firle Place and Beacon; (2) to Lewes, Southover, and Mount Harry, returning to Stanmer Park; (3) to Worthing, thence to Cissbury, for the excavations by Captain Oliver, and then to Findon; (4) to Bramber, then to Steyning and Wiston. Thursday, August 22—(1) To Pevensey, Hastings, and Battle Abbey, thence to the Sub-Wealden Boring, or to Norman Hurst (residence of Mr. Thomas Brassey, M.P.); (2) to Arundel, Amberley, and Parham; (3) to Chichester and Goodwood; (4) to Portsmouth, for steamer through the Solent for Alum Bay, the Needles and Freshwater Bay, Isle of Wight; to Portsmouth, for the Dockyard, Shipping, &c.; (5) to Hayward's Heath, for Paxhill, Wakehurst Place, West Hoathly Rocks, and Whiteman's Green Quarry, Cuckfield.

The Marine Aquarium, of which we shall take an opportunity of giving an account when it is in a more complete state, will of course be one of the chief objects of attrac-

tion to all the members of the Association, who will be admitted free, but "only a limited number daily." The great number of Lady Associates already announced is a prominent feature of the present meeting.

The following distinguished foreigners have already announced their intention of being present, viz. :—

Prof. Hébert, President of the Geological Society of France ; Prof. van Benéden, of Louvain, and his son, a naturalist of great ability ; Prof. Janssen, of Paris ; Prof. Panceri, of Naples ; Prof. H. A. Nicholson, of Toronto ; Prof. Zengler, of Prague ; Prof. Hale, of Albany, U.S. ; while invitations have been sent to the following, who have been compelled reluctantly to decline the invitation :—

Prof. Hofmeister, Prof. Sir W. G. Logan, of Montreal ; Prof. Clebsch, of Göttingen ; Prof. Daubrée, of Paris ; Prof. Young, of Dartmouth College, U.S. ; Prof. Asa Gray, of Cambridge, U.S. ; Prof. Gibbs, of Cambridge, U.S. ; Principal Dawson, of Montreal ; M. Quatrefages, of Paris ; Prof. Kirchhoff, of Heidelberg ; Prof. Helmholtz, of Berlin ; Prof. Shaler, of Harvard College, U.S.

The customary courtesy of the officers of the Association has enabled us to give our readers this week the President's Address, as well as the opening addresses in Sections A, B, C, and D.

Inaugural Address of Dr. William Carpenter, F.R.S., President

Thirty-six years have now elapsed since at the first and (I regret to say) the only meeting of this Association held in Bristol—which Ancient City followed immediately upon our National Universities in giving it a welcome—I enjoyed the privilege which I hold it one of the most valuable functions of these Annual assemblages to bestow ; that of coming into personal relation with those distinguished Men whose names are to every cultivator of Science as "household words," and the light of whose brilliant example, and the warmth of whose cordial encouragement are the most precious influences by which his own aspirations can be fostered and directed. Under the Presidency of the Marquis of Lansdowne, with Conybeare and Prichard as Vice-Presidents, with Vernon Harcourt as General Secretary, and John Phillips as Assistant Secretary, were gathered together Whewell and Peacock, James Forbes and Sir W. Rowan Hamilton, Murchison and Sedgwick, Buckland and De la Beche, Henslow and Daubeny, Roget, Richardson, and Edward Forbes, with many others, perhaps not less distinguished, of whom my own recollection is less vivid.

In his honoured old age, Sedgwick still retains, in the Academic home of his life, all his pristine interest in whatever bears on the advance of the Science he has adorned as well as enriched ; and Phillips still cultivates with all his old enthusiasm the congenial soil to which he has been transplanted. But the rest—our fathers and elder brother,—"Where are they?" It is for us of the present generation to show that they live in our lives ; to carry forward the work which they commenced ; and to transmit the influence of their own example to our own successors.

There is one of these great men, whose departure from among us since last we met claims a special notice, and whose life—full as it was of years and honours—we should have all desired to see prolonged for a few months, could its feebleness have been unattended with suffering. For we should all then have sympathised with Murchison, in the delight with which he would have received the intelligence of the safety of the friend in whose scientific labours and personal welfare he felt to the last the keenest interest. That this intelligence, which our own Expedition for the relief of Livingstone would have obtained (we will hope) a few months later, should have been brought to us through the generosity of one, and the enterprising ability—may I not use our peculiarly English word, the "pluck"—of another of our American brethren, cannot but be a matter of national regret to us. But let us bury that regret in the common joy which both Nations feel in the result ; and while we give a cordial welcome to Mr. Stanley, let us glory in the prospect now opening, that England and America will co-operate in that noble object which —far more than the discovery of the Sources of the Nile—our great Traveller has set before himself as his true mission, the Extinction of the Slave Trade.

At the last Meeting of this Association I had the pleasure of being able to announce that I had received from the First Lord of the Admiralty a favourable reply to a representation I had ventured to make to him, as to the importance of prosecuting on a more extended scale the course of inquiry into the Physical and Biological conditions of the Deep Sea, on which, with my colleagues Prof. Wyville Thomson and Mr. J. Gwyn Jeffreys, I had been engaged for the three preceding years. That for which I had asked was a Circumnavigating Expedition of at least three years' duration, provided with an adequate Scientific Staff, and with the most complete Equipment that our experience could devise. The Council of the Royal Society having been led by the encouraging tenor of the answer I had received, to make a formal application to this effect, the liberal arrangements of the Government have been carried out under the advice of a Scientific Committee which included Representatives of this Association. H.M. ship *Challenger*, a vessel in every way suitable for the purpose, is now being fitted out at Sheerness ; the command of the Expedition is intrusted to Captain Nares, an Officer of whose high qualifications I have myself the fullest assurance ; while the Scientific charge of it will be taken by my excellent friend Prof. Wyville Thomson, at whose suggestion it was that these investigations were originally commenced, and whose zeal for the efficient prosecution of them is shown by his relinquishment for a time of the important Academic position he at present fills. It is anticipated that the Expedition will sail in November next ; and I feel sure that the good wishes of all of you will go along with it.

The confident anticipation expressed by my predecessor, that for the utilisation of the total Eclipse of the Sun then impending, our Government would "exercise the same wise liberality as heretofore in the interests of Science," has been amply fulfilled. An Eclipse-Expedition to India was organised at the charge of the Home Government, and placed under the direction of Mr. Lockyer ; the Indian Government contributed its quota to the work ; and a most valuable body of results was obtained, of which, with those of the previous year, a Report is now being prepared under the direction of the Council of the Astronomical Society.

It has been customary with successive occupants of this Chair, distinguished as Leaders in their several divisions of the noble Army of Science, to open the proceedings of the Meetings over which they respectively presided, with a Discourse on some aspect of Nature in Relation to Man. But I am not aware that any one of them has taken up the other side of the inquiry—that which concerns Man as the "Interpreter of Nature ;" and I have therefore thought it not inappropriate to lead you to the consideration of the Mental processes, by which are formed those fundamental conceptions of Matter and Force, of Cause and Effect, of Law and Order, which furnish the basis of all scientific reasoning, and constitute the *Philosophia prima* of Bacon. There is a great deal of what I cannot but regard as fallacious and misleading Philosophy—"oppositions of Science falsely so called" —abroad in the world at the present time. And I hope to satisfy you, that those who set up *their own conceptions* of the Orderly Sequence which they discern in the Phenomena of Nature, as fixed and determinate *Laws*, by which those phenomena not only *are* within all Human experience, but always *have been*, and always *must be*, invariably governed, are really guilty of the Intellectual arrogance they condemn in the Systems of the Ancients, and place themselves in diametrical antagonism to those real Philosophers, by whose comprehensive grasp and penetrating insight that Order has been so far disclosed. For what love of the Truth, as it is in Nature, was ever more conspicuous than that which Kepler displayed in his abandonment of each of the ingenious conceptions of the Planetary System which his fertile Imagination had successively devised, so soon as it proved to be inconsistent with the facts disclosed by observation? In that almost admiring description of the way in which his enemy Mars, "whom he had left at home as a despised Captive," had "burst all the chains of the equations, and broke forth from the prisons of the tables," who does not recognise the justice of Schiller's definition of the real Philosopher, as one who always loves Truth better than his System? And when at last he had gained the full assurance of a success so complete that (as he says) he thought he must be dreaming, or that he had been reasoning in a circle, who does not feel the almost sublimity of the self-abnegation, with which, after attaining what was in his own estimation such a glorious reward of his life of toil, disappointment, and self-sacrifice he abstains from claiming the applause of his contemporaries, but leaves his fame to after ages in these noble words :—"The book is written ; to be read either now or by posterity, I care not which. It may well wait a

century for a reader, as God has waited six thousand years for an observer."

And when a yet greater than Kepler was bringing to its final issue that grandest of all Scientific Conceptions, long pondered over by his almost superhuman intellect—which linked together the Heavens and the Earth, the Planets and the Sun, the Primaries and their Satellites, and included even the vagrant Comets, in the *nexus* of a Universal Attraction—establishing for all time the truth for whose utterance Galileo had been condemned, and giving to Kepler's Laws a significance of which their author had never dreamed—what was the meaning of that agitation which prevented the Philosopher from completing his computation, and compelled him to hand it over to his friend? That it was not the thought of his own greatness, but the glimpse of the grand Universal Order thus revealed to his mental vision, which shook the serene and massive soul of Newton to its foundations, we have the proof in that beautiful comparison in which he likened himself to a Child picking up shells on the shore of the vast Ocean of Truth—a comparison which will be evidence to all time at once of his true Philosophy with his profound Humility.

Though it is with the Intellectual Representation of Nature which we call *Science*, that we are primarily concerned, it will not be without its use to cast a glance in the first instance at the other two principal characters under which Man acts as her Interpreter—those, namely, of the Artist and of the Poet.

The Artist serves as the Interpeter of Nature, not when he works as the mere copyist, delineating that which he sees with his bodily eyes, and which we could see as well as ourselves; but when he endeavours to awaken within us the perception of those beauties and harmonies which his own trained sense has recognised, and thus impart to us the pleasure he has himself derived from their contemplation. As no two Artists agree in the original constitutions and acquired habits of their Minds, all look at Nature with different (mental) eyes; so that to each, *Nature is what he individually sees in her.*

The Poet, again, serves as the Interpreter of Nature, not so much when by skilful word-painting (whether in prose or verse) he calls up before our mental vision the picture of some actual or ideal scene, however beautiful; as when, by rendering into appropriate forms those deeper impressions made by the Nature around him on the Moral and Emotional part of his own Nature, he transfers these impressions to the corresponding part of ours. For it is the attribute of the true Poet to penetrate the secret of those mysterious influences which we all unknowingly experience; and having discovered this to himself, to bring others, by the power he thus wields, into the like sympathetic relation with Nature—evoking with skilful touch the varied response of the Soul's finest chords, heightening its joys, assuaging its griefs, and elevating its aspirations. Whilst, then, the Artist aims to picture what he *sees* in Nature, it is the object of the Poet to represent what he *feels* in Nature; and to each true Poet, *Nature is what he individually finds in her.*

The Philosopher's interpretation of Nature *seems* less individual than that of the Artist or the Poet, because it is based on facts which any one may verify, and is elaborated by reasoning processes of which all admit the validity. He looks at the Universe as a vast Book lying open before him, of which he has in the first place to learn the characters, then to master the language, and finally to apprehend the ideas which that language conveys. In that Book there are many Chapters, treating of different subjects; and as Life is too short for any one man to grasp the whole, the Scientific interpretation of this Book comes to be the work of many Intellects, differing not merely in the range but also in the character of their powers. But whilst there are "diversities of gifts," there is "the same spirit." While each takes his special direction, the general Method of study is the same for all. And it is a testimony alike to the truth of that Method and to the Unity of Nature, that there is an ever-increasing tendency towards agreement among those who use it aright—temporary differences of interpretation being removed, sometimes by a more complete mastery of her language, sometimes by a better apprehension of her ideas—and lines of pursuit which had seemed entirely distinct or even widely divergent, being found to lead at last to one common goal. And it is this agreement which gives rise to the general belief—in many, to the confident assurance—that the Scientific interpretation of Nature represents her not merely as she *seems*, but as she *really is.*

When, however, we carefully examine the foundation of that assurance, we find reason to distrust its security; for it can be shown to be no less true of the Scientific conception of Nature, than it is of the Artistic or the Poetic, that it is *a representation framed by the Mind itself* out of the materials supplied by the impressions which external objects make upon the Senses; so that to each Man of Science, *Nature is what he individually believes her to be.* And that belief will rest on very different bases, and will have very unequal values, in different departments of Science. Thus, in what are commonly known as the "exact" Sciences, of which Astronomy may be taken as the type, the data afforded by precise methods of observation can be made the basis of reasoning, in every step of which the Mathematician feels the fullest assurance of certainty; and the final deduction is justified either by its conformity to known or ascertainable facts—as when Kepler determined the elliptic orbit of Mars; or by the fulfilment of the predictions it has sanctioned—as in the occurrence of an Eclipse or an Occultation at the precise moment specified many years previously; or, still more emphatically, by the actual discovery of phenomena till then unrecognised—as when the Perturbations of the planets, shown by Newton to be the necessary results of their mutual attraction, were proved by observation to have a real existence; or as when the unknown disturber of Uranus was found in the place assigned to him by the computations of Adams and Le Verrier.

We are accustomed, and I think most rightly, to speak of these achievements as triumphs of the Human Intellect. But the very phase implies that the work is done by Mental Agency; and the coincidence of its results with the facts of observation is far from proving the Intellectual process to have been correct. For we learn from the honest confession of Kepler, that he was led to the discovery of the Elliptic orbit of Mars by a series of happy accidents, which turned his erroneous guesses into the right direction; and to that of the passage of the Radius Vector over *equal areas in equal times*, by the notion of a whirling force emanating from the Sun, which we now regard as an entirely wrong conception of the cause of orbital revolution.* It should always be remembered, moreover, that the Ptolemaic system of Astronomy, with all its cumbrous ideal mechanism of "Centric and Excentric, Cycle and Epicycle, Orb in Orb," did intellectually represent all that the Astronomer, prior to the invention of the Telescope, could see from his actual standpoint, the Earth, with an accuracy which was proved by the fulfilment of his anticipations. And in that last and most memorable prediction which has given an imperishable fame to our two illustrious contemporaries, the inadequacy of the basis afforded by actual observation of the perturbations of Uranus required that it should be supplemented by an assumption of the probable distance of the disturbing Planet beyond, which has been shown by subsequent observation to have been only an approximation to the truth.

Even in this most exact of Sciences, therefore, we cannot proceed a step without translating the actual Phenomena of Nature into Intellectual Representations of those phenomena; and it is because the Newtonian conception is not only the most simple, but is also, up to the extent of our present knowledge, *universal* in its conformity to the facts of observation, that we accept it as the only Scheme of the Universe yet promulgated, which satisfies our Intellectual requirements.

When, under the reign of the Ptolemaic System, any new inequality was discovered in the motion of a Planet, a new wheel had to be added to the ideal Mechanism—as Ptolemy said, "to save appearances." If it should prove, a century hence, that the motion of Neptune himself is disturbed by some other attraction than that exerted by the interior Planets, we should confidently expect that not an *ideal* but a *real* cause for that disturbance will be found in the existence of another Planet beyond. But I trust that I have now made it evident to you, that this confident expectation is not justified by any absolute necessity of Nature, but arises entirely out of *our belief* in her Uniformity; and into the grounds of this and other Primary Beliefs, which serve as the foundation of all Scientific reasoning, we shall presently inquire.

There is another class of cases, in which an equal certainty is generally claimed for conclusions that seem to flow immediately from observed facts, though really evolved by Intellectual processes; the apparent simplicity and directness of those processes either causing them to be entirely overlooked, or veiling the assumptions on which they are based. Thus Mr. Lockyer

* See Drinkwater's "Life of Kepler," in the Library of Useful Knowledge, pp. 26 35.

speaks as confidently of the Sun's Chromosphere of incandescent Hydrogen, and of the local outbursts which cause it to send forth projections tens of thousands of miles high, as if he had been able to capture a flask of this gas, and had generated water by causing it to unite with oxygen. Yet this confidence is entirely based on the assumption that a certain line which is seen in the Spectrum of a hydrogen flame *means* hydrogen also when seen in the spectrum of the Sun's chromosphere; and high as is the probability of that assumption, it cannot be regarded as a demonstrative certainty, since it is by no means inconceivable that the same line *might* be produced by *some other* substance at present unknown And so when Dr. Huggins deduces from the different relative positions of certain lines in the spectra of different Stars, that these Stars are moving from or towards us in space, his admirable train of reasoning is based on the assumption that these lines have *the same meaning*—that is, that they *represent the same elements*—in every luminary. That assumption, like the preceding, may be regarded as possessing a sufficiently high probability to justify the reasoning based upon it; more especially since, by the other researches of that excellent observer, the same Chemical elements have been detected as vapours in those filmy cloudlets which seem to be stars in an early stage of consolidation. But when Frankland and Lockyer, seeing in the spectrum of the yellow Solar prominences a certain bright line not identifiable with that of any known Terrestrial flame, attribute this to a hypothetical new substance which they propose to call Helium, it is obvious that their assumption rests on a far less secure foundation; until it shall have received that verification, which, in the case of Mr. Crookes's researches on Thallium, was afforded by the actual discovery of the new metal, whose presence had been indicated by him by a line in the Spectrum not attributable to any substance then known.

In a large number of other cases, moreover, our Scientific interpretations are clearly matters of *judgment;* and this is eminently a *personal act*, the value of its results depending in each case upon the qualifications of the *individual* for arriving at a correct decision. The surest of such judgments are those dictated by what we term "Common Sense," as to matters on which there seems no room for difference of opinion, because every sane person comes to the same conclusion, although he may be able to give no other reason for it than that it appears to him "self-evident." Thus while Philosophers have raised a thick cloud of dust in the discussion of the basis of our belief in the existence of the world external to ourselves—of the Non Ego, as distinct from the Ego—and while every Logician claims to have found some flaw in the proof advanced by every other—the Common Sense of Mankind has arrived at a decision that is practically worth all the arguments of all the Philosophers who have fought again and again over this battle-ground. And I think it can be shown that the trustworthiness of this Common Sense decision arises from its dependence, not on any one set of Experiments, but upon *our unconscious co-ordination of the whole aggregate of our Experiences*—not on the conclusiveness of any one train of Reasoning, but on *the convergence of all our lines of thought towards this one centre.*

Now this "Common Sense," disciplined and enlarged by appropriate culture, becomes one of our most valuable instruments of Scientific inquiry; affording in many instances the best, and sometimes the only, basis for a rational conclusion. Let us take as a typical case, in which no special knowledge is required, what we are accustomed to call the "flint implements" of the Abbeville and Amiens gravel-beds. No logical proof can be adduced that the peculiar shapes of these flints were given to them by Human hands; but does any unprejudiced person now doubt it? The evidence of *design*, to which, after an examination of one or two such specimens, we should only be justified in attaching a probable value, derives an irresistible cogency from accumulation. On the other hand, the *im*probability that these flints acquired their peculiar shape by *accident*, becomes to our minds greater and greater as more and more such specimens are found; until at last this hypothesis, although it cannot be directly disproved, is felt to be almost inconceivable, except by minds previously "possessed" by the "dominant idea" of the modern origin of Man. And thus what was in the first instance a matter of discussion, has now become one of those "self-evident" propositions, which claim the unhesitating assent of all whose opinion on the subject is entitled to the least weight.

We proceed upwards, however, from such questions as the Common Sense of Mankind generally is competent to decide, to those in which special knowledge is required to give value to the judgment; and thus the interpretation of Nature by the use of that faculty comes to be more and more *individual;* things being perfectly "self-evident" to men of special culture, which ordinary men, or men whose training has lain in a different direction, do not apprehend as such. Of all departments of Science, Geology seems to me to be the one that most depends on this specially-trained "Common Sense;" which brings as it were into one focus the light afforded by a great variety of studies—Physical and Chemical, Geographical and Biological; and throws it on the pages of that Great Stone Book, on which the past history of our Globe is recorded. And whilst Astronomy is of all Sciences that which may be considered as most nearly representing Nature as she really is, Geology is that which most completely represents her as seen through the medium of the interpreting mind; the meaning of the phenomena that constitute its data being in almost every instance open to question, and the judgments passed upon the same facts being often different according to the qualifications of the several judges. No one who has even a general acquaintance with the history of this department of Science, can fail to see that the Geology of each epoch has been the reflection of the Minds by which its study was then directed; and that its true progress dates from the time when that "Common Sense" method of interpretation came to be *generally* adopted, which consists in seeking the explanation of past changes in the Forces at present in operation, instead of invoking the aid of extraordinary and mysterious agencies, as the older Geologists were wont to do, whenever they wanted—like the Ptolemaic Astronomers—"to save appearances." The whole tendency of the ever-widening range of modern Geological inquiry has been to show how little reliance can be placed upon the so-called "Laws" of Stratigraphical and Palæontological Succession, and how much allowance has to be made for local conditions. So that while the Astronomer is constantly enabled to point to the fulfilment of his predictions as an evidence of the correctness of his method, the Geologist is almost entirely destitute of any such means of verification. For the value of any prediction that he may hazard—as in regard to the existence or non-existence of Coal in any given area—depends not only upon the truth of the general doctrines of Geology in regard to the succession of Stratified Deposits, but still more upon the detailed knowledge which he may have acquired of the distribution of those Deposits in the particular locality. Hence no reasonably-judging man would discredit either the general doctrines or the methods of Geology, because the prediction proves untrue in such a case as that now about to be brought in this neighbourhood to the trial of experience.

We have thus considered Man's function as the Scientific Interpreter of Nature in two departments of Natural Knowledge; one of which affords an example of the strictest, and the other of the freest method, which Man can employ in constructing his Intellectual representation of the Universe. And as it would be found that in the study of all other departments the same methods are used, either separately or in combination, we may pass at once to the other side of our inquiry, namely, the origin of those Primary Beliefs which constitute the groundwork of all Scientific reasoning.

The whole fabric of Geometry rests upon certain Axioms which every one accepts as true, but of which it is necessary that the truth should be *assumed*, because they are incapable of demonstration. So, too, the deliverances of our "Common Sense" derive their trustworthiness from what we consider the "self-evidence" of the propositions affirmed.

This inquiry brings us face to face with one of the great Philosophical problems of our day, which has been discussed by Logicians and Metaphysicians of the very highest ability as Leaders of opposing Schools, with the one result of showing how much can be said on each side. By the *Intuitionalists* it is asserted that the tendency to form these Primary Beliefs is inborn in Man, an original part of his mental organisation; so that they grow up spontaneously in his Mind as its faculties are gradually unfolded and developed, requiring no other Experience for their genesis, than that which suffices to call these faculties into exercise. But by the advocates of the doctrine which regards *Experience* as the basis of all our knowledge, it is maintained that the Primary Beliefs of each individual are nothing else than generalisations which he formed of such experiences as he has either himself acquired or has consciously learned from others; and they deny that there is any original or intuitive tendency to the formation of such beliefs, beyond

that which consists in the power of retaining and generalising experiences.

I have not introduced this subject with any idea of placing before you even a summary of the ingenious arguments by which these opposing doctrines have been respectively supported; nor should I have touched on the question at all, if I did not believe that a means of reconcilement between them can be found in the idea that the *Intellectual Intuitions of any one Generation are the embodied Experiences of the previous Race.* For, as it appears to me there has been a progressive improvement in the *Thinking Power* of Man; every product of the culture which has preceded serving to prepare the soil for yet more abundant harvests in the future.

Now as there can be no doubt of the Hereditary transmission in Man of acquired constitutional peculiarities, which manifest themselves alike in tendencies to Bodily and Mental disease, so it seems equally certain that *acquired mental habitudes* often impress themselves on his organisation, with sufficient force and permanence to occasion their transmission to the offspring as *tendencies to similar modes of thought.* And thus, while all admit that *Knowledge* cannot thus descend from one generation to another, an increased *aptitude* for the acquirement, either of knowledge generally, or of some particular kind of it, may be thus inherited. These tendencies and aptitudes will acquire additional strength, expansion, and permanance, in each new generation, from their habitual exercise upon the materials supplied by a continually enlarged experience; and thus the *acquired* habitudes produced by the Intellectual culture of ages, will become "a second nature" to every one who inherits them.*

We have an illustration of this progress in the fact of continual occurrence, that conceptions which prove inadmissable to the minds of one generation, in consequence either of their want of intellectual power to apprehend them, or of their preoccupation by older habits of thought, subsequently find a universal acceptance, and even come to be approved as "self-evident." Thus the First Law of Motion, divined by the genius of Newton, though opposed by many Philosophers of his time as contrary to all experience, is now accepted by common consent, not merely as a legitimate inference from Experiment, but as the expression of a necessary and universal truth; and the same Axiomatic value is extended to the still more general doctrine, that Energy of *any* kind, whether manifested in the "molar" motion of masses, or consisting in the "molecular" motion of atoms, *must* continue under some form or other without abatement or decay; what all admit in regard to the indestructibility of Matter, being accepted as no less true of Force, namely, that as *ex nihilo nil fit*, so *nil fit ad nihilum* †

But, it may be urged, the very conception of these and similar great truths is in itself a typical example of Intuition. The men who divined and enunciated them stand out above their fellows, as possessed of a Genius which could not only combine but create, of an Insight which could clearly discern what Reason could but dimly shadow forth. Granting this freely, I think it may be shown that the Intuitions of individual Genius are but specially exalted forms of endowments which are the general property of the Race at the time, and which have come to be so in virtue of its whole previous culture. Who, for example, could refuse to the marvellous aptitude for perceiving the relations of Numbers, which displayed itself in the untutored boyhood of George Bidder and Zerah Colburn, the title of an Intuitive gift? But who, on the other hand, can believe that a Bidder or a Colburn could suddenly arise in a race of Savages who cannot count five? Or, again, in the history of the very earliest days of Mozart, who cannot fail to recognise the dawn of that glorious Genius, whose brilliant but brief career left its imperishable impress on the Art it enriched? But who would be bold enough to affirm that an infant Mozart could be born amongst a tribe whose only musical instrument is a tom-tom whose only song is a monotonous chant?

Again, by tracing the gradual *genesis* of some of those Ideas which we now accept as "self-evident"—such, for example, as that of the "Uniformity of Nature"—we are able to recognise them as the expressions of certain Intellectual tendencies, which have progressively augmented in force in successive generations, and now manifest themselves as Mental Instincts that penetrate and direct our ordinary course of Thought. Such Instincts constitute a precious heritage, which has been transmitted to us with ever-increasing value through the long succession of preceding generations; and which it is for us to transmit to those who shall come after us, with all that further increase which our higher Culture and wider range of Knowledge can impart.

And now, having studied the working action of the Human Intellect in the Scientific Interpretation of Nature, we shall examine the general character of its products; and the first of these with which we shall deal is our conception of *Matter* and of its relation to *Force.*

The Psychologist of the present day views Matter entirely through the light of his own Consciousness: his idea of Matter in the abstract being that it is a "something" which has a permanent power of exciting Sensations; his idea of any "property" of Matter being the mental representation of some kind of sensory impression he has received from it; and his idea of any particular kind of Matter being the representation of the whole aggregate of the Sense-perceptions which its presence has called up in his Mind. Thus, when I press my hand against this table, I recognise its unyieldingness through the conjoint medium of my sense of Touch, my Muscular sense, and my Mental sense of Effort, to which it will be convenient to give the general designation of the Tactile Sense; and I attribute to that table a *hardness* which resists the effort I make to press my hand into its substance, whilst I also recognise the fact that the force I have employed is not sufficient to move its mass. But I press my hand against a lump of dough; and finding that its substance yields under my pressure I call it *soft.* Or, again, I press my hand against this desk; and I find that although I do not thereby change its *form*, I change its *place*; and so I get the Tactile idea of *Motion.* Again, by the impression received through the same Sensorial apparatus, when I lift this book in my hand, I am led to attach to it the motion of *weight* or ponderosity; and by lifting different solids of about the same size, I am enabled, by the different degrees of exertion I find myself obliged to make in order to sustain them, to distinguish some of them as *light*, and others as *heavy.* Through the medium of another set of Sense-perceptions which some regard as belonging to a different category, we distinguish between bodies that *feel* "hot" and those that *feel* "cold;" and in this manner we arrive at the notion of differences of Temperature. And it is through the medium of our Tactile Sense, without any aid from Vision, that we first gain the idea of *solid form*, or the Three Dimensions of Space.

Again, by the extension of our Tactile experiences, we acquire the notion of *liquids*, as forms of matter yielding readily to pressure, but possessing a sensible weight which may equal that of solids: and of *air*, whose resisting power is much slighter, and whose weight is so small that it can only be made sensible by artificial means. Thus, then, we arrive at the notions of *resistance* and weight as properties common to all forms of Matter; and now that we have got rid of that idea of Light and Heat, Electricity and Magnetism, as "imponderable fluids," which used to vex our souls in our Scientific Childhood, and of which the popular term "Electric Fluid is a "survival," we accept these properties as affording the practical distinction between the "material" and the "immaterial."

Turning, now, to that other great portal of Sensation, the Sight, through which we receive most of the messages sent to us from the Universe around, we recognise the same truth. Thus it is agreed alike by Physicists and Physiologists, that *Colour* does not exist *as such* in the object itself; which has merely the power of reflecting or transmitting a certain number of millions of undulations in a second; and these only produce that affection of our consciousness which we call Colour, when they fall upon the retina of the living Percipient. And if there

* I am glad to be able to append the following extract from a letter which Mr. John Mill, the great Master of the Experimental School, was good enough to write to me a few months since, with reference to the attempt I had made to place "Common Sense" upon this basis (*Contemporary Review*, Feb. 1872):—"When states of mind in no respect inate or instinctive have been frequently repeated, the mind acquires, as is proved by the power of Habit, a greatly increased facility of passing into those states; and this increased facility must be owing to some change of a physical character in the organic action of the Brain. There is also considerable evidence that such acquired facilities of passing into certain modes of cerebral action can in many cases be transmitted, more or less completely, by inheritance. The limits of this power of transmission, and the conditions on which it depends, are a subject now fairly before the scientific world; and we shall doubtless in time know much more about them than we do now. But so far as my imperfect knowledge of the subject qualifies me to have an opinion, I take much the same view of it that you do, at least in principle."

† This is the form in which the doctrine now known as that of the "Conservation of Energy" was enunciated by Dr. Mayer, in the very remarkable Essay published by him in 1845, entitled "Die organische Bewegung in ihrem Zusammenhange mit dem Stoffwechsel."

be that defect either in the retina or in the apparatus behind it, which we call "colour-blindness" or Daltonism, some particular hues cannot be distinguished, or there may even be no power of distinguishing any colour whatever. If we were all like Dalton, we should see no difference, except in form, between ripe cherries hanging on a tree, and the green leaves around them; if we were all affected with the severest form of colour-blindness, the fair face of Nature would be seen by us as in the chiaroscuro of an Engraving of one of Turner's Landscapes, not as in the glowing hues of the wondrous Picture itself. And in regard to our Visual conceptions it may be stated with perfect certainty, as the result of very numerous observations made upon persons who have acquired sight for the first time, that these do *not* serve for the recognition even of those objects with which the individual had become most familiar through the Touch, until the two sets of sense-perceptions have been co-ordinated by experience.*

When once this co-ordination has been effected, however, the composite perception of Form which we derive from the Visual sense alone is so complete, that we seldom require to fall back upon the Touch for any further information respecting the quality of the object. So again, while it is from the co-ordination of the two dissimilar pictures formed by any solid or projecting object upon our two retinæ, that (as Sir Charles Wheatstone's admirable investigations have shown) we ordinarily derive through the Sight alone a correct notion of its *solid* form, there is adequate evidence that this notion, also, is a mental *judgment* based on the experience we have acquired in early infancy by the consentaneous exercise of the Visual and Tactile senses.

Take, again, the case of those wonderful instruments by which our Visual range is extended almost into the infinity of Space, or into the infinity of Minuteness. It is the mental not the bodily eye, that takes cognizance of what the Telescope and Microscope reveal to us. For we should have no well-grounded confidence in their revelations as to the *unknown*, if we had not first acquired experience in distinguishing the true from the false by applying them to *known* objects; and every interpretation of what we see through their instrumentality is a *mental judgment* as to the probable form, size, and movement of bodies removed by either their distance or their minuteness from being cognosced by our sense of Touch.

The case is still stronger in regard to that last addition to our Scientific *armamentum*, which promises to be not inferior in value either to the Telescope or the Microscope; for it may be truly said of the Spectroscope, that it has not merely extended the range of our Vision, but has almost given us a new sense, by enabling us to recognise distinctive properties in the Chemical Elements which were previously quite unknown. And who shall now say that we know all that is to be known as to any form of Matter; or that the science of the *fourth* quarter of this century may not furnish us with as great an enlargement of our knowledge of its Properties, and of our power of recognising them, as that of its *third* has done?

But, it may be said, is not this view of the Material Universe open to the imputation that it is "evolved out of the depths of our own consciousness"—a projection of our own Intellect into what surrounds us—an *ideal* rather than a *real* World? If all we know of Matter be an "Intellectual Conception," how are we to distinguish this from such as we form in our Dreams?—for these, as our Laureate no less happily than philosophically expresses it, are "true while they last." Here our "Common Sense" comes to the rescue. We "awake, and behold it was a dream." Every healthy mind is conscious of the difference between his waking and his dreaming experiences; or, if he is now and then puzzled to answer the question, "Did this really happen, or did I dream it?" the perplexity arises from the consciousness that it *might* have happened. And every healthy mind, finding its own experiences of its waking state not only self-consistent, but consistent with the experiences of others, accepts them as the basis of his beliefs, in preference to even the most vivid recollections of his dreams.

The Lunatic Pauper who regards himself as a King, the Asylum in which he is confined as a Palace of regal splendour, and his Keepers as obsequious attendants, is so "possessed" by the conception framed by his disordered intellect, that he *does* project it out of himself into his surroundings; his refusal to admit the corrective teaching of Common Sense being the very essence of his malady. And there are not a few persons abroad in the world, who equally resist the teachings of Educated Common Sense, whenever they run counter to their own preconceptions; and who may be regarded as—in so far—affected with what I once heard Mr. Carlyle pithily characterise as a "diluted Insanity."

It has been asserted over and over again, of late years, by a class of men who claim to be the only true Interpreters of Nature, that we know nothing but Matter and the Laws of Matter, and that Force is a mere fiction of the Imagination. May it not be affirmed, on the other hand, that while our notion of *Matter* is a Conception of the Intellect, *Force* is that of which we have the *most* direct—perhaps even the *only* direct—cognizance? As I have already shown you, the knowledge of Resistance and of Weight which we gain through our Tactile Sense is derived from our own perception of *exertion*; and in Vision, as in Hearing, it is the Force with which the undulations strike the sensitive surface, that affects our consciousness with Sights or Sounds. True it is that in our Visual and Auditory Sensations, we do not, as in our Tactile, *directly* cognosce the Force which produces them; but the Physicist has no difficulty in making sensible to us indirectly the undulations by which Sound is propagated, and in proving to our Intellect that the Force concerned in the transmission of Light is really enormous.*

It seems strange that those who make the loudest appeal to Experience as the basis of all knowledge, should thus disregard the most constant, the most fundamental, the most direct of all experiences; as to which the Common Sense of Mankind affords a guiding light much clearer than any that can be seen through the dust of Philosophical discussion. For, as Sir John Herschel most truly remarked, the universal Consciousness of mankind is as much in accord in regard to the existence of a real and intimate connection between Cause and Effect, as it is in regard to the existence of an Eternal World; and that consciousness arises to every one out of his own sense of *personal* exertion in the origination of changes by his individual agency.

Now while fully accepting the Logical definition of Cause as the "antecedent or concurrence of antecedents on which the Effect is invariably and unconditionally consequent," we can always single out one *dynamical* antecedent—the Power which does the work—from the aggregate of *material conditions* under which that Power may be distributed and applied. No doubt the term Cause is very loosely employed in popular phraseology; often (as Mr. Mill has shown) to designate the occurrence that immediately preceded the effect — as when it is said that the spark which falls into a barrel of gunpowder is the cause of its explosion, or that the slipping of a man's foot off the rung of a ladder is the cause of his fall. But even a very slightly trained Intelligence can distinguish the Power which acts in each case, from the Conditions under which it acts. The Force which produces the explosion is locked up (as it were) in the powder; and ignition merely liberates it, by bringing about new Chemical combinations. The fall of the man from the ladder is due to the Gravity which was equally pulling him down while he rested on it; and the loss of support, either by the slipping of his foot, or by the breaking of the rung, is merely that change in the material conditions which gives the Power a new action.

Many of you have doubtless viewed with admiring interest that truly wonderful work of Human Design, the Walter Printing Machine. You first examine it at rest; presently comes a man who simply pulls a handle towards him; and the whole inert mechanism becomes instinct with life—the blank paper continuously rolling off the cylinder at one end, being delivered at the other, without any intermediate human agency, as large sheets of print, at the rate of 15,000 in an hour. Now what is the *Cause* of this most marvellous effect? Surely it lies essentially in the Power of Force which the pulling of the handle brought to bear on the machine from some extraneous source of Power, which we in this instance know to be a Steam-engine on the other side of the wall. This Force it is, which, distributed through the various parts of the Mechanism, really performs the action of which each is the instrument; *they* only supply the vehicle for its transmission and application. The man comes again, pushes the handle in the opposite direction, detaches the Machine from the Steam-engine, and the whole

* Thus, in a recently recorded case in which sight was imparted by operation to a young woman who had been blind from birth, but who had nevertheless learned to work well with her needle, when the pair of scissors she had been accustomed to use was placed before her, though she described their shape, colour, and glistening metallic character, she was utterly unable to recognise them *as scissors* until she put her finger on them, when she at once named them, laughing at her own stupidity (as she called it) in not having made them out before.

* See Sir John Herschel's "Familiar Lectures on Scientific Subjects."

comes to a stand; and so it remains, like an inanimate corpse, until recalled to activity by the renewal of its Moving Power.

But, say the Reasoners who deny that Force is anything else than a fiction of the imagination, the revolving shaft of the Steam-engine is "Matter in Motion," and when the connection is established between that shaft and the one that drives the Machine, the *Motion* is communicated from the former to the latter, and thence distributed to the several parts of the Mechanism. This account of the operation is just what an observer might give, who had looked on with entire ignorance of every thing but what his *eyes* could *see;* the moment he puts his *hand* upon any part of the machinery, and tries to stop its motion, he takes as direct cognizance, through his sense of the Effort required to resist it, of the *force* which produces that motion, as he does through his *eye* of the motion itself.

Now since it is universally admitted that our notion of the External World would be not only incomplete, but erroneous, if our Visual perceptions were not supplemented by our Tactile, so, as it seems so me, our interpretation of the Phenomena of the Universe must be very inadequate, if we do not mentally coordinate the idea of Force with that of Motion, and recognise it as the "efficient cause" of those phenomena—the "material conditions" constituting (to use the old Scholastic term) only "their formal cause." And I lay the greater stress on this point, because the Mechanical Philosophy of the present day tends more and more to express itself in terms of *Motion* rather than in terms of *Force*—to become *Kinetics* instead of *Dynamics*.

Thus from whatever side we look at this question—whether the Common Sense of Mankind, the Logical Analysis of the relation between Cause and Effect, or the Study of the working of our own Intellects in the interpretation of Nature—we seem led to the same conclusion; that the notion of Force is one of those elementary Forms of Thought with which we can no more dispense, than we can with the notion of Space or of Succession. And I shall now, in the last place, endeavour to show you that it is the substitution of the Dynamical for the mere Phenomenal idea, which gives their highest value to our conceptions of that Order of Nature, which is worshipped as itself a God by the class of Interpreters whose doctrine I call in question.

The most illustrative as well as the most illustrious example of the difference between the mere Generalisation of Phenomena and the Dynamical conception that applies to them, is furnished by the contrast between the so-called Laws of Planetary Motion discovered by the persevering ingenuity of Kepler, and the interpretation of that Motion given us by the profound insight of Newton. Kepler's three Laws were nothing more than comprehensive statements of certain groups of Phenomena determined by observation. The *first*, that of the revolution of the Planets in Elliptical orbits, was based on the study of the observed places of Mars alone; it might or might not be true of the other Planets; for so far as Kepler knew, there was no reason why the orbits of some of them might not be the excentric circles which he had first supposed that of Mars to be. So Kepler's *second* law of the passage of the Radius Vector over equal areas in equal times, so long as it was simply a generalisation of facts in the case of that one Planet, carried with it no *reason* for its applicability to other cases, except that which it might derive from his erroneous conception of a whirling force. And his *third* law was in a like manner simply an expression of certain Harmonic relation which he had discovered between the times and the distances of the Planets, having no more *rational* value than any other of his numerous hypotheses.

Now the Newtonian "Laws" are often spoken of as if they were merely *higher generalisations* in which Kepler's are included; to me they seem to possess an altogether different character. For starting with the conception of two *Forces*, one of them tending to produce continuous uniform motion in a straight line, the other tending to produce a uniformly accelerated motion towards a fixed point, Newton's wonderful mastery of Geometrical reasoning enabled him to show that, if these *Dynamical* assumptions be granted, Kepler's *phenomenal* "Laws," being necessary consequences of them, must be *universally* true. And while that demonstration would have been alone sufficient to give him an imperishable renown, it was his still greater glory to divine that the fall of the Moon towards the Earth—that is, the deflection of her path from a tangential line to an ellipse—*is a phenomenon of the same order* as the fall of a stone to the ground; and thus to show the applicability to the entire Universe, of those simple Dynamical conceptions which constitute the basis of the Geometry of the Principia.

Thus, then, whilst no "Law" which is simply *a generalisation of Phenomena* can be considered as having any *coercive* action, we may assign that value to Laws which express *the universal conditions of the action of a Force*, the existence of which we learn from the testimony of our own consciousness. The assurance we feel that the Attraction of Gravitation *must* act under all circumstances according to its one simple Law, is of a very different order from that which we have in regard (for example) to the Laws of Chemical Attraction, which are as yet only generalisations of pheuomena. And yet even in that strong assurance, we are required by our examination of the basis on which it rests, to admit a *reserve* of the *possibility* of something different; a reserve which we may well believe that Newton himself must have entertained.

A most valuable lesson as to the allowance we ought always to make for the unknown "possibilities of Nature," is taught us by an exceptional phenomenon so familiar that it does not attract the notice it has a right to claim. Next to the Law of the Universal Attraction of Masses of Matter, there is none that has a wider range than that of the *Expansion of Bodies by Heat.* Excluding Water and one or two other substances, the fact of such expansion might be said to be *invariable*; and, as regards bodies whose Gaseous condition is known, the Law of Expansion can be stated in a form no less simple and definite than the Law of Gravitation. Supposing those exceptions, then, to be unknown, the Law would be *universal* in its range But it comes to be discovered that Water, whilst conforming to it in its expansion from $39\frac{1}{2}°$ *upwards* to its boiling-point, as also, when it passes into Steam, to the special law of Expansion of Vapours, is exceptional in its *expansion* also from $39\frac{1}{2}°$ *downwards* to its Freezing-point; and of this failure in the Universality of the Law, no rationale can be given. Still more strange is it, that by dissolving a little *salt* in water, we should remove this exceptional peculiarity; for *sea*-water continues to contract from $39\frac{1}{2}°$ downwards to its Freezing-point 12° or 14° lower, just as it does with reduction of temperature at higher ranges.

Thus from our study of the mode in which we arrive at those conceptions of the Orderly Sequence observable in the Phenomena of Nature which we call "Laws," we are led to the conclusion that they are Human conceptions, subject to Human fallibility; and that they *may* or *may not* express the Ideas of the Great Author of Nature. To set up these Laws as self-acting, and as either excluding or rendering unnecessary the Power which alone can give them effect, appears to me as arrogant as it is unphilosophical. To speak of *any* Law as "regulating" or "governing" phenomena, is only permissible on the assumption that the Law is the expression of the *modus operandi* of a Governing Power. I was once in a great City which for two days was in the hands of a lawless mob. Magisterial authority was suspended by timidity and doubt; the force at its command was paralysed by want of resolute direction. The "Laws" were on the Statute book, but there was no Power to enforce them. And so the Powers of evil did their terrible work; and fire and rapine continued to destroy life and property without check, until new Power came in, when the Reign of Law was restored.

And thus we are led to the culminating point of Man's Intellectual Interpretation of Nature—his recognition of the Unity of the Power, of which her Phenomena are the diversified manifestations. Towards this point all Scientific inquiry now tends. The Convertibility of the Physical Forces, the Correlation of these with the Vital, and the intimacy of that *nexus* between Mental and Bodily activity, which, explain it as we may, cannot be denied, all lead upward towards one and the same conclusion; and the pyramid of which that Philosophical conclusion is the apex, has its foundation in the Primitive Instincts of Humanity.

By our own remote Progenitors, as by the untutored Savage of the present day, every change in which Human agency was not apparent was referred to a particular Animating Intelligence. And thus they attributed not only the movement of the Heavenly bodies, but all the phenomena of Nature, each to its own Deity. These Deities were invested with more than Human power; but they were also supposed capable of Human passions, and subject to Human capriciousness. As the Uniformities of Nature came to be more distinctly recognised, some of these Deities were invested with a dominant control, while others were supposed to be their subordinate ministers. A serene Majesty was attributed to the greater Gods who sit above the clouds; whilst their inferiors might "come down to Earth in the likeness of Men." With

the growth of the Scientific Study of Nature, the conception of its Harmony and Unity gained ever-increasing strength. And so among the most enlightened of the Greek and Roman Philosophers, we find a distinct recognition of the idea of the Unity of the Directing Mind from which the Order of Nature proceeds; for they obviously believed that, as our modern Poet has expressed it—

> All are but parts of one stupendous whole,
> Whose body Nature is, and God the Soul.

The Science of Modern times, however, has taken a more special direction. Fixing its attention exclusively on the *Order* of Nature, it has separated itself wholly from Theology, whose function it is to seek after its *Cause*. In this, Science is fully justified, alike by the entire independence of its objects, and by the historical fact that it has been continually hampered and impeded in its search for the Truth as it is in Nature, by the restraints which Theologians have attempted to impose upon its inquiries. But when Science, passing beyond its own limits, assumes to take the place of Theology, and sets up its own conception of the *Order* of Nature as a sufficient account of its *Cause*, it is invading a province of Thought to which it has no claim, and not unreasonably provokes the hostility of those who ought to be its best friends.

For whilst the deep-seated instincts of Humanity, and the profoundest researches of Philosophy, alike point to Mind as the one and only source of Power, it is the high prerogative of Science to demonstrate the *Unity* of the Power which is operating through the limitless extent and variety of the Universe, and to trace its *Continuity* through the vast series of Ages that have been occupied in its Evolution.

SECTION A

MATHEMATICAL AND PHYSICAL SCIENCE

Opening Address by the President, Mr. Warren De La Rue, D.C.L., F.R.S.

My predecessors in this chair have addressed you on many subjects of high interest in Mathematical and Physical Science: I do not contemplate passing in review the recent discoveries in Astronomy and Physical Science, but intend to confine myself, in the main, to Astronomical Photography; and in selecting this branch of science as the subject of this introductory discourse, I think that I shall have your approval, not only because I have given special attention to that subject, but also because it is about to be applied to the determination of a fundamental element of our system, the solar parallax, by observations of the transit of Venus in 1874, and probably also in 1882.

Nothing is so lastingly injurious to the progress of science as false data, for they endure often through many centuries. False views, even if supported by some amount of evidence, do comparatively little harm, for every one takes a salutary interest in proving their falseness, and when this is done the path to error is closed, and the road to truth is opened at the same moment.

It will be conceded that Photography, when applied to scientific observation, undoubtedly preserves facts. But the question has sometimes been raised, Are photographic records absolutely trustworthy representations of the phenomena recorded? If not, what is the extent of truth, and where are the inlets for errors and mistakes? Not only has photographic observation gained a wide range of applications in astronomy, but in every other branch of physical science its help is daily more and more taken advantage of; and although, in speaking of this art, I shall confine myself to astronomy, the observations which I propose to make may be suggestive with reference to other branches of physics.

As an instance of the application of this art to optical physics, I may in this place call attention to the very successful delineation of the solar spectrum by Mr. Lewis M. Rutherfurd, of the United States. In Mr. Rutherfurd's spectrum, obtained by the camera, many portions and lines are shown (in the ultra-violet for instance), which, while imperceptible to the retina of the eye, impress themselves on the sensitive film. As a fact, lines which are single in Angström's and Kirchhoff's maps have been recorded by photography as well-marked double lines. I will now review the application of the art to astronomy.

Stellar photography was for some time applied at Harvard College Observatory, U.S., to double stars, for the purpose of determining by micrometric measurement their relative angle of position and distance. The zero of the angle of position was found by moving the telescope in right ascension after an impression had been taken, and taking a second one on the same plate; this process gave two sets of photographic images on the same plate, and the right line passing through the series gave the direction of the daily motion of the heavens. The probable error of a single measurement of the photographic distance of the images was found to be $\pm 0''\cdot 12$, or somewhat smaller than that of a direct measurement with the common filar micrometer. The late Prof. Bond, who applied photography to stellar astronomy, confining himself to stars brighter than the seventh magnitude, discussed the results in various numbers of the "Astronomische Nachrichten." No astronomer more unbiassed could have been selected to decide on the comparative value of the photographic and direct observational method. His discussion shows that the probable error of the centre of an image was $\pm 0''\cdot 051$, and that of the distance of two such centres was $\pm 0''\cdot 072$. Adopting the estimate of Struve, $\pm 0''\cdot 217$, as the probable error of a single measurement of a double star of this class with a filar micrometer, Prof. Bond shows that the measurement of the photographic images would have a relative value three times as great. He derived the further important conclusion, that deficiency of light can be more than compensated for by proportionate increase in the time of exposure. A star of the ninth magnitude would give a photographic image, after an exposure of ten minutes, with the Cambridge equatorial.

In the reproduction of stars by photography, recently undertaken by Mr. Rutherfurd, the objects to be secured being so minute, special precautions were found to be necessary in depicting them upon the sensitive film, so that their impressions might be distinguishable from accidental specks in the collodion plate. To prevent any such chance of mistake, Mr. Rutherfurd secures a double image of each luminary, the motion of the telescope being stopped for a short time (half a minute) between a first and second exposure of the plate; so that each star is represented by two close specks, so to speak, upon the negative, and is clearly to be distinguished by this contrivance from any accidental speck in the film. A map of the heavens is thus secured, very clear though delicate in its nature, but yet one upon which implicit reliance can be placed for the purposes of measurement. Prof. Peirce aptly says, "This addition to astronomical research is unsurpassed by any step of the kind that has ever been taken. The photographs afford just as good an opportunity for new and original investigation of the relative position of near stars as could be derived from the stars themselves as seen through the most powerful telescopes. They are indisputable facts, unbiassed by personal defects of observation, and which convey to all future times the actual places of the stars when the photographs were taken."

Mr. Asaph Hall, who shared with Prof. Bond the work of measuring the photographic images, and of reducing the measurements, has very recently subjected the photographic method to a critical comparison, with a view to deciding on its value when applied to the observation of the transit of Venus. He appears, as regards its application to stellar observations, to under-estimate the photographic method in consequence of want of rapidity; but he admits that in the case of a solar eclipse, or of the transit of a planet over the sun's disc, it has very great advantages, especially over eye-observations of contacts, inner and outer, of the planet and the sun's limb, and that the errors to which it is subject are worthy of the most thorough investigation. The observation of a contact is uncertain on account of irradiation, and is also only momentary: so that, if missed from any cause, the record of the event is irretrievably lost at a particular station, and long and costly preparations rendered futile. On the other hand, when the sky is clear, a photographic image can be obtained in an instant, and repeated throughout the progress of the transit, and even if all the contacts be lost, equally valuable results will be secured, if the data collected on the photographic plates can be correctly reduced, as will be proved hereafter to be undoubtedly possible. That the transit of Venus will be recorded by photography may now be announced as certain, as preparations are energetically progressing in England, France, Prussia, and America for obtaining photographic records. There is also a possibility of Portugal taking part in these observations; for it is contemplated by Señor Capello to transport the Lisbon photoheliograph to Macao. There are at present five photoheliographs in process of construction for the observing parties to be sent out by the British Government, under the

direction of the Astronomer Royal, Sir George B. Airy. The Russian Government will supply their own parties with three similar instruments; and I am also having constructed one of my own for this purpose and for future solar observations. All these instruments, made precisely alike, will embody the results of our experience gained during the last ten years in photoheliography at the Kew Observatory whilst belonging to this Association. One only of them, namely, the photoheliograph which has been at work for some years at Wilna, is of somewhat older pattern; but how great an advance even this instrument is on the original at Kew is proved by the delightful definition of the most delicate markings of the sun in the pictures which have reached this country from Wilna.

Hitherto sun-pictures have been taken on wet collodion; but a question has been raised whether it would not be better to use dry plates. On this point M. Struve informs us that, in two places—at Wilna, under the direction of Colonel Smysloff, and at Bothkamp, in Holstein, under Dr. Vogel—they have perfectly succeeded in taking instantaneous photographs of the sun with dry plates.

As far, however, as my own experience has gone, I still believe that the wet collodion is preferable to the dry for such observations.

Now, with reference to contact observations—which, it must be remembered, are by no means indispensable as far as photography is concerned—it may be conceded that there will attach to the record of the internal contact a certain amount of uncertainty, although not so great as that which affects optical observation. The photography which first shows contact may possibly not be that taken when the thread of light between Venus and the sun's disc is first completed, but the first taken after it has become thick enough to be shown on the plate; and this thickness is somewhat dependent on incidental circumstances—for example, a haziness of the sky, which, although almost imperceptible, yet diminishes the actinic brilliancy of the sun, and might render the photographic image of the small extent of the limb which is concerned in the phenomenon too faint for future measurements. On the other hand, having a series of photographs of the sun with Venus on the disc, we can, with a suitable micrometer—such as I contrived for measuring the eclipse pictures of 1860, and which, since then, has been in continuous use in measuring the Kew solar photograms *—fix the position of the centre of each body with great precision. But the reduction of the measured distances of the centre to their values in arc is not without difficulty. Irradiation may possibly enlarge the diameter of the sun in photographic pictures, and it may diminish the size of the disc of a planet crossing the sun, as is the case with eye-observations; but if the images depicted are nearly of the same size at all stations whose results are to be included in any set of discussions, then the ratio of the diameters of Venus and the sun will be the same in all the plates, and it will be safe to assume that they are equally affected by irradiation. The advantage which, therefore, will result by employing no less than eight instruments precisely alike, as are those now being made by Mr. Dallmeyer on the improved Kew model, is quite obvious. If other forms of instruments, such as will hereafter be alluded to, be used, it will be essential that a sufficient number of them be employed in selected localities to give also connected sets for discussion.

To give some idea of the relative apparent magnitudes of the sun and Venus, I may mention that at the epoch of the transit of 1874 the solar disc would, in the Kew photoheliograph, have a semi-diameter of 1965·8 thousandths of an inch, or nearly two inches; Venus a semi-diameter of 63·33 of these units; and the parallax of Venus referred to the sun would be represented by 47·85 such units, the maximum possible displacement being 95·7 units, or nearly $\frac{1}{10}$th of an inch.

When the photographs have been secured, the micrometric measurements which will have to be performed consist in the determination of the sun's semi-diameter in units of the scale of the micrometer, the angle of position of the successive situations of the planet on the disc, as shown on the series of photographs, and finally the distances of the centres of the planet and the sun. These data determine absolutely the chord along which the transit has been observed to within 0"·1; and an error of 1" in the measurement would give an error of only 0"·185 in the deduced solar parallax. Moreover the epoch of each photographic record is determinable with the utmost accuracy, the time of the exposure being from $\frac{1}{50}$ to $\frac{1}{100}$ of a second, or even less.

Now, although the truth of the foregoing remarks will be fully admitted, it will yet be well to point out in this place the inherent or supposed defects of the photographic method. These defects may principally be comprised under the head of Possibility of Distortion; and the importance of an investigation into this source of error will appear at once obvious in all cases where the position of a definite point with reference to a system of co-ordinates has to be determined from measured photographs, especially in such a refined application of it as that which it will have in the determination of the solar parallax.

The distortion of a photographic image, if such exist, may be either extrinsic or intrinsic—that is, either optical or mechanical. The instrumental apparatus for producing the image may produce optical irregularities before it reaches the sensitive plate; or an image optically correct may, by irregular contraction of the sensitive film in the process of drying, and other incidents of the process, present on the plate a faulty delineation. *

In general, two ways present themselves for clearing observations from errors. Either methods may be devised for determining the numerical amount of every error from any source, or by special contrivances the source of error may be contracted to such insignificant limits that its effect in a special case is too minute to exert any influence upon the result. Both these roads have been followed in the inquiry into the optical distortion of photographic images.

As regards the first, let it be supposed that, as in the Kew instrument, the primary image is magnified by a system of lenses before reaching the sensitive plate. The defects inherent to the optical arrangement will clearly affect every photographic picture produced by the same instrument; and hence a method suggests itself for determining absolutely the numerical effect of distortion at every point of the field. Let us assume that the same object, which may be a rod of unalterable and known length, be photographed in precisely the same manner in which celestial events are photographically recorded, the object being at a considerable distance; it may successively be brought into all possible positions in the field of the photoheliograph, and the length of the image on the photograph may be measured afterwards at leisure by means of a micrometer. These lengths will change relatively wherever distortion takes place; but by laying down these varying lengths we shall obtain an optical distortion-map of the particular instrument; and tables may be constructed giving in absolute numbers the corrections to be applied to measurements of positions on account of the influence of optical distortion. In this way the optical distortion of the combined object-glass and secondary magnifier is ascertained. The chief source of distortion, if such exist, will be in the secondary magnifier; and in order to ascertain its amount, a reticule of lines drawn at equal distances upon glass may (as has been done recently by Paschen and Dallmeyer) be placed in the common focus of the object-glass and secondary magnifier. The required data are then immediately given by the measurement of the resulting pictures of the parallelograms on the reticule. Mr. Dallmeyer has ascertained in this manner that no sensible distortion exists in the secondary magnifier constructed by him. The truth of the principle being granted, it was applied to a preliminary series for finding the distortion which affects the Kew instrument, which is not nearly so perfect as those more recently constructed; and the results were so satisfactory that, instead of a single rod, a proper scale, fifteen feet in length, representing a series of rectangles distributed over half the radius of the field has been erected; and the process of absolutely determining the optical distortion of the Kew photoheliograph is now in active progress, and will be used for the new instruments to be employed in observing the transits of Venus.

The second method of dealing with optical distortion aims at total exclusion of this source of error. It has been proposed by American astronomers, who intend taking part in the coming observations of the transit of Venus, to exclude the secondary magnifier, and, in order to obtain an image of sufficient diameter, to employ a lens of considerable focal length, say 40 ft., which would give an image as large as with the Kew photoheliograph—

* In this micrometer, which is capable of giving radial distances, angles of position, and also rectangular co-ordinates, the accuracy of linear measurements does not depend on the doubtful results given by a long run of a micrometer screw.

* It has been proposed, in order to obviate any possible alteration of the sensitive surface, to use the Daguerreotype instead of the collodion process. The former, however, is so little practised, and, moreover, is so much more troublesome, that it does not seem to be advisable to adopt it, especially as the subsequent measurements would present greater difficulties than occur with collodion pictures.

namely, 4 in. in diameter. As it would be inconvenient to mount such an instrument equatorially, it is proposed to fix it in the meridian in a horizontal position, and reflect the sun in the direction of its axis by means of a flat mirror moved by a heliostat. There cannot be any doubt about the fact that the image so produced would be nearly free from optical distortion, if the interposed mirror did not introduce a new source of error. The difficulty of producing a plane mirror is well known; and there is a difficulty in maintaining its true figure in all positions; there is also a liability of the disturbance of the rays by currents of heated air between the mirror and object-glass: moreover, with such an instrument, position-wires could not be defined with sharpness on the photographs. On the whole, greater reliance may be placed on a method which admits the existence of a distorting influence, but has at the same time means of checking and controlling it numerically.

Great attention has been paid by me at various times to those effects of distortion which might arise from the process of drying. The results to which the experiments lead seem to prove that there is no appreciable contraction except in thickness, and that the collodion film does not become distorted, provided the rims of the glass plates have been well ground: this point is a fundamental one. But in such observations as that of the transit of Venus, no refinement of correction ought to be neglected; hence fresh experiments will be undertaken to set at rest the question whether distortion of the film really takes place when proper precautions are taken. This will be done both by the method I have employed before, and also in accordance with M. Paschen's proposal to measure images of such reticules as above described: this reticule might, as he has suggested, be photographed during the transit of Venus, so that each plate would thus bear data for the correction due to unequal shrinking, if such were to take place.

It has been objected by some astronomers who have casually examined solar photograms that the limb of the sun appears as a consequence of the gradual shading off, even under a small magnifying power, not bounded by a sharp contour; but the measurements of such photograms which have been made during the last ten years of pictures, taken under the most varying conditions which influence definition, have proved that even the worst picture leads to a very satisfactory determination of the sun's semi-diameter and centre; moreover, an independent examination of this question by M. Paschen gave as the result that the mean error of a determination is only $\pm$ 0·008 millimetre with a sun-picture of 4 Paris inches in diameter; this corresponds to $\pm$ 0"·135, and it is nearly three times less than that resulting from a measurement with the Königsberg heliometer.

Nevertheless it will be seen from the foregoing remarks that I have not hesitated to arouse your attention to the fact that Astronomical Photography is about to be put to the severest test possible in dealing with such a fundamental problem of astronomy as the determination of the sun's distance from the earth. An intimate knowledge of the subject, however, and experience with respect to work already accomplished in the Kew ten-year solar observations, inspire me with a confident anticipation that it will prove fully equal to the occasion.

So much for performances to be looked forward to in the future: now let me briefly review what Astronomical Photography has already undoubtedly accomplished.

In the first instance the possibility proved of giving to the photographic method of observation a trustworthiness which direct observations can never quite obtain, will render the results of our discussion of the ten years' solar observations at Kew more free from doubts than those observational series on the Sun's spots which have preceded ours. The evidence of a probable connection between planetary positions and solar activity, and the evidence which we have published on the nature of spots as depressions of solar matter, could never have been brought forward but for the preservation of true records of the phenomena through a number of years, while the closer agreement of the calculated results in reference to solar elements is itself evidence of the intrinsic truthfulness of the method, and gives the highest promise that our final deductions, which will be completed in the course of the ensuing year, will not be unworthy the exertions which I, in conjunction with my friends B. Stewart and B. Loewy, have constantly devoted to this work during a period of fully ten years. Not only will some doubtful questions be set finally at rest by it, but new facts of the greatest interest will result, bearing on the laws which appear to govern solar activity.

By nothing, however, would the claims of photographic observation, as one of the most important instruments of scientific research, seem to be so thoroughly well established as by the history of recent solar eclipses. It will be recollected that in 1860 for the first time the solar origin of the prominences was placed beyond doubt solely by photography, which preserved a faithful record of the moon's motion in relation to these protuberances. The photographs of Tennant at Guntour, and of Vogel at Aden, 1868, and also those of the American astronomers at Burlington and Ottumwa, Iowa, in 1869, under Profs. Morton and Mayer, have fully confirmed those results. In a similar manner the great problem of the solar origin of that portion of the corona which extends more than a million of miles beyond the body of the sun has been, by the photographic observations of Col. Tennant and Lord Lindsay in 1871, set finally at rest, after having been the subject of a great amount of discussion for some years.

The spectroscopic discovery in 1869 of the now famous green line, 1474 K, demonstrated undoubtedly the self-luminosity, and hence the solar origin of part of the corona. Those who denied the possibility of any extensive atmosphere above the chromosphere received the observation with great suspicion; but in 1870 and again in 1871 it was fully verified. So far, therefore, the testimony of spectroscopic observations was in favour of the solar origin of the inner corona.

Indeed the observations of 1871 have proved hydrogen to be also an essential constitutent of the "coronal atmosphere," as Janssen proposes to call it—hydrogen at a lower temperature and density, of course, than in the chromosphere. Janssen was further so fortunate as to catch glimpses of some of the dark lines of the solar spectrum in the coronal light, an observation which goes far to show that in the upper atmosphere of the sun there are also solid or liquid particles, like smoke or cloud, which reflect the sunlight from below. Many problems, however, even with reference to the admittedly solar part of the corona, are unsettled. The first relates to the nature of the substance which produces the line 1474 K. Since it coincides with a line in the spectrum of iron, it is by many considered due to that metal; but then we must suppose either that iron vapour is less dense than hydrogen gas, or that it is subject to some peculiar solar repulsion which maintains it at its elevation, or other hypotheses may be suggested for explaining the fact. Since the line is one of the least conspicuous in the spectrum of iron and the shortest, and as none of the others are found associated with it in the coronal spectrum, it seems natural, as many have done, to assume at once that it is due to some new kind of matter. But the observations of Angström, Roscoe, and Clifton, and recently those of Schuster regarding the spectrum of nitrogen, render it probable that elementary bodies have only one spectrum, and since in all experimental spectra we necessarily operate only on a small thickness of a substance, we cannot say what new lines may be given out in cases where there is an immense thickness of vapour; and hence we cannot conclude with certainty that because there is an unknown line in the chromosphere or corona, it implies a new substance. Another problem, the most perplexing of all, is the reconciliation of the strangely discordant observations upon the polarisation of the coronal light; but I will at once proceed to the points on which photography alone can give us decisive information.

The nature and conditions of the outer corona (the assemblage of dark rifts and bright rays which overlies and surrounds the inner corona) was very incompletely studied; and the question whether it is solar was not finally settled in the opinions of astronomers of high repute. Some believed it to be caused by some action of our atmosphere; and others supposed it due to cosmical dust between us and the moon. The bright light of the corona and the prominences most undoubtedly cause a certain amount of atmospheric glare; and although it is difficult to see how this is to account for the rays and rifts, it would be rash to deny that it may do so in some manner yet to be discovered. It is quite certain that some of the phenomena observed just at the beginning and end of totality are really caused by it. A light haze of meteoric dust between us and the moon might give results much resembling those observed; but when we come to details this theory seems to be doubtful.

Here photography steps in to pave the way out of the existing doubts. If the rays and rifts were really atmospheric, it would hardly be possible that they should present the same appearance at different stations along the line of totality; indeed, they would

probably change their appearance every moment, even at the same station. If they are cislunar, the same appearances could not be recorded at distant stations. It is universally admitted that proof of the invariability of these markings, and especially of their identity as seen at widely separated stations, would amount to a demonstration of their extra-terrestrial origin. Eye-sketches cannot be depended on; the drawings made by persons standing side by side differ often to an extent that is most perplexing. Now photographs have, undoubtedty, as yet failed to catch many of the faint markings and delicate details; but their testimony, as far as it goes, is unimpeachable. In 1870, Lord Lindsay at Santa Maria, Prof. Winlock at Jerez, Mr. Brothers at Syracuse, obtained pictures some of which, on account partly of the unsatisfactory state of the weather, could not compare with Mr. Brothers' picture obtained with an instrument of special construction; * but all show one deep rift especially, which seemed to cut down through both the outer and inner corona clear to the limb of the moon. Even to the naked eye it was one of the most conspicuous features of the eclipse. Many other points of detail also come out identical in the Spanish and Sicilian pictures; but whatever doubts may have still existed in regard of the inner corona were finally dispelled by the pictures taken in India, in 1871, by Col. Tennant and Lord Lindsay's photographic assistant, Mr. Davis.

None of the photographs of 1871 show so great an extension of the corona as is seen in Mr. Brothers' photograph, taken at Syracuse in 1870; but, on the other hand, the coronal features are perfectly defined on the several pictures, and the number of the photographs renders the value of the series singularly great. The agreement between the views, as well those taken at different times during totality as those taken at different stations, fully proves the solar theory of the inner corona. We have in all the views the same extensive corona, with persistent rifts similarly situated. Moreover there is additional evidence indicated by the motion of the moon across the solar atmospheric appendages, proving in a similar manner as in 1860, in reference to the protuberances, the solar origin of that part of the corona.

It will be well here to mention a difficulty which occurs in recording the fainter solar appendages, namely the encroachment of the prominences and the corona on the lunar disc when the plates have to be over-exposed in order to bring out the faint details of the corona. It is satisfactory to find that whenever a difficulty arises it can be mastered by proper attention. Lord Lindsay and Mr. Ranyard have successfully devoted themselves to experiments on the subject. They tested whether reflections from the back surface of the plate played any part in the production of the fringes: for this purpose plates of ebonite and the so-called nonactinic yellow glass were prepared; and it was immediately found that the outer haze had completely disappeared in the photographs taken on ebonite, while on the yellow glass plates it is much fainter than on ordinary white glass plates. By placing a piece of wetted black paper at the back of an unground plate, the outer haze was greatly reduced; but by grinding both the back and the front surfaces of a yellow glass plate, and covering the back with a coating of black varnish, it was rendered quite imperceptible, thus showing the greatest part of the so-called photographic irradiation to be due to reflection from the second surface.

In connection with the solution of the most prominent questions connected with the solar envelopes, it may not be without great interest to allude to another point conclusively decided during the last annular eclipse of the sun, observed by Mr. Pogson on the 6th of June of this year, as described by him in a letter to Sir G. B. Airy. In 1870 Prof. Young was the first to observe the reversal of the Frauenhofer lines in the stratum closest to the sun. Now, in 1871 doubts were thrown upon the subject. It appears that the reversed lines seem to have been satisfactorily observed by Captain Maclear at Bekul, Colonel Tennant at Dodabetta, and Captain Fyers at Jaffna. The observations of Pringle at Bekul, Respighi at Poodocottah, and Pogson at Avenashi were doubtful, while Mosely at Trincomalee saw nothing of this reversal, which is, according to all accounts, a most striking phenomenon, although of very short duration. Mr. Lockyer missed it by an accidental derangement of the telescope. The reversal and the physical deductions from it are placed beyond doubt by Mr. Pogson's observation of the annular eclipse on June 6. At the first internal contact, just after a peep in the finder had shown the moon's limb lighted up by the corona, he saw all the dark lines reversed and bright, but for less than two seconds. The sight of beauty above all was, however, the reversion of the lines at the breaking-up of the limb. The duration was astonishing—five to seven seconds; and the fading-out was gradual, not momentary. This does not accord with Captain Maclear's observations in 1870, who reports the disappearance of the bright spectrum as "not instantly, but so rapidly that I could not make out the order of their going." Prof. Young again says that "they flashed out like the stars from a rocket-head." But discrepancies in this minor point may be accounted for by supposing differences in quietude of that portion of the sun's limb last covered by the moon.

The mention of the solar appendages recalls to mind another instance in which photography has befriended the scientific investigator. I allude to the promising attempt which has been made by Prof. Young to photograph the protuberances of the sun in ordinary daylight. A distinct reproduction of some of the double-headed prominences on the sun's limb was obtained; and although as a picture the impression may be of little value, still there is every reason to believe, now that the possibility of the operation is known, that with better and more suitable apparatus an exceedingly valuable and reliable record may be secured. Prof. Young employed for the purpose a spectroscope containing seven prisms, fitted to a telescope of $6\frac{1}{2}$-inch aperture, after the eye-piece of the same had been removed. A camera, with the sensitive plate, was attached to the end of the spectroscope, the eye-piece of which acted in the capacity of a photographic lens, and projected the image on the collodion film. The exposure was necessarily a long one, amounting to three minutes and a half. The eye-piece of the spectroscope was unsuitable for photographic purposes, and only in the centre yielded a true reproduction of the lines free from any distortion. A larger telescope, with a suitable secondary magnifier, will be required, in order to secure a more defined image.

I have hitherto spoken of the successful applications of photography to astronomy; but I must point out also some cases where it has failed. Nebulæ and comets have not yet been brought within the grasp of this art, although, perhaps, no branch of astronomy would gain more if we should hereafter succeed in extending to these bodies that mode of observing them. There is theoretically, and even practically, no real limit to the sensitiveness of a plate. Similarly with reference to planets great difficulties still exist, which must be overcome before their phases and physical features can be recorded to some purpose by photography; yet there is great hope that the difficulties may be ultimately surmounted. The main obstacle to success arises from atmospheric currents, which are continually altering the position of the image on the sensitive plate; the structure of the sensitive film is also an interfering cause for such small objects. A photograph taken at Cranford of the occultation of Saturn by the moon some time ago exhibits the ring of the planet in a manner which holds out some promise for the future.

The moon, on the other hand, has been for some time past very successfully photographed; but no use has hitherto been made of lunar photographs for the purposes of measurement.

The photographs of the moon are free from distortion, and offer therefore material of incalculable value as the basis of a selenographic map of absolute trustworthiness, and also for the solution of the great problem of the moon's physical libration. This question can be solved with certainty by a series of systematic measurements of the distance of definite lunar points from the limb. Mr. Ellery, Director of the Observatory of Melbourne, has sent over an enlargement of a lunar photograph taken with the Great Melbourne Telescope, in which the primary image is $3\frac{3}{16}$ inches in diameter. Such lunar negatives would be admirably adapted for working out the problem of the physical libration, and also for fundamental measurements for a selenographic map; the more minute details, however, would have to be supplied by eye-observations, as the best photograph fails to depict all that the eye sees with the help of optical appliances. On the other hand, selenographic positions would be afforded more free from error than those to be obtained by direct micrometrical measurements.

Although, as I have stated, I do not contemplate passing in review recent discoveries in astronomy, I must not omit to call your attention to some few subjects of engrossing interest. First,

* Mr. Brothers had, in 1870, the happy idea to employ a so-called rapid rectilinear photographic lens, made by Dallmeyer, of 4 inches aperture and 30 inches focal length, mounted equatorially, and driven by clockwork; and he was followed in this matter by both Col. Tennant and Lord Lindsay in 1871. The focal image produced, however, is far too small ($\frac{3}{16}$ of an inch, about); therefore it will be desirable in future to prepare lenses of similar construction, but of longer focal length and corresponding aperture.

with reference to the more recent work of Dr. Huggins. In his observations he found that the brightest line of the three bright lines which constitute the spectrum of the gaseous nebulæ was coincident with the brightest of the lines of the spectrum of nitrogen; but the aperture of his telescope did not permit him to ascertain whether the line in the nebulæ was double, as is the case with the line of Nitrogen. With the large telescope placed in his hands by the Royal Society, he has found that the line in the nebulæ is not double, and in the case of the great nebula in Orion it coincides in position with the less refrangible of the two lines which make up the corresponding nitrogen-line. He has not yet been able to find a condition of luminous nitrogen in which the line of this gas is single and narrow and defined like the nebular line.

He has extended the method of detecting a star's motion in the line of sight by a change of refrangibility in the line of a terrestrial substance existing on the star to about 30 stars besides Sirius. The comparisons have been made with lines of hydrogen, magnesium, and sodium. In consequence of the extreme difficulty of the investigation, the numerical velocities of the stars have been obtained by estimation, and are to be regarded as provisional only. It will be observed that, speaking generally, the stars which the spectroscope shows to be moving from the earth, as Sirius, Betelgeux, Rigel, Procyon, are situated in a part of the heavens opposite to Hercules, towards which the sun is advancing; whilst the stars in the neighbourhood of this region, as Arcturus, Vega, and α Cygni, show a motion of approach. There are, however, in the stars already observed, exceptions to this general statement; and there are some other considerations, as the relative velocities of the stars, which appear to show that the sun's motion in space is not the only or even in all cases the chief cause of the observed proper motions of the stars. In the observed stellar motions we have to do probably with two other independent motions—namely, a movement common to certain groups of stars and also a motion peculiar to each star. Thus the stars, $\beta\ \gamma\ \delta\ \epsilon\ \zeta$, of the Great Bear, which have similar proper motions, have a common motion of recession; while the star α of the same constellation, which has a proper motion in the opposite direction, is shown by the spectroscope to be approaching the earth. From further researches in this direction, and from an investigation of the motions of stars in the line of sight in conjunction with their proper motions at right angles to the visual direction obtained by the ordinary methods, we may hope to gain some definite knowledge of the constitution of the heavens.

This discovery supports, in a somewhat striking manner, the views which Mr. Proctor has been urging respecting the distribution of the stars in space. According to these views there exist within the sidereal system subordinate systems of stars forming distinct aggregations, in which many orders of real magnitude exist, while around them is relatively barren space. He had inferred the existence of such systems from the results of processes of equal-surface charting applied successively to stars of gradually diminishing orders of brightness. He found the same regions of aggregation, whether the charts included stars to the sixth order only or were extended, as in his chart of the northern heavens, to the tenth and eleventh orders; and these regions of aggregation are the very regions where the elder Herschel found the faintest telescopic stars to congregate. Applying a new system of charting to show the proper motions of the stars, he found further evidence in favour of these views. The charts indicated the existence of concurrent motions among the members of several groups or sets of stars. Selecting one of the more striking instances as affording what appeared to him a crucial test of the reality of this *star-drift*, Mr. Proctor announced his belief that whenever the spectroscopic method of determining stellar motions of recess or approach should be applied to the five stars, $\beta\ \gamma\ \delta\ \epsilon$ and ζ Ursæ Majoris, these orbs (which formed a drifting set in the chart of proper motions) would be found to be drifting collectively either towards or from the earth: this has been confirmed.

The time has now come for more closely investigating the various theories which have been propounded by such profound thinkers as Tyndall, Tait, Reynolds, and others, to account for the phenomena of Comets. I do not propose to enter into a statement of these theories; but I venture to call attention to Zöllner's views, which have recently given rise to a great amount of controversy. In doing so, I am solely influenced by a desire to give information on this subject, without implying thereby that I give my adherence, or even preference, to his theory.*

* See Appendix, p. 12.

The vaporisation of even solid bodies at low temperatures suggests that a mass of matter in space will ultimately surround itself with its own vapour, the tension of which will depend upon the mass of the body (that is, upon its gravitative energy) and the temperature. If the mass of the body is so small that its attractive force is insufficient to give to the enveloping vapour its maximum tension for the existing temperature, the evolution of vapour will be continuous until the whole mass is converted into it. It is proved by analysis that such mass of gas or vapour in empty and unlimited space is in condition of unstable equilibrium, and must become dissipated by continual expansion and consequent decrease of density. It follows that celestial spaces, at least within the limits of the stellar universe, must be filled with matter in the form of gas.

A fluid mass existing in space at a distance from the sun or other body radiating heat would, if its mass were not too great, be converted entirely into vapour after the lapse of sufficient time. But if the fluid mass approach the sun, solar heat would occasion a more rapid development of vapour on the sunward side; and the total vaporisation would require an incomparably short time with reference to the interval necessary in the former case; this time would be shorter the smaller the mass of the body. Prof. Zöllner points to the smaller comets, which often appear as spherical masses of vapour, as examples of such bodies, while the spectra of some of the nebulæ and smaller comets render the existence of fluid masses giving out vapour highly probable.

The self-luminosity and train of comets he refers to other causes. Two causes only are known through the operation of which gases become self-luminous—elevation of temperature (as by combustion), or electrical excitement. Setting aside the first as involving theoretical difficulties, the second cause is demonstrated by him to be sufficient to account for the self-luminosity and the formation of the train, provided it be granted that electricity may be developed by the action of solar heat, if not in the process of evaporation, at least in the mechanical and molecular disturbances resulting from it. The production of electricity by such processes within the limits of our experience, must be admitted as a well-known fact. The spectrum of the vaporous envelope of a comet, illuminated in this manner, must necessarily be that produced by the passage of an electrical discharge through vapour identical in substance with a portion of the comet's nucleus, from which the envelope is derived. As, according to this supposition, water and liquid hydrocarbons are important constituents of these bodies, the spectra of the comets should be such as belong to the vapours of these substances; and in this manner the resemblance and partial coincidence of the observed cometic spectra with those of gaseous hydrocarbons is explained.

The form and direction of the train indicate undoubtedly the action of a repulsive force; and Prof. Zöllner asserts that the assumption of an electrical action of the sun upon bodies of the solar system is necessary and sufficient to account for all the essential and characteristic phenomena of the vaporous envelope and the train. The direction of the train, towards or from the sun, is, according to this theory, to be easily explained by the supposition of a variability in the mutual electrical conditions. This accords perfectly with the phenomena observed in the development of electricity by vapour-streams in the hydroelectric machine, where the sign of electricity depends upon the presence or absence of various substances in the boiler or the tubes.

The theory acquires an additional interest from Schiaparelli's remarkable discovery of the identity of the paths of certain comets with great meteor-streams, since the meteoric masses must inevitably be converted into vapour on approaching the sun, with the exhibition of the characteristic appearances of the comets.

The intimate connection of planetary configuration and solar spots, of the latter and terrestrial magnetism and auroral phenomena, must tend to establish also a connection between solar spots and solar radiation. It is demonstrated by the researches of Piazzi Smyth, Stone, and Cleveland Abbe, that there is a connection between the amount of heat received from the sun and the prevalence of spots—a result clearly in harmony with those derived from recent investigations into the nature of the solar atmosphere. Further, in a paper by Mr. Meldrum, of Mauritius, which will be read before you during this session, most remarkable evidence is given on the close connection of these phenomena. It appears that the cyclones of the Indian Ocean have a periodicity corresponding with the sun-spot periodicity; so that if an observer in another planet could see and measure the

sun-spots and cyclones (earth-spots), he would find a close harmony between them. Such a connection will probably be found to exist over the globe generally; but with reference to the Indian Ocean it may be stated as a matter of fact, from Mr. Meldrum's discussion of twenty-five years' observations, that in the area lying between the equator and 25° south latitude, and between 40° and 110° east longitude, the frequency of cyclones has varied during that period directly as the amounts of sun-spots. I am glad to be able announce that Mr. Meldrum, in order to place the deductions on a still broader foundation, proposes to investigate these laws on a plan perfectly in agreement with our method of determining the areas of solar disturbances, the results of which have been published from time to time during the last ten years. Moreover the observations on the periodic changes of Jupiter's appearance, and the observations of Mr. Baxendell that the convection currents of our earth vary according to the sunspot period—all these results, seemingly solitary, but truly in mysterious harmony, point to the absolute necessity for establishing constant photographic records of solar and terrestrial phenomena all over the world. No astronomer or physicist should lose any opportunity of assisting in this great aim, by which alone unbiassed truthful records of phenomena can be preserved. What is more, no system of observations can be carried on at a less expense.

We have hopes of seeing the photographic method as applied to sun-observations joined to the work of the Greenwich Observatory; but what is further wanted is the erection of instruments for photographic records and of spectroscopes in a number of observatories throughout the world, so as to obtain daily records of the sun and to observe magnetical and meteorological phenomena continuously in connection with solar activity. Meteorological observation is storing up useful facts; but they can only be dealt with effectually if investigated in close parallelism with other cosmical phenomena. Only when this is done may we hope to penetrate the maze of local meteorological phenomena and elevate meteorology to the rank of a science. The time has really come not only for relieving private observers from the systematic observation of solar phenomena, but for drawing close ties between all scattered scientific observations, so as to let one grand scheme embrace the whole; and no method seems to be so well adapted to bring about this great achievement than the method of photographing the phenomena of nature, which in its very principle carries with it all extinction of individual bias.

In conclusion I cannot refrain from making a passing allusion to a Royal Commision, presided over by the Duke of Devonshire, which has been sitting for some time past; for I believe that its labours will have an important bearing on all that relates to scientific education and the promotion of science in this country. The time has come when the cultivation of science must be protected and fostered by the State; it can no longer be safely left to individual efforts. If England is to continue to hold a high position among civilised nations, the most anxious care must be given to the establishment by the State of such an organised system for the advancement of science and the utilisation of the work of scientific men as will be in harmony with similar organisations in neighbouring states — for examples, France, Germany, and Russia.

APPENDIX

Certain conclusions at which Prof. Zöllner arrives in the investigation of several points bearing on the theory which he defends are, quite independent of the latter, of high scientific value.

First, with reference to the density of atmospheric air, which (in accordance with the considerations mentioned in stating his views) he supposes to fill the interstellar space everywhere, he assumes for the purposes of calculation that the temperature of space is that of melting ice, and finds that the lower limit of density for a portion of gas in space is $\frac{1}{10^{346}}$ of that of the air at the earth's surface, a value so small that if a mass of air which, at its ordinary density upon the earth's surface, occupies a volume of one cubic decimetre (a litre), were reduced to the density expressed by this fraction, it would fill a sphere whose radius would not be traversed by a ray of light in less than 10^{98} years. These values indicate a density which would have no appreciable effect whatever upon rays of light or upon the motion of bodies in space, and which would become still less if the temperature of space be taken, with Fourier, at $-60°$ C., or with Pouillet, at $-132°$ C. But as every solid body must, by virtue of its gravitative energy, condense the gas into an atmospheric envelope round itself, the density of the latter will solely depend on the size and mass of the body. Prof. Zöllner finds by calculation that, for instance, the density of air thus forming an atmosphere round the moon must be $\frac{1}{10^{333}}$ of that of the air of the earth's surface. This is in accord with the fact that no trace of a lunar atmosphere has as yet been detected. But the values become very great for the larger planets, quite great enough to manifest absorptive effects upon the light reflected from them. Considering that there are peculiarities in the spectra of Uranus, Neptune, and also of Jupiter, which appear to indicate atmospheric influences, Prof. Zöllner's results are not without deep interest, and certainly suggestive of further inquiry.

Secondly, with reference to the supposition that a body may be at the same time under the influence of gravitative and electrical agencies, it was necessary for the author of this theory to discuse the quantitive difference in their effect upon ponderable masses at a distance. The discussion shows that, if the mass increases, gravitation preponderates over electricity; if the mass decreases sufficiently, the contrary takes place. It follows that the cometary nuclei, as masses, are subject to gravitation, while the attenuated vapours developed from them yield to the action of free electricity of the sun. Prof. Zöllner has based upon Hankel's numerous and careful researches on the determination of atmospheric electricity, in absolute measure, an analytical inquiry into the motion of a small sphere under the action of gravity and atmospheric electricity, which leads to some remarkable results. Supposing the free electricity of the sun to be not greater than that repeatedly observed on the earth's surface, and to be uniformly distributed, it would communicate to a sphere having a diameter of 11 millimetres and a weight of $\frac{1}{100}$ of a milligramme, and starting from the sun, by the time it had moved as far away as the mean distance of Mercury, a velocity per second of 3,027,000 metres, or 408·4 German geographical miles.* This velocity is such that in two days it would pass over a space of 70,540,000 German geographical miles, a magnitude quite of the same order as those recorded by cometary astronomy. The discussion was undertaken to prove that there is no need for assuming the existence of any unknown repulsive agency, but that electrical energy not greater than that observed on the earth's surface is amply sufficient to account satisfactorily for the phenomena presented by cometic trains.

SECTION B

CHEMICAL SCIENCE

OPENING ADDRESS BY THE PRESIDENT, DR. J. HALL GLADSTONE, F.R.S.

ONE of my fellow-students in the laboratory of the late Prof. Graham began the study of Chemistry because he wanted to be a Geologist, and he had read in some Geological Catechism that, in order to be versed in that science, it was necessary, as a preliminary step, to gain a knowledge of Chemistry, Mineralogy, Zoology, Botany, and I know not what besides. My friend became a chemist, and found that enough for the exercise of his faculties. Yet the catechism had truth on its side; for so intertwined are the various branches of observational or experimental research, that a perfect understanding of one can only be obtained through an acquaintance with the whole cycle of knowledge.

Yet, on the other hand, who can survey the whole field even of modern Chemistry? There was a time, doubtless, in the recollection of the more venerable of my auditors, when it was not impossible to learn all that chemists had to teach; but now that our "Hand Book" has grown so large that it would take a Briareus to carry it—and it requires a small army of abstractors to give the Chemical Society the substance of what is done abroad—we are compelled to become specialists in spite of ourselves. He who studies the general laws of Chemistry may well turn in despair from the ever-growing myriads of transformations among the compounds of carbon; we have agricultural, physiological, and technical chemists; one man builds up new substances, another new formulæ; while some love the rarer metals, and others find their whole soul engrossed by the phenyl compounds.

How is this necessity of specialisation to be reconciled with the necessity of general knowledge? By our forming a home

* Fifteen to a degree of longitude on the Equator.

for ourselves in some particular region, and becoming intimately conversant with every feature of the locality and their choicest associations, while at the same time we learn the general map of the country, so as to know the relative position and importance of our favourite resort, and to be able—when we desire it—to make excursions elsewhere.

To facilitate this is one of the great objects of the British Association. The different Sections are like different countries, and leaving the insular seclusion of our special studies, we can pass from one to the other, and gain the advantages of foreign travel.

From this chair I must of course regard Chemistry as the centre of the universe, and in speaking of other sections I must think of them only in their relation to ourselves. There is that rich and ancient country, Section A, which, according to the Annual Report, comprises several provinces—Mathematics, Astronomy, Optics, Heat, Electricity, and Meteorology.

Mathematics and Astronomy.—It was when the idea of exact weights and measures was projected into it that Alchemy was transmuted into Chemistry: as our science has become more refined in its methods its numerical laws have become more and more significant, and it may safely be predicted that the more closely it is allied with general physics, the greater will be the mathematical knowledge demanded of its votary. But till lately the Chemist and the Astronomer seemed far asunder as the heavens and the earth, and none could have foretold that we should now be analysing the atmospheres of the sun and stars, or throwing light on the chemical composition of planetary nebulæ and the heads of comets. There is in this, too, as in other things, a reciprocal benefit; for we are encouraged to hope that this celestial chemistry will reveal to us elements which have not yet been detected among the constituents of our globe.

Light, Heat, and Electricity.—How intimately are these associated with the chemical force, or rather how easily are these Protean forces transformed into one another! The rays of the sun coming upon our earth are like a chemist entering his laboratory; they start strange decompositions and combinations not only in the vegetable kingdom, but also among inorganic gases and salts; they are absorbed selectively by different bodies which they penetrate, or are refracted, dispersed, and polarised according to the chemical composition and structure of the substance. All this has been the subject recently of much scientific research; and I need scarcely remind you of the beautiful art of photography as one of the results of photo-chemistry, or of the benefits that have arisen from a study of circular polarisation, indices of refraction, and especially spectrum-analysis. In regard to the latter, however, I would remark that while the optical examination of the rays emitted by luminous vapours has yielded most brilliant results, there is another kind of spectrum-analysis—that of the rays absorbed by various terrestrial gases, liquids, and solids—which has already borne valuable fruit, and which, as it is far more extensively applicable than the other, may perhaps play a still more important part in the Chemistry of the future. The dispersion of the rays of the spectrum is certainly due to the chemical nature of the body through which they pass, but this is as yet almost unbroken ground waiting for an explorer. As to heat, it has ever been the tool of the chemist; and it would be difficult to over-estimate the significance of researches into the specific heat, or the melting- and boiling-points of elements and their compounds. The laws of chemical combination have been elucidated lately by thermo-chemical researches; it has been sought to establish a connection between the absorption or radiation of heat and the complexity of the chemical constitution of the active body; while the power of conducting heat, or of expanding under its influence, offers a promising field of inquiry. As to electrical science, one department of it—Galvanism—is strictly chemical: the electrolytic cell does our work; and indeed we claim half the electric telegraph, for while the needle may oscillate in Section A, the battery belongs to B.

Last in Section A comes Meteorology; and there are chemical questions concerning the constitution of the atmosphere, its changes, and the effect of its occasional constituents upon vegetable and animal life, which merit the deepest attention of the physiologist, philanthropist, and statesman.

If we turn to Section C, there is an outlying province belonging to us, namely, Mineralogy, which lies on the frontiers of Geology. A vast and very promising region is the origin and mode of formation of different minerals: this has attracted some explorers during the past year; but in order to investigate it properly the geologist and the chemist must travel hand in hand. Geology, in demanding of us the analysis of earths and ores, rocks and precious stones, repays us by bringing to our knowledge many a rare element and strange combination.

When we pass from C to D, that is, from the crust of the globe to the organised beings that inhabit and adorn it, we are introduced into new regions of research. When organic chemistry was young, Cuvier said of it, "Dans cette nouvelle magie, le chimistre n'a presque qu'à vouloir: tout peut se changer en tout peut l'extraire de tout"; and though we have now learnt much of the laws by which these magical transformations proceed, they far transcend the dreams of the French philosopher; there is yet no visible limit to the multitude of products to be derived from the vegetable and animal world, and their changes seem to afford boundless scope for chemical ingenuity. The benefit here is also reciprocal; for the physiologist enters by our aid into the wonderful laboratory of the living plant or animal, and learns to estimate the mode of action of different foods and medicines. There have lately been some good researches of this character; the difficulties are great, but the results to be achieved are worthy of any effort.

There may be little intercourse between us and the geographers in E, but we stand in no distant relationship with many of the subjects discussed in F. Economic science embraces the chemical arts from cookery upwards; such imperial questions as that of the national standards, or the patent laws, interest us greatly; the yield of our corn-fields is increased through our knowledge of the constituents of soils and manures, and upon many of the chemical manufactures depend in no small degree the commerce and the wealth of Britain.

In this most important branch of technical chemistry we need the skill of the mechanician; and this introduces us to Section G. One of the questions of the day will illustrate the connection between these varied departments of study. Statistics prove that the consumption of coal is now advancing, not at the gradual pace which recent calculations allowed, but at a rapidly accelerating speed, and they make the householder anxious about rising prices, and the political economist about the duration of our coal-fields. It is well known that there is a great waste of fuel throughout the country, as the maximum of heat produced by the combustion is very far from being ever utilised; and it will be for the combined wisdom of the chemist, physicist, and mechanician to devise means for reducing this lavish expenditure, or to indicate other available sources of power.

While this correlation of the natural sciences renders it desirable that the votary of one should have some general acquaintance with the rest, the correlation of all knowledge shows that no education can be complete which ignores the study of nature. A mind fed only on one particular kind of lore, however excellent that kind may be, must fail of proper nourishment. I am not going to say a word against philological studies; I am too fond of them myself for that; and I could wish that the modern languages were taught more, and the classic languages were taught better than they are at present. What I do contend for is, that chemistry (or some cognate branch of science) should have an honoured place in the education of every English lady and gentleman. I say purposely "an honoured place," for at present where chemistry is introduced we too often find the idea latent which was expressed by one principal of a lady's college, who told a friend of mine that he was to give the girls a course of pretty experiments, but she did not expect him to teach them anything; and we know that when boys repeat chemical experiments at home it is looked upon as an amusement, a philosophical one no doubt, but rather objectionable, inasmuch as they spoil their mother's towels and singe their own eyebrows.

Of course some knowledge of chemistry is indispensable for a large number of our manufacturers, and for the medical profession, while it is extremely valuable to the farmer, the miner, and the engineer. It will also be readily granted that information about the air we breathe, the water we drink, the food we live upon, the fuel we burn, and the various common objects we handle, must be of service to every man. But we are met by the advocates of the old system of education with the remark that the value of school-teaching does not depend so much upon the information given as upon the mental training. This I admit; though it seems to me that if the same training can be secured by two studies, the one of which (like the making of Latin verses) gives no information at all, and the other (like chemical analysis) imparts some useful knowledge, we should

prefer the latter. But I hold that, as a means of educating the mental faculties, chemistry, faithfully taught, has in many respects the advantage over literary studies. There is superabundant scope for the exercise of the memory; the powers of observation are developed by it to a wonderful degree; the reasoning powers may be well disciplined on the philosophy of chemical change, or the application of the laws of Dalton, Mitscherlich, and Avogadro; while the imagination may be cultivated by the attempt to form a conception of the ultimate particles of matter, with their affinities and atomicities, as they act and react upon one another under the control of the physical forces.

Our Government insists on a certain standard of education for all who are allowed to teach in our elementary schools. In those schools which receive no State aid it is only public opinion which can insist that the teacher shall be duly qualified himself. Such bodies as the British Association form this public opinion, and will deserve well of their country if they demand that these masters and mistresses shall know something of the material universe in which they move, and be able to impart to every child such scientific knowledge as shall afford him an interesting subject for thought, give him useful information, and discipline his mental powers.

Among the many services rendered by the monthly reports of the progress of chemistry which the Chemical Society publishes, and the British Association helps to pay for, there is one which is rather salutary than pleasant. They bring prominently before our notice the fact that in the race of original research we are being distanced by foreign chemists. I refer not to the quality of our work, about which opinions will probably differ, but to the quantity, which can be determined by very simple arithmetic. This is a matter of no small importance, not only for the honour of England, but still more for the advancement of science, and the welfare of man. From the Physical Chair of this Association last year, a note of warning was uttered in the following words, after a reference to the sad fate of Newton's successors, who allowed mathematical science almost to die out of the country:—"If the successors of Davy and Faraday pause to ponder even on *their* achievements, we shall soon be again in the same state of ignominious inferiority." The President of the Chemical Society, also in the last Anniversary Address, drew attention to the diminished activity of Chemical discovery, and to the lamentable fewness of original papers communicated. He traces this chiefly to "the non-recognition of experimental research by our universities," and suggests that in granting of science-degrees every candidate should be required, as in Germany, to prove his ability for original investigation.

Concurring in this, I would remark that other causes have also been assigned, and other suggestions have been made. There is the small recognition of original research even by our learned societies—at least such recognition as will come home to the understanding of the general public. It is true the Fellowship of the Royal Society is awarded mainly for original discoveries, and there are two or three medals to be disposed of annually; but these distinctions fall to the lot of the seniors in science, often men who are beyond the need of encouragement, and though they doubtless are serviceable as incentives, there is many a beginner in the honourable contest of discovery who is too modest even to hope for the blue ribbon of science. While the Victoria Cross is awarded to few, every soldier who has borne part in a victory expects his clasp, and so might every man who has won victories over the secrets of nature fairly look for some public recognition. It has been suggested, for instance, that the Royal Society, in addition to the F.R.S., might institute an Associateship, with the letters A.R.S., designed exclusively for those younger men who have shown zeal and ability in original research, but whose discoveries have not been sufficient to entitle them already to the Fellowship. It is suggested, too, that the Chemical Society might give some medal, or diploma, or some similar distinction, to those who contribute papers of sufficient merit.

But beyond this is the non-recognition of scientific research by society in general. We can scarcely expect the average enlightened Englishman to be anything but scared by a graphic formula, or a doubly sesquipedalian word containing two or three compound radicals; but he need not continue to talk of the four elements, or of acids being neutralised by sugar. But, indeed, the so-called educated classes in England are not only supremely ignorant of science, they have scarcely yet arrived at the first stage of improvement—the knowledge of their own ignorance. Then, again, there is the excessive preference of practical over theoretical discoveries; or rather, perhaps, the inability to appreciate anything but tangible results. Thus a new aniline compound is nothing unless it will dye a pretty colour; if we speak of the discovery of a new metal by the spectroscope, they simply ask—What is it useful for? and the rigorous determination of an atomic weight has for them no meaning nor interest nor beauty. The general appreciation of science must be of gradual growth; yet there are wealthy men who know its value, and who might well become the endowers of research. There are, indeed, at present funds available for the purpose—such as the Government grant, and the surplus funds of this association; but the money is given simply to cover actual outlay, and this, though very useful, scarcely meets the case of those young philosophers who have no balance at their bankers, and yet must live. Will not some of these wealthy men endow experimental scholarships, or professorships, in connection with our colleges, institutions, or learned societies? As an instance of the good that may be effected in this way, may be cited the Fullerian professorships; and as a very recent example, worthy of all honour, may be mentioned the purpose of Mr. J. B. Lawes, not only to continue his elaborate experiments at Rothamsted throughout his lifetime, but to place his laboratory and experimental fields in trust, together with 100,000*l*., so that investigations may be continued in the wider and more scientific questions which the progress of agriculture may suggest.

The Government of our country, through the Science and Art Department, renders good assistance to the teaching of science; and if the recommendations of the Royal Commission on Scientific Instruction and the Advancement of Science be adopted, the introduction of practical examinations for the obtaining of certificates for a superior grade of science-master will certainly foster a spirit of research. It has been generally held that the promotion of research is within the legitimate scope of Government; and where, as in the case of Aristotle and Alexander, genius and industry have been sustained by princely munificence, the happiest results have ensued. Yet this question of Government aid is a delicate one: for genius, when put into swaddling clothes, is apt to be stifled by them; and were science to depend on political favour or imperial support, it would be a fatal calamity. Still I think it will be everywhere admitted that science might with propriety be subsidised from the public funds in cases where the results may be expected to confer a direct benefit upon the community, and where the inquiry, either from its expense, its tediousness, its uninteresting character, or the amount of co-operation required, is not likely to be carried out by voluntary effort. The astronomical work which is paid for by Government bears upon navigation, and answers both these requirements; and it is easy to conceive of inquiries in our own science that might equally deserve the assistance of the State. Some of these might also more than repay the outlay, though perhaps the profit would not fall into next year's budget.

I believe that this diminution of original research, which we deplore, is partly due to a cause in which we rejoice—the recent extension of science-teaching. The professorships of chemistry are scarcely more numerous now than they were twenty years ago, while the calls upon the professor's time in conducting classes or looking over examination papers have greatly augmented. Thus some of the most capable men have been drawn away from the investigation of nature; and in order to afford them sufficient leisure for the purpose, means must be found to multiply the number of the professorships in our various colleges.

While the rudiments of science are being infused into our primary education, now happily becoming national, while physical science is gradually gaining a footing in our secondary and our large public schools, and while it is winning for itself an honoured place at our universities, it is to be hoped that many new investigators will arise, and that British chemists will not fall behind in the upward march of discovery, but will continue hand in hand with their continental brethren thus to serve their own and future generations.

SECTION C

GEOLOGICAL SECTION

OPENING ADDRESS BY THE PRESIDENT, R. A. C. GODWIN-AUSTEN, F.R.S.

THE Geological Section is fortunate in respect of this year's place of meeting of the British Association. The county of Sussex presents a wide range to the geological observer; there

is the great fresh-water Wealden series, next the entire Cretaceous group, then portions of the Nummulitic group, including the unique fossiliferous beds of Bracklesham. At Selsey is to be seen a remnant of a definite Tertiary period, of which at no other place in England is there any record. Lastly, the evidence as to local conditions during the Glacial period is peculiarly interesting. This rich field has not wanted for competent labourers, foremost amongst whom must be named Dr. Gideon Mantell, who in his day did so much by his zeal and knowledge to diffuse a taste for his favourite pursuit. There must also be added the names of Mr. Martin, of Pulborough, and Mr. Dixon, of Bognor.

It might perhaps be a fitting preliminary to the local communications which we may expect in the course of this meeting, should I here give a summary of what has been already done with reference to the geology of this S.E. of England; but to many who meet now in this section, very much of such a survey would be familiar. Instead of this I propose to call attention to what is the peculiar feature of our local geology, namely, its great Wealden formation, the product of that vast lake or sound, which at a time before a particle of the chalk hills of Sussex had been formed, covered an area larger than the whole of the south-east of this island. What I shall endeavour to put before you, a point not generally understood, is with reference to the place of formations akin to our Wealden, in the records of past time, and enable you to realise what were then the geographical conditions of the northern hemisphere, what the distribution and extent of other areas of fresh water, the equivalents of our Wealden.

Place of the Fresh- and Brackish-water formations on the Geological Scale

If a general view be taken of the successive physiographical conditions of bygone geological periods, it is seen in respect of each, such as those of the Palæozoic period, or of the Mesozoic such as for the Jurassic, Cretaceous, and Nummulitic, which all represent distinct periods of past time, and are all the products of purely marine conditions, that what is at present terrestrial surface, was at those times to a great extent covered by water, and that the great geological formations are merely old sea-beds.

When on a projection of the northern hemisphere, the known extent of each of these old seas is represented, as on the accompanying maps, it is also seen to how great an extent at those times the area of water exceeded what it has at present; at each of these great periods the northern hemisphere must have presented just such a preponderance of water which the southern hemisphere does at present; and it is further to be remarked how closely the area of one period of northern geological submergence corresponds with the others, as the Nummulitic with the Cretaceous, and the Cretaceous with the Jurassic. Whatever the course, there is to be seen in this a recurrence of like conditions at enormously long intervals of time.

If next the internal evidence to be derived from these Mesozoic formations be taken, it is to be seen, as is familiar to most geologists, that each, when most complete, presents a like order of change, from its older to its newer portions.

Over the mid-European area shallow-water accumulations, such as shingle and sand-zones (infra-Liassic), preceded the deeper water Lias-shales and limestones. Jurassic oolites follow upon these, indicating somewhat decreased depths for the Middle Jurassic series. Oscillations of surface mark this period; and with respect to its physiography, Mr. Darwin has given his opinion that the Malay Archipelago, with its numerous large islands separated by wide and shallow seas, probably represents the former state of Europe, when the Middle Jurassic beds were accumulating. Next follow deep-water depositions, when the widely spread Kimmeridge series was formed, ending upwards with the Portland beds.

The Cretaceous group, as it is exhibited here in the South of England, where its vertical thickness is very great, presents in its lower beds (Neocomian) a marine fauna which indicated to Edward Forbes a limited sea, with depths not exceeding eighteen fathoms. Sand-zones hundreds of feet in thickness overlie these. The argillaceous Gault, in its composition and fauna, is a deep-water deposit, followed by shallower-water sands (Upper Green Sand) indicating oscillating conditions as to depth of water. To which succeeds the widely-spread oceanic depositions of the white chalk. Here recurring conditions come about in like order as in the Jurassic series; and a corresponding illustration might be derived from the physical changes indicated in the course of the Nummulitic period.

In respect to none of these marine geological formations is there any indication whatever that one passed into, or was in continuous sequence with, another, either stratigraphically or geologically; on the contrary, wherever there is apparent continuity, either upwards or downwards, it is by change or transition from one set of conditions to another wholly different. The purely Marine Upper Silurian beds of the Welsh border are followed conformably by the Old Red Sandstone, which last is now universally accepted as a lacustrine formation, the place of which, in time, was intermediate between the middle Palæozoic group, and the Upper or Carboniferous, which commenced with the so-called "Devonian." The positions and extent of the "Old Red" lacustrine beds in all parts of the British Islands indicate, even at this day, to what extent Silurian sea-bed had become terrestrial surface, to which the lacustrine basins were subordinate.

In the contrary direction, and in our own area, the next group indicating widely spread marine conditions, that represented by the Devonian and Mountain limestone formations, sets in, as in North Devon, with shallow-water sands, and a marine fauna (Lower Devonian) in sequence in "Old Red" depositions, with fresh-water fishes and crustaceans. There is no continuity from "Old Red" into the earliest Devonian beds, any more than from uppermost Silurian into Lower "Old Red" (Phillips's Geology of Oxford, pp. 77—79).

The later Palæozoic ocean-floor, now one mountain limestone, in turn become terrestrial surface on which the Coal-measures were accumulated, and over which the abundant vegetation of that period established itself. The Coal-measures represent so much of the surface of their time, as from position favoured expanses of fresh and brackish waters, and of alterations from one set of conditions to the other.

Geologists are familiar with the amount of physical change which took place over the European area after the coal-growth period. The subsequent condition of surface which resulted is still distinctly traceable. The Perm-Trias period presents true Aralo-Caspian conditions, physically defined, subordinate to the same Continental area.

The marine Jurassic series next in sequence was succeeded by that period of terrestrial conditions to the more detailed physiography of which I here propose to call your attention. It may suffice on this occasion to state that at the end of the great Cretaceous period, the area of those seas, in our hemisphere down to depths at which the great chalk-floor had been deposited, became part of a continental land, on which the fresh-water formations of the times which preceded the marine Nummulitic were accumulated.

These evidences of successive physical conditions over the northern hemisphere indicate an order of recurrence of corresponding conditions, and, as already noticed, of a progress of change which, in the course of each period, came about in a corresponding order. Great periods, during which wide marine conditions prevailed, alternated with others of wide terrestrial surfaces. The marine periods, as we measure them by the products of the agents which seas and oceans call into action, must have been of vast duration. In like manner we may feel assured that the great fresh-water formations are not, as some geologists have supposed them, mere subordinate parts of the great marine groups, as our "Wealden" of the "Cretaceous," but rather true intermediate groups, of equal geological value with them in the estimate of past time.

The Wealden Formation

Mr. Martin proposed this designation for the assemblage of fresh-water depositions exhibited in the counties of Kent, Surrey, and Sussex, and which may be described generally as consisting of thick accumulations of sands and sandstones, for a lower or earlier part, surmounted by a great argillaceous deposit (Weald clay). Mr. Webster suggested the propriety of uniting the Purbeck beds Hastings sands, and Weald clay into one group, the whole being mainly a consecutive fresh-water series. It must be understood, however, that there is not a definite line separating the Hastings sands from the Weald clay; all that is signified is that sands predominate for the lower, and clays for the upper portion of the Wealden depositions; but just as thick bands of clay occur in the lower series, so bands of sandstone occur in the upper.

The arrangement adopted by the Geological Survey, in descending order, is Weald clay, Tunbridge Wells sand, Wadhurst clay, Ashdown sands, Ashburnham beds, which in Sussex are the equivalent of the Purbeck beds of Dorsetshire.

The Lower Sands are well seen on the coast at Hastings,

whence they took their name, and extend thence continuously to near Horsham, rising into the central ridge of the Wealden elevations of St. Leonard's, Tilgate, and Ashdown Forests. On every side this tract is bounded by the Weald Clay, which extends to the base of the escarpment of the Lower Green Sand, beneath which it passes.

This surface of fresh-water strata, so defined, extends for seventy miles from E. to W., and has a breadth from N. to S. of thirty-five miles. Over the whole of this area the fresh-water depositions attain a great thickness; the lower sandy group may be taken at 820 feet, and the Weald Clay at 450 feet at least.

To realise the conditions under which these accumulations were formed, the now upraised central Sandstone ranges must be put back to their original horizontal position, and the whole series must be regarded as the infilling by fresh-water rivers of what was an area of depression, with reference to the terrestrial surface of the time. This Wealden formation can be traced far beyond the limits of the denudation of the S.E. counties. In a southerly direction it occurs in the Isle of Wight, with its two divisions of Weald clay and Lower sands. In this quarter the Weald clay is reduced to a thickness of 68 feet. In a westerly direction (Swanage Bay) the Wealden sands have a great thickness, and are surmounted by only a thinnish band of Weald clay or deep-water deposit, and both divisions decrease rapidly, in the extension of the formation across the Isle of Purbeck, and have not been recognised in the Isle of Portland, from which, if they even extended there, they must be denuded off.

In a northerly direction, several sections about Oxford, as from Shotover Hill to Great Hazeley, from Wheatley to Tetsworth, from Brill through Long Crenden to Thame, from Whitchurch to Aylesbury, extending from S.W. to N.E. for a breadth of thirty miles, show Purbeck beds, and fresh-water ferruginous sands passing beneath Cretaceous beds. It is obvious that the Wealden formation has been cut back in this quarter, and that originally it had a much greater extension. In this quarter, too, the ferruginous sands overlap the Purbeck beds, showing that the lake had here widened its area beyond the dimensions of the Purbeck lake.

From Oxford* to the Vale of Wardour is an interval of seventy miles, from over which the Portland Oolite has been removed, except at Swindon, at which place there are beds which are unmistakeably referable to the Purbeck group; and it is a fair inference that it is to this denudation that the absence of the lacustrine depositions is to be attributed, which everywhere on our area, and on much of that of Continental Europe which was adjacent, follow next upon the Portland stage. Such being the case, the smallest possible dimensions which can be assigned to the great Wealden lake, are that it extended from beyond Aylesbury to Portland for 120 miles, and from Portland to the Boulonnais for 200 miles.

From Rye to Portland the Wealden beds pass out of sight beneath the level of the English Channel. The valley of the Channel is the result of the disturbance which produced the E. and W. lines of the South of England, and was produced subsequently to the Nummulitic period.

Dr. Fitton remarks that the subdivisions of the Wealden formation, especially at its upper part, being in some measure arbitrary, it is difficult to determine to which of the three groups any outlying depositions ought to be referred. (Geol. Trans. vi., p. 323.)

Such a difficulty existed when corresponding portions of a formation were supposed to require an agreement in mineral character and composition; but it happened at all times, as now, with respect to the depositions within areas of water, whether of lakes or seas, that the beds which were strictly equivalent in respect of time, varied from place to place, from marginal shingle to submarginal sand-zones, and deeper and most distant argillaceous ar calcareous mud-beds. Considered in this way, the distant Oxford and Buckingham portions of the Wealden formation, are referable to the submarginal accumulations of the great lake, and may be synchronous with "Wealden clays." For the threefold division of the Wealden series into Purbeck beds, Hastings sands, and Weald clay, must therefore be substituted the more natural divisions of Lower Wealden for the Purbeck series, and Upper Wealden for the series as exhibited in the south-east of England may be of sand and sandstone or Weald clay, according to local conditions of depth.

There are indications that changes in the area surrounding the Wealden formation took place in the progress of that series; the lower and earlier sandy deposits indicate only inconsiderable depths of water. Yet the vertical thickness of the series may be estimated at nearly 2,000 feet; for that area at least progressive depression must have been going on, but not uninterruptedly. As regards the upper and lower divisions of the formation, the difference consists in the greater coarseness of the detritus of the upper, and in the evidence of strong currents settling in definite directions in an extension of the area and of an increased depth, so that at the later stage a central area of deep-water depositions may be defined as well as the directions in which such conditions thinned away. Great changes took place in the depth of the water of the lake, as indicated by the alternations of the drift-sand beds with deeper-water mud deposits, and in places by the conversion of lake-bed into land-surface, upon which plant-growths established themselves for considerable periods of time, and which were again submerged.

Such changes as these seem to imply change in the physical geography of the land region to which this great fresh-water area was subordinate—such, for instance, as would give rise to larger rivers, great influx of fresh waters, and stronger currents.

The successive conditions indicated by the great Wealden group, as a whole, are, for the first stage, that of an extensive shallow lake, or sound, at the sea-level of the time, the inflowing waters to which were largely charged with lime derived from the surface of Portland Oolite, from which they came. This is the Purbeck stage, which commenced with a long period of purely fresh-water conditions. Brackish-water conditions followed with a change of fauna. Mollusca, such as *Corbula*, *Cardium*, *Modiola*, *Rissoa*, appear, presenting—as was observed by the late Edward Forbes—the change of character which the Caspian-sea Molluscs have at present in adapting themselves to brackish-water.

During the Middle Purbeck series the alternations from fresh to brackish water conditions were frequent, and apparently of short duration, till finally it was closed as it commenced, by a thick set of purely fresh-water depositions.

The changes in the Purbeck series are readily accounted for by reference to areas of water such as occur on the American coast at present, and which may be salt or brackish, according to the extent to which the sea-waters are excluded by sand-bars from mixing with the fresh waters flowing from the land.

The S. and E. coast-line of our Wealden lake must be looked for beyond the area of our island.

Wealden Formations of the European Surface

The elliptical form of the Wealden elevation and denudation has its completion on the east in Picardy, across the English Channel. In the Boulonnais there occur ferruginous sands like those of Shotover, full of fresh-water shells (*Unio*) overlying Purbeck limestone, and passing beneath the Cretaceous formation, just as happens in this country. These Wealden beds are not now of any considerable thickness, having been reduced by the denudation of the district. They are so mixed up with pebble-beds in places as clearly to indicate a marginal line, which may safely be placed to the north of the Boulonnais denudations; for the Wealden depositions proper hardly rise to the level of the Palæozoic rocks of Marquise. The great fissures and pot-holes in the limestones there, which have been produced under subærial conditions, and filled with sand, mould, and much vegetable matter, had been produced antecedently to the deposition of the Gault over that area.

The Wealden beds of the Boulonnais were formed beneath the waters of the same lake as our own. This fresh-water area had an extension southwards; thus M. D'Archiac refers the mottled clays beneath the iron sands and sandstones at Havre to the Wealden series of this country, so that the limits of our lake in that direction, or in the south, lay somewhere along the line of the English Channel.

Sixty miles to the south of the Boulonnais is a district known as the Pays de Bray, which is an elliptical valley of elevation and denudation, like our own Wealden on a small scale, extending from Beauvais to Neufchâtel, a distance of forty-five miles. In this denudation the lowest beds exposed belong to the marine Jurassic series (Portland Kimmeridge). Next above the Portland stone is a Wealden formation. "Les dépots regardés comme fluviatiles sont les plus voisins de létage Portlandien et forment le groupe inférieur du terrain Néocomien" (Graves, Oise, p. 55). The remains of the fishes, *Cyrenæ*, *Cyprides*, and ferns are such as occur in our Wealden.

* *Vide* evidence as to range of Wealden deposits, Phillips' "Geology of Oxford."

The thickness of this fresh-water formation is inconsiderable compared with our Wealden. The separation of the fresh-water formation from the marine Portland is well defined; not so that betwixt the Wealden and Neocomian. Here, as in the Punfield section, the fresh-water and marine conditions seem to have alternated, and the manner in which this takes place suggests the supposition that the influx of a considerable body of fresh water from the land of the time took place not far from this place.

Neufchâtel is seventy miles south of Boulogne; the Wealden beds, as we have seen, indicate that the series extended southwards from Marquise; and it is no unreasonable supposition that the deposits of this Pays de Bray were formed under the waters of the same lake as were those of our own Wealden.

Such, then, were the dimensions of the Wealden Lake or Sound; it extended from parts of Buckingham, on the north, half across the English Channel on the south, a breadth of 160 miles. In the contrary direction it reached from Wiltshire into France, beyond Beauvais for 250 miles.

In another part of France, Depart. de l'Aube, Mr. Cornuel has described a fluvio-lacustrine formation between the Jurassic and Cretaceous formations at Vassy, containing *Iguanodon*, several species of *Unio* and *Planorbes*. The lacustrine formation at Cimey is in a corresponding geological position.

In the Jura, Villers, Forcine-le-bas, the Portland beds are followed by hard bluish marls, calcareous marls, and gypsum, the whole very like our Purbeck series. These lacustrine formations are interesting, as they seem to show the existence of a chain of lakes stretching across France into Switzerland for 260 miles, with a general direction parallel to the axis of Artois, and thus connected as part of one great lake system with our Wealden.

In France, Depart. des Deux Charentes, some 350 miles due south of our Sussex coast, there occurs a great fresh-water formation in intermediate position between the Portland Oolite and what were then the lowest beds of the Cretaceous series. Like our own Wealden, this also is exhibited over a surface from which the Cretaceous strata have been denuded. This formation has engaged the attention of many French geologists, more particularly of M. Coquand, who has determined its age and purely lacustrine character, and who puts it as the equivalent of the Purbeck beds of England; in this he seems to be guided by the general likeness as to composition and the presence of *Physa Bristowi*, a well-known Purbeck species.

The sequence of events at this place was as follows:—Subsequently to the formation of the Portland Oolite the sea-bed became terrestrial surface, and subsequently again to that, a depression extending from Chateauneuf, near Angoulême, to beyond the Island of Oléron, became the site of a great fresh-water lake. From St. Jean d'Angely to Chateauneuf is a distance of thirty-five miles, and from Chateauneuf to Oléron, S.E. to N.W., is upwards of 100 miles; but then figures do not give the full dimensions of this fresh-water area, as its deposits have been reduced by denudation on the north, and passes beneath the Cretaceous series on the south. The original lake must have had a westerly extension seawards, and its area must have equalled that of Lake Ladoga.

The feeders of this lake are more easily accounted for than in the case of our own Wealden. Such a lake would necessarily have received all the streams descending from the western slopes of a terrestrial surface of very ancient date, namely, the granitic district of Central France.

In North Germany there is a well-exhibited Wealden formation, extending from Bentheim by Rheine, with a breadth from north to south of twelve miles. From Ibbenhüsen it reaches on the south side of the Triassic and Palæozoic axis of Osnaburg for many miles. It is everywhere in an intermediate position betwixt the Upper Jurassic and Lower Cretaceous formations. On the north of the axis it spreads for seventy miles to Minden, certainly as far as north as the Steinhuder Meer to near Hanover, and as far south as the Hils district. From west to east the ascertained extent of this lake is upwards of 120 miles.

At Bentheim the dark Wealden clays, with bands of limestone and spathic iron ore, with *Cyrenæ*, *Melaniæ*, &c., like those of Sussex here, are 400 metres thick, so that the real dimensions of this northern lake were very much greater than has been here given.

These large lacustrine areas imply that there was at that time a corresponding extent of terrestrial surface. And it may fairly be asked, what is the geological evidence of such a condition? There occur over parts of Belgium the remains of such a terrestrial condition of surface beneath the lower Cretaceous beds there (Tourtia) consisting of variegated sands and clays, with much diffused vegetable matter, and occasionally with beds of lignite; such surfaces can be traced along the line of the Belgian coal-field (Mons), and overlying parts of the Palæozoic series. These beds are not of sufficient dimensions to be termed lacustrine, but have all the characters of the deposits of ponds and marshes; and M. Dumont has properly referred them to the Wealden period. Such like evidence of terrestrial conditions recur over a wide European area; such are the subcretaceous beds of pisiform iron ore, of subaerial origin, and the wide area over which fresh-water sands with *Pterophyllum*, *Pecopteris*, *Cycadises*, &c., of our Wealden are met.

The break betwixt the marine Jurassic and Cretaceous formations is very distinct, physically and zoologically; and it may be fairly asked, in what way do the forms entombed in the products of the intercalated period of terrestrial surface conditions serve to throw any light on what took place during that long interval of time?

That the earliest Purbeck-Wealden fauna should have Jurassic relations, that is to say, that it must have synchronised with such, wherever that formation was being continued, is only what might be expected; for the whole of the bed of the Jurassic seas in the northern hemisphere was not converted into subærial surface at once. Midway in the course of the Purbeck-Wealden series there is evidence of the recurrence of marine conditions with Portlandian forms, such as *Ostra distorta* and *Hemicidaris purbeckensis*. It was on this ground that Prof. E. Forbes suggested the propriety of placing the Purbeck series with the Jurassic in systematic grouping; for it showed that up to the time of the Middle Purbeck beds the marine fauna of the nearest seas was still Jurassic.

The considerable extent of land surface in the northern hemisphere during the whole of the marine Jurassic period, and the local conversion of any portions of such sea-bed into land, whether in the course of the deposition of the Lower Jurassic series (Stonesfield), or between the Lower and Middle (Brora, Staffin), or at the uppermost stage (Portland), would be merely the addition of so much more to the existing land.

The forms of life which would colonise such new surfaces would be such as migrated from the older adjacent lands; if any change should have taken place in the fauna or flora of such old land-surface, in the course of the production of the marine Jurassic series, it would be recorded in the forms entombed in the lacustrine formations of the several stages here alluded to.

The fossil plants and fresh-water shells from Brora, Lock Staffin, and the Wealden seemed at first to certain well-known and competent naturalists to show that an identical set of forms ranged throughout. A minutely critical examination has since indicated shades of difference; yet it may be questioned whether such are greater than different localities in the same zoological province now present, allowance being made for differences of these old estuarine and lacustrine areas.

The relations of the land-surface forms of the Wealden formations of the European surface has been recognised by all naturalists as being Jurassic rather than Cretaceous. In this the Purbeck-Wealden group offers an exact counterpart zoologically and geologically, of the Permian-Trias group; just as the marine zoological relations of the Permian are Palæozoic, so those of the Purbeck are Jurassic; and when next after each of these, and after the wide spread of purely marine conditions over the northern hemisphere at each period, the marine fauna is seen to have undergone a complete change, in the one case Palæozoic forms go out, and for ever, to be succeeded by Mesozoic or Jurassic; in the other Jurassic forms go out and the Lower Cretaceous come in, and are those which interchange with the uppermost Wealden fauna at Punfield and the Pays de Bray.

Did time allow, I might call attention to the results of the labours of the distinguished palæontologists who have described the forms of life of the Wealden period, both of animals and plants. From them we know that crocodiles and chelonians, referable to many genera, abounded in the Wealden waters. These, with the cycadeæ of the land, sufficiently mark the temperature of that time as being much higher than it is here at present. With respect to the numerous large terrestrial Dinosaurs, it is observable that as yet they are nearly all peculiar to our Wealden lake. The relative level of this lake seems throughout to have been such as to have admitted of easy communication and interchange with the waters of the sea; and this condition may serve to account for some of the peculiarities which its fauna presents.

SECTION D

SUB-SECTION ANTHROPOLOGY

Opening Address by the President, Colonel A. Lane Fox

After some opening remarks, the author said :—"As one of those who for some years past have taken part in those practical measures which have been as yet only partially and feebly instrumental in promoting the union of the anthropological sciences, it occurs to me that the present occasion may be a fitting one for expressing some of the views which have suggested themselves to me in the course of my experience whilst so engaged. I propose, therefore, after considering briefly the existing phases of one or two of the more important questions with which anthropology has to deal, and saying a few words on the relative value of certain classes of evidence, to speak of the anomalies and misadjustments in what may be called the machinery of anthropological science, defects in the existing constitution of some of the societies which either are or ought to be included amongst the branches of our great subject. In the remarks which I shall offer upon this subject it is not my wish that any undue weight should attach to the particular suggestions which I may be called upon to make as in any way emanating from this chair. My object is rather to draw the attention of anthropologists to the urgent necessity which exists for better organisation than to propound any particular schemes of my own; indeed, so rapidly do our views change in the infancy of a science that I should be sorry to bind myself over to accept many of my own opinions a couple of years hence, for there is, perhaps, no branch of study to which we may more truly apply the dictum of Faraday that "the only man who ought really to be looked upon as contemptible is the man whose ideas are not in a constant state of transition."

Amongst the questions which anthropology has to deal with, that of the descent of man has been so elaborately treated, and at the same time popularised by Mr. Darwin, that it would be serving no useful purpose were I to allude to any of the arguments on which he has based his belief in the unbroken continuity of man's development from the lower forms of life. Nor is it necessary for one to discuss the question of the *monogenesis* or *polygenesis* of man. On this subject also Mr. Darwin has shown how unlikely it is that races so closely resembling each other, both physically and mentally, and interbreeding as they invariably do, should on the theory of development have originated independently in different localities. Neither are we now, I think, in a position to doubt that civilisation has been gradually and progressively developed, and that a very extended, though not by any means uniform, period of growth must have elapsed before we could arrive at the high state of culture which we now enjoy. The arguments of our sectional president, Sir John Lubbock, on this subject may, I think, be accepted generally as those of the best exponent of these views in our own time; such was the opinion, as we learn from various authorities, that was held by most of the ancient authors, and it tallies in all respects with the phenomena of progress now observable in the world around us, or which have been recorded in history. . . .

How far the first beings worthy of being called men may have possessed superior organic psychical powers to their predecessors, and whether the superior functions of the human mind were developed slowly or rapidly is a point on which it is more difficult to form an opinion. In contrasting the psychical differences between man and the lower animals, it is so invariably the practice, and indeed so impossible to avoid including in our estimate of the human intellect all that conscious education and unconscious infantile culture has added to the powers of the mind, that unless we were able to try the experiment of the Egyptian king, and send children to be brought up with animals apart from all intercourse with the human race, we could not place ourselves in a position to compare truly the innate capacities of the two, or to form any just estimate of the difficulties which primæval man, even supposing him to have possessed mental powers equal to our own, must have encountered in the first stages of human culture. It has been shown by Prof. Huxley and others that there is really no cerebral barrier between men and animals, nor does it appear beyond the pale of possibility that a slight increase in the vividness or permanence of the impressions of external objects upon the mind over that possessed by the brutes, might, by marking more clearly the sequence of events, be sufficient to imitate that faculty for improvement which is the special characteristic of man.

Be that as it may, there is, I believe, nothing in the constitution of our own minds which can lead us to doubt that the progress of our first parents must have been extremely slow, or that the slight improvement observable in the implements of the neolithic over those of the palæolithic age, did actually correspond to the continuous progression of human culture during enormous periods of time.

Now, if it is true that during the countless ages included in the palæolithic and neolithic periods, which we know to have been marked by great geological changes, by the union and separation of great continents, by great changes of climates, and by the migration of various classes of fauna into distant parts of the earth, the progress of mankind was as slow and gradual as we are warranted in supposing it to have been by the relics which have been left us, considering how short the period of history during which the rapid development of civilisation has taken place is, in comparison with the long periods of time of which we have been speaking, and that progress is always advancing at a rapidly increasing ratio, we need find no difficulty in supposing that where savages are now found in the employment of implements corresponding to those of the neolithic age, they present us with fairly correct pictures of neolithic culture, being really in point of time only a little behind us in the race of improvement. It is reasonable also to suppose that the use of such tools by savages, and the culture associated with them, was also like that of our neolithic parents inherited from lower conditions of life, and that being slow and continuous, it was sufficiently stable to enable us to trace connections between people in the same stage now widely separated, and between them and our own neolithic ancestors.

The most remarkable analogies are in reality found to exist between races in the same condition of progress, and it is to the study of these analogies, with the view of ascertaining their causes and histories, that the attention of anthropologists has of late been especially drawn, and on this subject I propose to make a few observations.

There are two ways in which it has been attempted to account for those analogous coincidences, one by the hypothesis of inheritance to which I have already referred, the other by the view of the independent origin of culture in distant centres, assimilated in consequence of the similitude of the condition under which it arose. It is said that the wants of man being identical, and the means of supplying those wants by external nature being alike, like causes would produce like effects in many cases. There can be little doubt that many remarkable analogies have arisen in this manner, especially amongst the very variable myths, customs, religions, and even languages of savage races, and that it would be dangerous to assume connection to have existed except in cases where a continuous distribution of like arts can be traced. On the other hand, we should commit a grave error if we were to assume the hypothesis of independent origin, because no connection is found to exist at the present time, for we are as yet almost entirely ignorant of the archæology of savage and barbarous races. It is but fifteen years since we began to study the prehistoric archæology of our own race, which has already carried us so far on the road towards connecting us with savages; and can we say what further connections may be brought to light when the river drifts of such rivers as the Niger or the Amazons come to be studied. Nor can it fairly be said that the wants of mankind are alike in all cases; for if we adopt the principle of evolution, it is evident that the wants of man must have varied in each successive stage of progress, diminished culture being associated with reduced wants, thus carrying us back to a condition of man, in which, being analogous to the brutes, he could scarcely be said to have any wants at all of an intellectual or progressive character.

It would be an error to apply either of these principles exclusively to the interpretation of the phenomena of civilisation. In considering the origin of species, we are under the necessity of allying ourselves either on the side of the *monogenists* or that of the *polygenists*, but in speaking of the origin of culture, both principles may be, and undoubtedly are, applicable; there is in fact no royal road to knowledge on this subject by the application of general principles; the history of each art, custom, or institution, must be dilligently worked out by itself, availing ourselves of the clue afforded by race as only the most probable channel of communication and development. We may be certain however that in all cases culture was continuously and slowly developed. . . .

There is but one existing race the habits of which are suffi-

ciently well known, which can be said to present in any great degree the characteristics of a primæval people, and that is the Australians. As I have elsewhere noticed, all the weapons and tools of the Australians, whatever the uses to which they are applied, are closely allied to each other in form. The spear, the club, the malga, the boomerang, and the heileman, or rudimentary shield, all pass into each other by sub-varieties and connecting links, and all consist of the but slightly modified natural forms of the stems of trees, and other natural productions. The Australian in his arts corresponds the most closely of any people now living to those of the palæolithic age. His stone axe is sometimes held in the hand when used, and like the palæolithic man, he has not yet conceived the idea of boring a hole through it for the insertion of a handle. In some cases he cannot without instruction even understand the use of such a hole when he sees it in the axes of European manufacture. A most remarkable instance of this was brought to my notice not long ago by Mr. Grimaldi, who found on the site of a deserted native camping-ground, a European axe having a hole for the handle, which the natives, unable to conceive the use of this part, had filled up with gum, and hafted by means of a withy bent round the outsides of the hole, in accordance with their traditional custom. In the temporary museum established here during the meeting of the Association, you will see a case containing knives of stone, glass, and iron, all of exactly the same form, and hafted, if one may use such a term for the attempt to form a handle, precisely in the same manner; showing with what tenacity these people retain their ancient forms, even after they have been supplied with European materials.

Now it has been shown that in some cases—and here I especially refer to the account lately published by Mrs. Millett, of the Native School, established under conditions only partially favourable to its success, in the interior of Western Australia *—The Australians are found to be not only capable, but even quick in receiving instruction. It is evident, therefore, that we should be wrong if we were to attribute the extraordinary retardation of culture on the Australian continent to racial incapacity *alone*; racial incapacity is one item, but not the only item to be considered in studying the development of culture.

The earliest inhabitants of the globe as they spread themselves over the earth, would carry with them the rudiments of culture which they possessed, and we should naturally expect to find that the most primitive arts were, in the first instance, the most widely disseminated. Amongst the primæval weapons of the Australians I have traced the boomerang, and the rudimentary parrying shield—which latter is especially a primitive implement—to the Dravidian races of the Indian peninsular and to the ancient Egyptians, and although this is not a circumstance to be relied upon by itself, it is worthy of careful attention in connection with the circumstance that these races have all been traced by Prof. Huxley to the Australoid stock, and that a connection between the Australian and Dravidian languages has been stated to exist by Mr. Morris, the Rev. R. Caldwell, Dr. Bleek, and others.† And here I must ask for one moment to repeat the reply which I have elsewhere given to the objection which has been made to my including these weapons under the same class, "that the Dravidian boomerang does not return like the Australian weapon." The return flight is not a matter of such primary importance as to constitute a generic difference, if I may use the expression, the utility of the return flight has been greatly exaggerated; it is owing simply to the comparative thinness and lightness of the Australian weapon. All who have witnessed its employment by the natives, concur in saying that it has a random range in its return flight. Any one who will take the trouble to practise with the different forms of this weapon, will perceive that the essential principle of the boomerang, call it by whatever name you please, consists in its bent and flat form, by means of which it can be thrown with a rotatory movement, thereby increasing the *range and flatness of the trajectory*. I have practised with the boomerangs of different nations. I made a *fac simile* of the Egyptian boomerang in the British Museum, and practised with it for some time upon Wormwood Scrubs, and I found that in time I could increase the range from fifty to one hundred paces, which is much farther than I could throw an ordinary stick of the same size with accuracy. I also succeeded in at last obtaining a slight return of flight; in fact it flies better than many Australian boomerangs, for they vary considerably in size, weight, and form, and many will not return when thrown. The efficacy of the boomerang consists entirely in the *rotation*, by means of which it sails up to a bird upon the wing and knocks it down with its rotating arms; very few of them have any twist in their construction. The stories about hitting an object with accuracy behind the thrower are nursery tales; but a boomerang, when thrown over a river or swamp will return and be saved. . . . . To deny the affinity of the Australian and Dravidian or Egyptian boomerang on account of the absence of a return flight would be the same as denying the affinity of two languages whose grammatical construction was the same because of their differing materially in their vocabularies.

(*To be continued.*)

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Kinetic Energy

PROFESSOR EVERETT asks from what source is the gain of Kinetic energy in water which has flowed from higher to lower latitudes derived? I answer, undoubtedly from the earth's rotation. If so, it will be asked, what becomes of the Kinetic Energy which disappears when water flows from a lower to a higher latitude? Mr. Ferrel, a physicist of high authority in all questions relating to the earth's rotation, says that it is all consumed in friction. "If a free body on the earth's surface," says Mr. Ferrel, "should be moved from a lower to a higher latitude without friction by a force in the direction of the meridian, it would acquire a certain amount of relative eastward velocity, which would be the same (whether the body moved toward the pole with a very slow uniform velocity arising from a single impulse, or whether it moved with a continual accelerated velocity down a gradient by the force of gravity. If a particle of atmosphere or of the ocean is moved in the same way by a similar force, and does not acquire the same amount of relative eastward velocity, *the difference between the velocities in the two cases is the true measure of the effect of friction.*" (NATURE, June 13).

In my last two letters on the subject, I have inadvertently made a similar statement. But as regards the amount of energy lost being the measure of the effect of the friction, we are, I fear, evidently both wrong. A considerable amount of the 9,025 foot-pounds of energy would be consumed, not in friction, but in work of rotation. But let it be observed that so far as the argument under discusssion is concerned, it is a matter of perfect indifference in what way the energy is consumed. The point which Prof. Everett, Mr. Ferrel, and all those who defend Dr. Carpenter's theory has to explain is this, *viz.*, How is it that six foot-pounds of energy can carry a pound of water from the equator to latitude 60°, while during the passage of the pound of water not less than 9,925 foot-pounds of energy is consumed in overcoming the resistance to its eastward motion? How is it that in a fluid, in which the molecular resistance to motion is equal in all directions, a body manages to lose 1,500 times more energy in moving in one direction than it does in another, and yet the velocity of motion is the same in both directions? Then if this cannot be explained, how is the gravitation theory of oceanic circulation to be maintained?

AIR AND RAIN

Air and Rain. By R. A. Smith, Ph.D., F.R.S., General Inspector of Alkali Works. (Longmans, 1872.)

THIS work contains the germs of a system of chemical climatology. It indicates a plan of testing the purity of the atmosphere of localities with regard to certain constituents of organic origin—the *débris* of living things—by washing the air, and determining the character and amount of the substances in solution by certain micro-chemical methods. By the systematic repetition of these testings, the possibility is foreshadowed that we may be enabled to classify such atmospheres, and actually to assign to them quantitative sanitary values. It thus points out how we may be able to estimate the difference between the vitiated air of the town and the pure air of the country. Our senses and experience tell us plainly of the existence of such differences; but chemistry has been hitherto powerless to detect them. "It seemed to many as if the eye had obtained a mysterious power of seeing what was scarcely capable of being proved to be within the domain of substance, and the smell had a power of observing what was more an influence than a positive thing." Cavendish, nearly a century ago, asserted that chemical experiments could not distinguish the air of London from the air of the country; and in spite of the labours of Bunsen and Regnault, Frankland and Williamson, which have rendered gasometry more susceptible of refinement and accuracy than any other branch of chemical analysis, this assertion seems as true of to-day as it was of the time when uttered. Hitherto chemists, in judging of the quality of the air of any locality, have been obliged to content themselves with determining the proportion of oxygen and carbonic acid which it contains, in conformity with the practice of their ancestors of a century back. Gradually, however, they have been forced to the conclusion that such determinations have very little positive value in enabling them to assign a value to the sanitary condition of an atmosphere—that oxygen was no panacea, nor carbonic acid as deadly as strychnine; and thus we have been thrown back upon our unaided senses to distinguish between the good and the evil. Supposing that some Martin Chuzzlewit, going out to another Eden, required information respecting the sanitary condition of the settlement, the chemist could tell him something concerning the water he might have to drink, but he would be utterly unable to enlighten him respecting the air he would be compelled to breathe. Some such considerations prompted the inquiries which have resulted in this book. Dalton's assertion that he could not distinguish the air of Manchester from that of Helvellyn, or generally the air which depresses from that which cheers and invigorates, seems to have forcibly impressed the author. For upwards of forty years he has laboured to remove the stigma on chemical analysis, and in this volume he concentrates his thoughts and experimental results. "It was with the desire," he says, "of clearing the mystery of air to some extent that I have devoted so much of my time to the subject; and now I feel that, whilst I have succeeded in doing much of that which I intended to do, I have not got beyond the limits which earlier observers attained by the mere fineness of unaided sense, and by sound reasoning without experiment. Still I hope I shall be found to have put their suspicions into plainer language, proved that which they only imagined, and given in detail that which they only in a general, and, we may add, in a vague manner, had attained."

Dr. Smith first sets out by defining the composition of a normal atmosphere, as deduced from the many analyses which have been published, and from numerous supplementary determinations of his own made on air collected in various parts of Great Britain and on the Continent. In the outset he insists on the value of minuteness in reading the figures; differences which in the eyes of most chemists are of little value, are to him full of meaning. Every deviation from the standard of purity is to be rigidly criticised. Thus, the difference between 20·980 and 20·999 in the percentage amount of oxygen means a difference of 190 parts in a million. If this consisted of organic matter, or the gases of putrefaction, it might become of the gravest consequence. Certainly 190 parts of putrefying matter in 1,000,000 parts of water—equal to 13·3 grains per gallon—would be considered as an enormous quantity. But, comparatively speaking, we drink only a small quantity of water, and the whole 13 grains would not be swallowed in a single day; whereas we draw through our lungs nearly a couple of thousand gallons of air daily. But, indeed, differences much greater than this are found to exist. Thus, the air of a theatre sometimes contains as little as 20·7 per cent. of oxygen, and even this is by no means an exceptionally small quantity for such a place; and yet this amounts to a deviation of 3,000 parts in a million from the standard of purity.

In speaking of the proportion of carbonic acid in the air, the author bases certain considerations (p. 11) upon the assumption that this gas is washed out by falling rain. But is this supposition exactly confirmed by experiment? Saussure, it is true, thought that he could detect a difference in the amount of carbonic acid between the air over the Lake of Geneva and that over the land; but such differences have not been found by other experimenters. Sea air contains about three volumes of the gas in 10,000 volumes; whilst the air of the land contains only four volumes. But this difference is due more to the influence of the land than to any absorptive action exerted by the sea. Indeed, from a consideration of the laws of gaseous absorption, it can be shown that the pressure exerted by the relatively small quantity of carbonic acid present in the air is unable to bring about any perceptible variation in its amount over sea and land.

Having fixed on his standard of purity, Dr. Smith proceeds to examine vitiated air and to trace its effects on breathing. For this purpose he used an air-tight chamber in which one or more persons could be seated; and from time to time he collected and analysed samples of the enclosed air, and compared the analytical numbers with the sensations experienced and noted at the moment of collection. The details of these experiments are of great interest, and merit careful study. That they were not unattended with danger is evident from the experience of a young lady "who was extremely fond of pure air," but who in the cause of science "was anxious to be in the

chamber when the candles went out." At such a time there would be about 19 per cent. of oxygen and 2·1 per cent. of carbonic acid in the chamber. No person had been in the chamber previously. "She stood five minutes perfectly well, and making light of the difficulty; but suddenly became white, and could not come out without help. She was remarkably healthy, never was ill, and was troubled with no fear of the air in which she stood."

From the air to the rain which falls through it, is but a single step; for if, as our author says, there is life and death in the air, we must believe the same of the rain, which collects the solids and liquids, gases and vapours which float about in the atmosphere. These ingredients of rain water can, indeed, be shown by chemical analysis; and by the microscope distinctions may be drawn between the air of various localities, without putting the health to the test. The author proceeds to describe his methods of testing rain water; but as the details of the scheme are mainly of interest to chemists, we must refer any curious readers to the book itself. Much of the work herein detailed was done years ago; long, indeed, before Pasteur had enlightened us as to the great reservoir of life which exists in our atmosphere. In 1852 Dr. Smith showed how complicated a fluid rain is. However carefully collected, albuminous bodies, the remains of living creatures, and minute animalculæ, may invariably be detected in it. "These creatures," says Dr. Smith—anticipating Dr. Frankland's aphorism, "Ohne Phosphor gar kein Leben"—"are sufficient of themselves to show the existence of phosphates, whilst sulphates and lime may be readily obtained. In examining the Thames water I often found that the readiest way of collecting phosphates and magnesia was to wait for the animalcules to do it."

Through the kindness of a number of gentlemen, Dr. Smith was enabled to make numerous collections of rain water from as far north as the Hebrides and as far west as Valentia. The results of the samples of the analysis may be thus briefly summarised:—The rain over the sea contains chiefly common salt, which crystallises clearly; but it also contains sulphates, and in larger proportion to the chlorides than is found in sea water. The amount of these sulphates increases inland before large towns are reached. They are to be regarded as the measure of the products of decomposition, the sulphuretted hydrogen from putrifying organic compounds becoming oxidised in the atmosphere. Within certain limitations, they may be taken as an index of the amount of sewage in the air. We accordingly find in the large towns the amount of the sulphates is greatly increased, owing to the combustion of the sulphur in coal, as well as the decomposition of organic matter contained in protein substances. When the sulphuric acid increases more rapidly than the ammonia, the rain-water becomes acid, and when the amount of this free acid reaches two or three grains in a gallon, or forty parts in a million, there is no hope for vegetation in a climate such as we have in the northern parts of this country. These free acids are not found with certainty where combustion or manufactures are not the cause. The amount of ammoniacal salts in the rain water increases with the number of towns in the district. This ammonia comes partly from the coal, and partly from the decomposition of albuminoid substances, which, indeed, may also be detected in the rain water. It is very interesting to compare the relative purity of the atmospheres of our cities and large towns, as determined by this method of air-washing. Upon the whole, that of London appears to be the best, and that of Glasgow decidedly the worst. Calling the amount of sulphuric acid in sea air 100, the average amount in that of London is 352, and in that of Manchester 513. In Glasgow the amount of ammonia is 150, in London it is 115; the amount of albuminoid ammonia in London air is only 109, whereas in Glasgow it is more than twice that amount, viz. 221. These analyses show unmistakably in what the evil of overcrowding consists; and it is with this subject on which he is thus led to speak that Dr. Smith closes his book. We commend his remarks to our City Improvement officials:—"Let those courts, alleys, and streets, which show the greatest mortality and the worst air, be destroyed or improved, without foolish mercy. There is a want of willingness to pull down dangerous property, but a readiness to rush forward to save the life of the greatest criminals. Reason is out of the question in the matter. We are misled by an uneducated feeling. We like to save property, forgetting that deadly weapons and poisons are subject to peculiar laws, and their indiscriminate use is forbidden to the nation. And houses that produce death are not property; as well might a man claim his debts as such. If a man sells unwholesome meat the law interferes; if he sells the use of a room with fever in it, the nation seems not to complain. Officers of health point out such places, but the public still refuse to destroy them, and great numbers are slain annually by legal methods, while strict methods are taken to prevent a few annually being killed by arsenic—a death more agreeable than the lingering misery in the lower parts of our crowded towns. I know that the lowest classes living in poisoned houses die from other causes than bad air; but I am speaking of air at present, and that is one of the causes. The time must come—and the sooner the better—when it shall be enacted that no land shall contain more people per acre than we know by experience in several places can live healthily thereon. The same thing must be said regarding houses, although these are more difficult for governments to deal with, because of the degradation of some of the population. Still the limitation must be attained, and for that we must strive."

T. E. THORPE

THE IRON AND STEEL INSTITUTE

THE Fourth Annual Provincial Meeting of the Iron and Steel Institute was held recently (August 6th to 9th inclusive) in Glasgow, under the presidency of Mr. Henry Bessemer, and it has been, if it were possible, even more successful than any of the previous reunions, furnishing thereby the best proof that such an association actually was a desideratum, and of the hearty co-operation which its establishment has called forth, from all interested directly or indirectly in the development of the Iron and Steel manufactures of Great Britain.

Since the three previous meetings were all held in the iron districts south of the Tweed, it is the more gratifying on this occasion to find that the first meeting of the Institution in Scotland should have turned out so eminently successful, and so marked by the hearty welcome with which Scotch ironmasters have received their Southern

competitors in the trade; and it cannot but be observed that since the foundation of the Institute, a very different spirit has infused itself among the members of the iron and steel trades in general, as they no longer keep themselves jealously aloof from one another, but, on the contrary, are now pleased to meet, and in a spirit of generous rivalry to interchange their ideas, thereby to some extent, at least, tacitly acknowledging that the advancement of industry of the country at large, so far from being prejudicial to, is in reality ultimately connected with, the interests of each individual manufacturer also. It is the recognition of this principle which has enlisted the sympathies of those engaged in the iron and steel industries, and has contributed so much to the success of the Institute, which at this moment, including those candidates nominated at the present meeting, numbers no less than 602 members—a surprising result when it is remembered that the Association is now only in the fourth year of its existence.

The Glasgow meeting of the Institute commenced on Tuesday, August 6th, when its members assembled in the Corporation Galleries, Sauchiehall Street, which had most liberally been placed at the disposal of the Council of the Institute by the Lord Provost and Magistrates of the City; the proceedings being prefaced by a short introductory address from the President (Mr. Bessemer), together with a few words of welcome from the Lord Provost of Glasgow.

The Secretary then announced that the Council had recommended Mr. Isaac Lothian Bell, of Newcastle, as president-elect, and nominated Mr. Edward Williams, of Middlesborough, as vice-president in the place of Mr. Bell, as also Messrs. W. S. Roden, C. W. Siemens, H. Sharpe, W. Nielson, and J. Hunter to the vacancies caused by the retirement of the other members of the Council by rotation, which recommendations were unanimously adopted by the meeting.

The Foreign Secretary read out the names of those gentlemen connected with the foreign iron trade then present at the meeting, amongst whom were representatives of France, Belgium, Germany, Sweden, and the United States of America.

The election of members was then proceeded with, after which an extremely interesting paper, "On the Coal and Ironstone Strata of the West of Scotland," was read by Mr. James Geikie, of the Geological Survey, in which a general sketch of the geology of the district, with special reference to the occurrence and nature of the coal and ironstone deposits, was given in a concise yet extremely lucid communication, the delivery and discussion of which occupied the remaining available time of this day's meeting. Visits were subsequently made by the members to some of the neighbouring works, and more particularly to the Blochairn Iron Works, where considerable attention was paid to Mr. Graham Stevenson's new mode of reversing rolling mills then in operation.

On the following day (Wednesday) the meeting commenced at 10.30 A.M. by the reading of a paper by Mr. J. F. Mayer, of Glasgow, "On the Rise and Progress of the Iron Manufacture of Scotland," which was an historical sketch of the subject, commencing from the year 1760 when iron was first smelted at Carron, near Falkirk, and continuing it down to the present time, when the Scotch iron manufacture occupies so prominent a position in the British iron trade. Attention was specially directed to such improvements in the manufacture of iron as had originated in this part of Scotland, amongst which were mentioned the use of raw coal instead of coke in iron smelting by Condie at Govan, the employment of hot blast by Nielson, and the utilisation of the black band ironstone by Daniel Mushet, discoveries which, it may be said, were the making of the Scotch iron trade.

The next two communications related to the different systems for reversing the rolls in rolling wrought iron; the first of these by Mr. J. D. Napier, "On Napier's differential gear for reversing rolling mills," illustrated by models, described the application at the Codnor Park Iron Works in Derbyshire of a differential clutch, identical in principle with the differential breaks used by him in the windlasses of ships; whilst the second, by Mr. Graham Stevenson, "On Reversing Rolling Mills," advocated the employment of his conical clutch, which had been inspected the previous afternoon at the Blochairn Iron Works. These two papers were discussed together, and gave rise to a very animated debate, in the course of which much valuable information was elicited from the observations made by members practically acquainted with the subject. The balance of opinion appeared, however, to be in favour of Mr. Napier's differential clutch, the extreme simplicity of which appeared to give it advantages over any hitherto applied form of reversing gear, not excluding the conical clutch of Mr. Stevenson, which, nevertheless, was admitted to work very satisfactorily.

The meeting then broke up, most of the members proceeding by a special train to inspect the Iron Works at Gortsherrie, Coatbridge, Summerlee, and Monkland. Amongst the novelties examined on this excursion may be mentioned the new coal-cutting machine, invented by Messrs. Miller and Anderson of Coatbridge, then at work in the No. 3 pit, Gortsherrie, belonging to Messrs. William Baird and Co.

This machine is stated to cut 350 ft. of coal per shift of 8 hours, yielding 75 tons, or equal to the united turn out of 40 men, whilst it only requires two to attend to it, being driven by compressed air at a pressure of 45 lbs. to the square inch, brought in cast iron pipes some 300 fathoms from the shaft. As six additional machines are in course of construction for Mr. Baird, it is evidently regarded as a success; and it is hoped that in these days of incessant strikes it may prove capable of doing all it is represented to do, and thus be the means of checking in some degree the exorbitant demands of the colliers.

At the North British Iron Works, at Coatbridge, M. Dormoy's patent puddling furnace, with revolving rabble, driven by steam power, was shown in full operation, and appeared to elicit the very general expression of opinion that the invention, even if ingenious and practical, had come out too late in the day. Now that the more perfect system of rotary puddling of Mr. Danks has proved successful in dispensing with the labour of the puddler altogether, it is not likely that the ironmaster of the future will be content with a system which at best is only an improved manual process for puddling iron.

At the Monkland Iron and Steel Works the interest of the visitors was concentrated in inspecting the two blast furnaces constructed on Ferrie's patent coking principle. These furnaces have a height of no less than 90 ft., and are so arranged that, when fed at the top with the raw coal and iron ore mixed together, the coal, as it descends, becomes coked in the upper portion of the furnace, before it reaches the smelting region of the furnace lower down. Great economy in fuel is claimed for this arrangement; it being considered that the heat and combustible gases driven off and lost, when the coal is previously coked as at present in separate coking ovens or heaps, are utilised entirely in the Ferrie blast furnace.

The favourable opinion expressed by several of the members of the Institute, will, it is understood, lead to the erection of several of these furnaces, both in the district and probably in England also.

The meeting on Thursday commenced at 10.30 A.M., and was opened by the reading of a paper by Dr. A. K. Irvine, of Glasgow, "On a new miner's safety lamp," in which the author described an invention of a most ingenious character, which is likely to prove of great service in coal mines troubled with explosive gases, since, besides serving the purpose of an ordinary safety lamp, it sounds a note of warning to the workman the moment the air around becomes so charged with firedamp as to be

dangerous or explosive. The principle of the lamp is based on the fact that when a mixture of any inflammable gas or vapour, with air in explosive proportions, is lighted on the surface of wire gauze, having meshes sufficiently small to prevent the passage of flame, and a suitable tube or chimney is placed above, so as to prevent admission to the chimney except through the wire gauze, a musical sound is produced varying in pitch with the size of the flame and dimensions of the chimney.

A number of interesting experiments were exhibited to illustrate this principle, and various miner's lamps as constructed were exhibited and tested in mixtures of air with ordinary coal gas, when they at once indicated the danger as soon as the atmosphere by which they were surrounded contained sufficient gas to be dangerous, by emitting a strong clear sound like that of a horn, which could be heard at a considerable distance. Another form of this lamp was also shown, intended to be employed as a stationary warning apparatus or alarum after being placed in any part of the mine considered likely to ensure the safety of the workmen, so that it might sound the danger signal before the air around it was so far charged with fire-damp as to become explosive. The novelty and importance of such an invention were apparent to an audience of practical men; and besides passing a cordial vote of thanks to the inventor, arrangements were made for at once fully testing its merits by its practical employment in some English collieries noted for fire-damp.

After an interesting paper by Mr. D. Rowan, of Glasgow, "On the rise and progress of the iron shipbuilding trade in Scotland," which, however, was of a purely historical and statistical nature; the next communication was made by Mr. Lauth, of Pittsburg, United States, "On Lauth's system of rolling iron by three high rolls." The improvements proposed in this system of rolling, which is in itself very old, consisted in making the central roll of less diameter than the two others, which are of ordinary size, and in having it fixed, whilst the two others are adjustable by screws. In the hard rolls the bottom roll alone is driven, both the middle and top roll being carried round by friction. All expansion or contraction is prevented by a stream of water constantly kept running on to the roll; and great rapidity in rolling, as well as economy in labour, is claimed for this system. In the discussion which followed, the general opinion appeared to be that, although such rolls were well adapted for plates, in this country they were less adapted for rail rolling, owing to the greater difficulty in adjusting the grooves so as to turn out rails as correct in section as was insisted upon by our and most of the Continental engineers, but not in the United States; also because the necessity for three rails would still further augment the immense stock of rolls requisite to suit the multiplicity of sections required in the English trade, as well as increase the labour and time required in changing the rolls.

The next paper was by Mr. A. Spencer, of West Hartlepool, "On further improvements in Spencer's Rotary Puddling Furnace" a model of the furnace in its present form being exhibited, and its construction, mode of fettling, and working, fully entered into by the author; after which, owing to time not permitting a lengthy paper by Mr. J. Guildford Smith, of Philadelphia, "On the Westward development of the Iron Manufacture of the United States," was taken as read; and after passing votes of thanks to the Lord Provost and civic authorities of Glasgow, the Council of the Philosophical Society, the Committee of the Royal Exchange, the local Committee, and the President of the Institute, the proceedings of the meeting were brought to a close.

In the afternoon an excursion was made by a special train to the Coltness and Mossend Ironworks, the members of the Institute being entertained on their return at a banquet given in the Corporation Galleries by the local Committee of the Institute.

An interesting feature in connection with the meeting was the arrangement of a temporary museum in the Corporation Galleries containing models, specimens, and objects of all kinds bearing more or less directly on the Iron and Steel manufacture, many of the articles exhibited being of great interest.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Solar Outbursts and Magnetic Storms

IN the French *Comptes Rendus* of August 4, which has lately reached this country, is an account by Father Secchi of a remarkable outburst from the sun's limb witnessed by him on July 7, which lasted from $3^h\ 30^m$ to $6^h\ 50^m$ (Roman time, I presume), or nearly $2^h\ 40^m$ to $6^h\ 0^m$ (Greenwich time).

A magnetic storm commenced at Greenwich at $5^h\ 0^m$ precisely on the same day. Its indications began at that time with unusual suddenness and strength, on all the magnetic indicators, namely the declination-needle, the horizontal force magnetometer, the vertical force magnetometer, the earth-current wire, in an approximate N.E. and S.W. direction, and on the earth-current wire in an approximate N.W and S E. direction The disturbance lasted, gradually diminishing, to the evening of July 9. During a part of the time it was accompanied with aurora.

I do not venture upon the question whether there really was any connection between the solar outburst and the terrestrial magnetic storm, but I will remark that, if there was such connection, the transmission of the influence from the sun to the earth must have occupied $2^h\ 20^m$; or a longer time if Father Secchi did not see the real beginning of the outburst. This, if established, would be an important cosmical fact; and, at any rate, the notification of this apparent retardation may direct the attention of observers of similar phenomena in future to a new element in their interpretation.

G. B. AIRY

Royal Observatory, Greenwich, August 14

Ocean Circulation

ALTHOUGH no mathematician, and only an amateur in physics, it appears to me that the difficulties and objections of Mr. Croll on this subject may be obviated, and the whole question elucidated by a reference to the admitted facts, and a common sense interpretation of them. And first, as to the fact that the surface water of the Atlantic Ocean, in moving northwards from the equator to 60° lat., has almost wholly lost the easterly motion of rotation it should have brought with it. This loss is imputed by Mr. Croll to friction only, and he argues that the much lower velocity of the northward current must, therefore, be wholly neutralised by friction. This is his main argument, which he has repeatedly adduced, and to which he has hitherto received no reply. But, although his reasoning might be admitted if the conditions affecting the two motions were the same, it seems to me to be quite inapplicable to the present case. If, in the temperate zone, the ocean extended uninterruptedly in an east and west direction round the globe, it would no doubt retain a considerable portion of the equatorial eastern motion, and whatever deficiency existed might fairly be imputed to friction. But the Atlantic is actually like a huge lake, with continuous eastern and western shores, and the water which flows northwards along the eastern shore is prevented from moving eastwards, not by friction against water or even against the shore, but by having to perform work in lifting or heaping up the water against the shore, just as the water of a pond or lake is heaped up on the leeward side by a strong wind. As the direction of the motion of the water will, however, by the hypothesis, be oblique or somewhat north of east, some of the motion will be diverted northwards along the eastern shore, and thus tend to increase the northerly flow. The 9 925 pounds of energy (according to Mr. Croll) are not therefore consumed in overcoming the frictional resistance to eastward motion, but for the most part in doing the actual work of overcoming gravitation and holding up the waters at a higher level, and the theoretical amount of this rise can, no doubt, be easily calculated for us by Mr. Croll.

The case of the water moving northward is very different,

There is a clear passage into the polar area, and probably up to and beyond the pole; and within this area there is a continual diminution of bulk of the entering water as it becomes cooled, as well as a continual subsidence of the surface water, producing a partial depression to be constantly filled by water from the south. Experiment proves that if at one end of a vessel of warm water ice is applied at the surface, the cooled water instantly sinks, and its place is taken, not by water rising upwards from below, but by a horizontal movement of the surface gradually propagated to the other end of the vessel, while the descending cold water creeps along the bottom, and gradually acquiring a higher temperature, rises and completes the circuit. It is somewhat difficult to conceive, theoretically, how such a circulation can commence, because the cooled atoms of water must displace others before they can descend, and these again must displace others, and so on over the whole mass. The amount of energy due to the superior weight of the first-cooled atoms may appear inadequate to perform so much work, but nevertheless circulation does commence and indefinitely continues so long as a difference of temperature of the two ends of the vessel is kept up. The extreme mobility of the particles of water, and the almost total absence of friction between them, seems to be influential in producing this result; and it is not probable that any minute difference of level that may be caused on the surface of the water by difference of temperature has anything to do with the motion; and I cannot help thinking that the supposed six-feet incline from the equator to lat. 60° is, if it exists, by no means an effective cause of the oceanic circulation.

ALFRED R. WALLACE

I THINK the root of Mr. Croll's difficulty (see NATURE, p. 324) is to be found in his overlooking the possibility of energy becoming potential in the distribution of oceanic water.

Water running in any direction in the northern hemisphere tends to swerve to its own right, and if this tendency is checked (as it is in fact by the presence of continents) its layers of equal density will be tilted up on the right, the limit of tilt being the angle whose tangent is the quotient of the tendency to swerve by the force of gravity. This consideration is, I think, sufficient to deprive Mr. Croll's argument of one of the two legs on which it stood.

Mr. Ferrel's argument from the tides is quite conclusive in showing that the forces arising from difference of temperature are of sufficient magnitude to keep up an oceanic circulation. Thus the other leg of Mr. Croll's argument is gone.

Mr. Croll may well retract his previous assertion that the difference of kinetic energy is consumed in friction, for he was in a fair way to bring the earth to a standstill.

Brighton, August 20 J. D. EVERETT

Spectrum of Aurora

A FINE aurora was seen at Bedford on Thursday night between midnight and one o'clock. It was brightest under the Polar Star near the horizon, where the colour was a pale green; whilst overhead the hue often changed to a rosy red. On directing a spectroscope at the most brilliant part, a bright green line (W.L. 557) was very distinct, and two or three faint nebulous bands more refrangible were visible; but the red line was not to be seen, though carefully looked for on the rosy parts of the aurora. Objects around were faintly illuminated as if by a young moon. At one time two very faint pale green streamers were seen stretching from the north to a little east of the zenith.

Blackheath, August 11 J. P. MACLEAR

The Method of Least Squares

As the wording of Prof. Hall's letter in NATURE for July 25 might imply that he was calling attention to evidence that would change the opinion expressed in my letter, it seems to me worth while to state that at the time of writing that letter I was acquainted with the passages in question, and to repeat my assertion that with reference to the *method of least squares* I should not regard the neglect of Lagrange's memoir as an omission. Also in spite of Encke's and Prof. Hall's remarks, I think it has received as much attention as, viewed practically, its importance entitled it to.

With regard to the principle of the Arithmetic Mean, I may add that I have devoted the greater part of a tolerably long memoir to its consideration, and feel sure that no remarks on the subject contained in a few lines could be rendered even intelligible.

J. W. L. GLAISHER

Blackheath, August 11

NOTES

WE are informed that M. Faye will in all probability be M. Delaunay's successor as Director of the Observatory at Paris. In the meantime M. Matthieu supplies his place *pro tem.*

THE French Academy has elected two foreign correspondents in the section of botany—M. Planchon in the place of M. Lecoq, and M. Weddel in the place of Prof. Mohl.

THE American Association for the Advancement of Science was to commence its sittings yesterday at Dubuque, Iowa. Prof. J. Lawrence Smith, of Louisville, had been elected President, and Prof. Alexander Winchell, of Ann Arbor, Vice-President. It was announced that the citizens of Dubuque had determined that all members attending the meeting should be entertained at their private residences free of charge during the session; and their travelling expenses would also probably be remitted by the various railroad and steamboat lines. A very successful meeting was anticipated.

AT the recent combined First B.A., First B.Sc., and Preliminary Scientific (M.B.) Examinations of the University of London, Mr. J. M. Lightwood, of Trinity Hall, Cambridge, obtained the Exhibition in Mathematics and Philosophy; Mr. R. E. Carrington, of Guy's Hospital, the Exhibitions in Chemistry and in Zoology; and Mr. J. C. Saunders, of Downing College, Cambridge, the Exhibition in Botany.

WE regret to announce the death of Mr. Frederick Carpenter Skey, C.B., F.R.S., which took place on Thursday last at his residence, Mount Street, Grosvenor Square. Mr. Skey was in his 73rd year. He was in early life a pupil of the celebrated Dr. Abernethy, to whom he was articled in 1816 by the Royal College of Surgeons. About 1826 he was appointed Demonstrator of Anatomy at St. Bartholomew's Hospital. Subsequently he founded the Aldersgate School of Medicine, which became one of the largest in London. From that time to his death Mr. Skey enjoyed the reputation of being in the first rank of London surgeons. His writings on medical subjects were numerous and important, and on subjects connected with sanitary science his communications to the public journals were frequent.

THE following is the list of candidates who have been successful in obtaining Royal exhibitions of 50*l.* per annum each for three years in the Science and Art Department, and free admission to the course of instruction at the following institutions:—To the Royal School of Mines, Jermyn Street—William Carter, Ambrose R. Willis, and Alexander Gibson. To the Royal College of Science, Dublin—Arthur G. Meeze, Denis Coyle, and Ernest H. Cook.

A NATURAL History Society has been formed at Madrid called "La Sociedad Española de Historia Natural," under the presidency of Don Miguel Colmeiro. The first part of its publication has reached this country, and contains the regulations of the Society, an account of the meetings held by it up to this time, and papers by Poey on Ichthyology, by Colmeiro on the Fumitories of Spain and Portugal, by Espada on the Volcano of Ansango, by Solano on a Meteoric Stone, by Espada on New America Batrachians, and by Perez Arcas on New Reptiles and Insects of the Spanish Fauna. It is extremely well printed, and is illustrated by three capital plates. The subscription to the

society is 12*s.* 6*d.* Anyone desiring to become a member may address himself to Don Serafin de Uhagon, Sordo 27, Madrid, the treasurer, or to any other member.

PRIZES for Collections of Economic Entomology are offered for competition in 1873, and the following rules relating thereto have been issued by the Royal Horticultural Society:—10*l.* for a collection of British insects injurious to some one order of plant used for food—as Cruciferæ, Leguminosæ, or corn. The order may be selected by the competitor. 3*l.* for a miscellaneous collection of British insects injurious to plants used as food. 5*l.* for a collection of British beetles injurious to timber and fruit trees either growing or felled. 2*l.* for a collection of British insects injurious to some one timber or fruit tree. The insects are to be exhibited in their various stages of development, accompanied by specimens, models, or drawings of the injuries caused by them. The collections are to be sent in addressed to James Richards, Assistant-Secretary, Royal Horticultural Society, South Kensington, on or before November 1, 1873.

THE threatened destruction of the "Cursus," at Stonehenge, by the ploughing up of the land, is attracting so much public attention, that we may hope it will be in time to arrest this piece of Vandalism.

THE largest and most important of the fragments of the carved column dug up by Mr. Wood at a depth of 23 feet on the supposed site of the Temple of Diana at Ephesus, has been set up in the Græco-Roman room at the British Museum. It measures about 6 feet in height and 18½ feet in circumference, and it is supposed to have formed a portion of the first drum of one of the thirty-six Ionic carved columns which, with ninety-one others, supported and adorned the structure. Portions of the base and capital of the column were also found close by. On the side of the drum, which has sustained comparatively slight injury, there are five figures of considerable beauty, but all more or less mutilated. Of only two of these can the identity be determined—namely, the figures of Mercury and Victory. The former is perfect, with the exception of the face, which is slightly mutilated, and is regarded by competent judges as a work of considerable merit.

DR. HAYDEN, in charge of the Geological Survey of the Territories, having completed his preliminary arrangements at Ogden, has separated his forces into two divisions, one of which was to proceed to Fort Hall, with waggons and a suitable outfit, to be changed into a pack train at Fort Hall, and thence to travel up the Snake Valley, under the direction of Mr. Stevenson; the other division, under the doctor's own charge, was to start soon for Fort Ellis, and expected to be at work there by the 1st of July. Among other interesting observations already made by Dr. Hayden's expedition, was the occurrence of invertebrate animal life in great abundance in the Great Salt Lake. This fact is not entirely new, as the existence of dipterous larvæ in these waters has already been recorded by Captain Stansbury and others.

PROF. DAVIDSON, of the United States Coast Survey, has recently, before the Academy of Sciences of San Francisco, contested the theory of Mr. Octave Pavy in regard to polar currents and the topography of the polar regions. In his paper the professor maintains, in opposition to the views of Mr. Pavy, that the currents flow eastward through the straits north of the American continent, and that the current through Behring Straits is local, and unimportant in its effects as regards the polar basin; that Wrangell's Land is not a region continuous to a great distance toward the pole, as contended by Mr. Pavy, but a small island or cluster of islands.

THE BRITISH ASSOCIATION MEETING AT BRIGHTON

BRIGHTON, *Tuesday Morning*

THERE is a general agreement that the Brighton meeting of the British Association is a brilliant one; though we fear that this phrase, as used among Brightonians, refers rather to the fashionable character of the audiences at the various sections than to the scientific value of the papers read. Not that this latter has been below the average; but so far at least there has been no one paper or discussion which has placed a distinctive character on the meeting of 1872 as marking an epoch in scientific thought. We miss, also (no doubt owing to the remoteness of the locality from the great intellectual foci of the north), the familiar faces of many who are wont to add life and interest to our meetings; while the London *savans* do not appear to muster in greater force than when the meeting is held 300 miles from the metropolis. The spacious dome of the Pavilion was crowded to its utmost capacity on Wednesday evening, to hear Dr. Carpenter's opening address; and so admirable are the acoustic properties of the building, that each word was distinctly heard in every corner, if we may use the term in describing a circular room. Among the distinguished visitors, the curiosity of the audience was about equally divided between Mr. Stanley and the ex-Emperor of the French, both of whom occupied seats on the platform. The total number of tickets issued up to Wednesday evening was 2,140, or only 400 short of the Edinburgh total. Although the rooms in which the various sections are held are scattered, the distances are not great, and the splendid weather makes it easy to get from one to another. The localities selected give rise to some singular incongruities; as when wandering into the Friends' Meeting House, where Section G finds its local habitation, we heard a paper read from the "Ministers' Gallery," "On the progress of invention in breech-loading small arms during the past twenty years."

At the meeting of the General Committee previously held, the Report of the Council was read, in which the following are the more important features:—

The Council announce that a vacancy has occurred in the number of the trustees in consequence of the death of Sir Roderick Murchison, and take this opportunity of expressing their regret at the great loss which science has sustained by his death. He worked long, earnestly, and with eminent success in the sciences of geology and geography, and was at all times a steady patron of rising scientific men in all branches of science. He was a member and strenuous supporter of this Association at its first formation in 1831, and continued until the close of his life a very constant attendant at its meetings and a firm promoter of its interests. The Council recommend that Sir John Lubbock, Bart., be selected to fill the vacancy.

The next subject referred to is the appointment of the Committee to promote observations on the Total Solar Eclipse of December last, from which a Report will be read in due course. The results will be published by the Association to form part of a series uniform with the contemplated reports of the Royal Astronomical Society of the observations of the eclipses of 1860 and 1870.

There were five other resolutions referred to the Council for consideration or action, upon which the proceedings of the Council have been as follows:—

First resolution:

"That the President and Council of the British Association be authorised to co-operate with the President and Council of the Royal Society, in whatever way may seem to them best, for the promotion of a circumnavigation expedition, specially fitted out to carry the physical and biological exploration of the deep sea into all the great oceanic areas."

A copy of this resolution was forwarded to the Royal Society, and a committee was appointed, consisting of the president and officers of the Association, Dr. Carpenter, Prof. Huxley, Mr. Gwyn Jeffreys, Mr. C. W. Siemens, and Prof. Williamson, and authorised to co-operate with the Committee of the Royal Society in carrying out the objects referred to in the resolution. The expedition has been organised, the ship *Challenger* is being fitted out at Sheerness, Capt. Nares has been appointed to the command, and Prof. Wyville Thomson (who has obtained three years' leave of absence from the University of Edinburgh) is appointed to the scientific charge, with an adequate staff under him. It is hoped that the expedition will sail about the end of November.

Second resolution :

1. "That it is desirable that the British Association apply to the Treasury for funds to enable the tidal committee to make observations and to continue their calculations.

2. "That it is desirable that the British Association should urge upon the Government of India the importance, for navigation and other practical purposes and for science, of making accurate and continued observations on the tides at several points on the coast of India."

With the result of these applications we have already informed our readers, and discussed the bearings on the future of Science of the attitude of the Government.*

Third resolution :—

"That the Council of the Association be requested to take such steps as to them may seem most expedient in support of a proposal, made by Dr. Buys Ballot, to establish a telegraphic meteorological station at the Azores."

The Council appointed a Committee of their own body to report upon this proposal. The Committee, after due deliberation, reported that while sympathising with the proposal made by Dr. Buys Ballot, they cannot recommend a grant of money to be made by the Association for carrying it out. In this recommendation the Council concur.

Fourth resolution :—

"That the Council be requested to take into consideration the desirability of the publication of a periodic record of advances made in the various branches of sciences represented by the British Association."

The Council, after a careful consideration of this proposal, are not prepared to recommend the Association to undertake the publication of a periodic record of advances made in the various branches of science represented by the sections of the British Association. They are of opinion that in so vast an undertaking special societies should be invited to prepare such records, the action of the Association being limited to occasional grants in aid. They are of opinion, however, that the Association would do well to promote the more frequent publication in their proceedings of critical reports on various branches of science, of the same nature as those which have already rendered previous volumes so valuable to investigators.

Fifth resolution :—

"That the Council of this Association be requested to take such steps as may appear to them desirable with reference to the arrangements now in contemplation to establish 'leaving examinations,' and to report to the Association on the present position of science-teaching in the public and first grade schools.

"That the Council be requested to take such steps as they deem wisest in order to promote the introduction of scientific instruction into the elementary schools throughout the country."

A Committee, consisting of the President and the General Officers, Mr. G. Busk, Mr. Debus, Dr. Duncan, Mr. Fitch, Prof. M. Foster, Mr. F. Galton, Dr. Hirst, Prof. Huxley, Sir John Lubbock, Bart., Sir J. Paget, Bart., Rev. Prof. Price, Prof. H. J. S. Smith, Prof. Stokes, Prof. Tyndall, and Prof. Williamson, was appointed to consider the first of these resolutions, and to report on them to the Council.

In accordance with the recommendation of this Committee the Council adopted the following resolution :—

"That having had under consideration the requests which the Committee of Masters of Schools have made to the Universities of Oxford and Cambridge upon points in which the Education of the Universities and Schools came into contact, the Council of the British Association recommend that arithmetic, and either elementary physics or chemistry experimentally treated, be introduced into the leaving examinations as compulsory subjects.

"That the Head Masters of Public Schools be requested to furnish the Council with information about the present position of Science-teaching in their Schools."

The Council have communicated thereon with the Universities of Oxford and Cambridge, but at present no decision respecting "leaving examinations" has been arrived at in these Universities.

In accordance with the terms of the resolutions passed by the General Committee last year, appointing a Committee on science lectures and organisation, the action proposed to be taken by this Committee in the following resolutions was referred to the Council and sanctioned.

"1. That a Sub-Committee, consisting of Dr. Carpenter, Prof. Williamson, Prof. W. G. Adams, Dr. Hirst, Mr. Geo. Griffith, Dr. Michael Foster, and Prof. Roscoe, be appointed for one year for the purpose of preparing a list of Lecturers for the consideration of this Committee, and of communicating with the various towns with the view of establishing a system of Science Lectures throughout the country.

"2. That the names of the proposed Lecturers be selected (with their consent) from amongst the Members of the General Committee of the Association, or from amongst the Graduates of any University in the United Kingdom; and that the subjects upon which the Lectures be delivered shall be such as are included in one or other of the Sections of the Association."

The Committee have drawn up a Report, dealing generally with the subject of their inquiry, which the Council recommend should be referred to the Committee of Recommendations.

The Council have had under consideration the question of enabling Members, who are unable to be present at the Meetings, to obtain the Journal and other printed papers, and they have adopted a Regulation as follows :—

"The Journal, President's Address, and other Printed Papers, issued by the Association during the Annual Meeting, will be forwarded daily to Members and others on application and prepayment of 2*s.* 6*d.* to the Clerk of the Association, on or before the first day of the meeting."

The Council have added the following names of gentlemen, present at the last meeting of the Association, to the list of Corresponding Members, viz. :—His Imperial Majesty the Emperor of the Brazils, Prof. Dr. Colding, Dr. Güssfeldt, Dr. Lüroth, Dr. Lutken, Dr. Joseph Szabó.

The following resolution was then agreed to :—"That the members in the following list be constituted, with the president and vice-presidents of the meeting, the past presidents of former years, the trustees, the general and assistant-general secretaries, a Committee of Recommendations, viz. :—Mr. Gassiot, Prof. Henry Smith, Colonel Strange, Prof. Williamson, Mr. Abel, Prof. Martin Duncan, Dr. Burdon Sanderson, Colonel Lane Fox, Prof. Michael Foster, Sir Walter Elliot, Prof. Wyville Thomson, Sir Henry Rawlinson, Mr. Newmarch, Mr. J. G. Fitch, Prof. Hawkins, Mr. Siemens, Mr. Hawkshaw."

* See NATURE, vol. vi., p. 157.

The incident of greatest interest in Thursday's meetings was when, at the close of Sir John Lubbock's presidential address to Section D, he alluded to the unworthy treatment which Dr. Hooker had received at the hands of a department of the Government, the name of the distinguished Director of Kew bringing down a perfect storm of applause, which was repeated when Dr. Carpenter, in proposing a vote of thanks to Sir John, spoke of the "low and degrading view of science" entertained by a member of Her Majesty's Government. The Section adopted the following resolution :—"That this section would view with regret any change introduced into the botanical establishment at Kew which would tend to affect its completeness, or to impair its scientific character; and that the attention of the Council be called to the subject, with a request that they will take any steps they may deem desirable." This resolution was carried to the Committee of Recommendations, where, however, we regret to say, it halted, and was not allowed to proceed.

The *soirée* on Thursday evening was a highly successful one, and well brought out the capabilities of Brighton and the Brightonians for managing entertainments of this kind. The arrangements, indeed, may be said to have been perfect; and there was a veritable *embarras de richesse* of objects of interest. The magnificent array of microscopes, the splendid Willett collection of the fossils of Sussex, the collection of living flowering plants of the county formed by the Brighton and Sussex Natural History Society, and the pictures in the new museum gallery, were alike objects of attraction. It was universally admitted to be one of the most brilliant gatherings ever held in Brighton.

On Friday Section E was of course the one object of popular attraction. The scenic, not to say dramatic, character of the narrative by which Mr. Stanley preceded the reading of his paper produced a great effect, though probably the discussion which followed was hardly so exciting as the popular expectation had calculated on. Sir Henry Rawlinson's graceful acknowledgment, as President of the Geographical Society, of the sense entertained of Mr. Stanley's energy, and of the substantial value of his services to Dr. Livingstone, met with a hearty response. With regard to the general upshot of the "Livingstone Day," it may be said that while Mr. Stanley's narrative itself carried conviction to the minds of some who were previously sceptical, the manner in which it was delivered was unfortunate in the extreme. In the lamentable episode at the dinner of the Medico-Chirurgical Society on Saturday, when Mr. Stanley abruptly left in consequence of a discourtesy offered him by some of the members, there was undoubtedly fault on both sides, though nothing can justify the want of courtesy exhibited towards a stranger and a guest.

Not more than fifty individuals were collected in the room of Section A, at the Albion Hotel, to hear the most important proposition made at this meeting, by Lieut.-Col. Strange, in the form of a paper entitled, "On the duty of the British Association with respect to the distribution of its funds." The view of the distinguished author of the paper was that which has already been advocated in our columns,* that the Association ought not to grant money in aid of objects which it is the duty of the State to undertake. Such a course, he maintains, only encourages the Government in its present Philistine attitude towards Science; while if a contrary course were pursued, though Science might for a time suffer, a sounder and truer policy would ultimately be forced. In the discussion which followed the reading of the paper, the chief objection started to the proposal was that it will be necessary first of all to raise up a race of statesmen who have received a more complete scientific training, and will consequently have minds more open to the value of scientific research. This argument was forcibly advocated by Prof. H. Smith; to whom Col. Strange replied that, if we are to wait for this, we must be content to be a whole generation behind France and Germany, which countries are both keenly alive to the necessity of the promotion of scientific inquiry.

* See Nature Vol. vi. p. 297.

Saturday was, as usual, a kind of half-day, the brilliant weather inducing all who could possibly avail themselves of the various attractions in the form of excursions, scientific or picturesque, in the neighbourhood.

On Monday Section F was crowded to hear Miss Lydia Becker read her paper "On the attendance and education of girls in the elementary schools of Manchester." The object of the paper was to enforce the necessity for giving equal advantages to girls as to boys in the matter of education; and it was listened to with marked attention, the discussion which followed exciting also great interest. Considerable astonishment was caused by the statement that even the last Revised Code enforced a higher standard for male than for female pupil-teachers. On this the President of the Section, Prof. Fawcett, commented severely, and strongly urged the justice of allowing women to exercise the highest gifts of their nature as freely as men. The discussion proceeding this morning in the same section as Miss Shirreff's paper on Female Education, embraces the higher rather than the primary department of the subject, and will be the great feature of to-day's proceedings.

At the meeting of the General Committee held yesterday letters of invitation for the meeting of 1874 were read from Belfast, Glasgow, Bristol, and Bath.

Mr. De La Rue proposed that Belfast should be selected for 1874. Mr. Pengelly seconded, and the resolution was carried unanimously.

Prof. Williamson proposed that Dr. James P. Joule, LL.D., D.C.L., F.R.S., be appointed president-elect of the Association for the meeting at Bradford, which was seconded by Prof. Rankine, supported by Sir W. Thomson, and carried by acclamation.

The next meeting was fixed for September 19, 1873.

The Earl of Rosse, Lord Houghton, Right Hon. W. E. Forster, M.P., Mayor of Bradford, Mr. Gassiot, D.C.L., F.R.S., Prof. Phillips, D.C.L., F.R.S., Mr. T. Hawkshaw, F.R.S., were requested to accept the office of vice-presidents-elect of the Association.

The following alterations were made in the list of the ordinary members of the Council :—Mr. De La Rue, Mr. W. H. Flower, Sir Henry Rawlinson, and Mr. Sclater, were substituted for Prof. Foster, Mr. Gassiot, Mr. Simon, and Mr. Wallace.

Dr. Michael Foster was appointed one of the general secretaries, in the place of Dr. T. Thomson, and Mr. John Ball, F.R.S., Colonel A. Lane Fox, F.G.S., F.S.A., and Mr. Gwyn Jeffreys, F.R.S., were appointed auditors. The other officers were re-elected.

The lecture in the evening by Prof. Clifford, "On the Aims and Instruments of Scientific Thought," was undoubtedly the great intellectual treat of the meeting. It is impossible to give in a few words any idea of the lecture, which we hope to reprint at length. Suffice it to say that it presented some of the most abstruse problems which can form the subject of scientific thought, in a manner so lucid and sparkling as to enchain the audience in rapt attention, notwithstanding that it was unillustrated by a single experiment, like the very beautiful ones exhibited at Mr. Spottiswoode's admirable lecture to working men delivered the previous Saturday evening, of which a report will be found in our columns.

The number of distinguished foreigners attending the meeting is considerably larger than was anticipated. Among those not already named may be mentioned Dr. Hilyard, of the U.S. Coast Survey, Prof. Semper, of Wurtemberg, Prof. Gervais, of Paris, Prof. Gaudrey, of Paris, M. Georges Pouchet, Dr. Anton Dohrn, Prof. Richter, of St. Petersburg, &c.

Mr. Spottiswoode's Lecture to Working Men on Sunlight, Sea, and Sky

There are many ways in which men have looked at life, the higher kind of life, that ideal which each of us forms in his own mind to which we each hope that we are always tending. But all these various ideas may for the most part be grouped under two heads: the Ideal of Rest, and the Ideal of Work. "Rest, rest!" said a brave old German worker, "shall I not have Eternity to rest in?" That represents one view. "Work, work!" said another. "must I not work now, that I may the better work in Eternal Life?" That represents the other. But without entering upon the somewhat transcendental question of a future life, these ideas and aspirations have a meaning and reality even in the life which we now live. How do we hope to spend the leisure which old age may some day bring? Or, nearer still, when the day's work is done, and the day itself is not quite spent; or when such holiday as may befall each of us comes round, how do we hope to spend the time? Do we long for mere rest, for that

> land
> In which it seemed always afternoon.

Do we desire to sit us

> down upon the yellow sand
> Between the sun and moon upon the shore,

and sing with the lotus eaters

> All things have rest; why should we toil alone,
> Nor steep our brows in slumber's holy balm,
> Nor hearken what the inner spirit sings.
> There is no joy but calm.

Or do we rather with Ulysses say,

> How dull to pause, to make an end
> To rust unburnished, not to shine in use!
> As tho' to breathe were life. Life piled on life
> Were all too little, and of one to me
> Too little remains; but every hour is saved
> From that eternal silence, something more,
> A bringer of new things; and vile it were
> For some [few] suns to store and hoard myself,
> And this gray spirit yearning in desire
> To follow knowledge like a sinking star
> Beyond the utmost bounds of human thought.

To which of these two ideals I myself lean has perhaps already betrayed itself; and that being so, I shall venture to consider your presence here a proof that, for this evening at least, you side with me, and that you are willing to spend an hour of your leisure in an intellectual effort to see a little deeper into those phenomena which Nature in this place and at this season displays with such profusion and splendour.

But at the outset I must warn you that we are met by a difficulty, for the surmounting of which you must rely upon yourselves rather than upon me. It is this: the phenomena to which I propose to draw your attention, although taking place nearly every day, and all day long, and in almost every direction, are veiled from our eyes; and it is only by the use of special appliances to aid our eyes that they can be made visible. It will be my business to supply these appliances, and, reproducing on such scale as may be possible within these four walls the optical processes which are going on in the sea and sky outside, to exhibit the hidden phenomena of which I am speaking But it must be your part to transport yourselves mentally from the mechanism of the lecture-room to the operations of Nature, and by a "scientific use of the imagination" (to adopt what has now become a household word at these meetings) to connect the one with the other.

Now the main point in question is this: that light, when subjected to the very ordinary processes of reflexion from smooth surfaces, such as a window, a mahogany table, or the sea itself, or when scattered to us from the deep clear sky, undergoes in many cases some very peculiar changes, the character and causes of which we have come here to investigate. The principal appliance which will be used to detect the existence of such changes, as well as to examine their nature, consists of this piece of Iceland spar, called—from the man who first constructed a compound block of the kind—a Nicol's prism, and this plate of quartz or rock crystal; both of which, as you will observe when the light passes through them, are clear, transparent, and colourless, and both of which transmit the direct light from the electric lamp with equal facility, however they may be turned round about the beam of light as an axis.

If, however, instead of allowing the beam to fall directly upon the Nicol, we first cause it to be reflected from this plate of glass, we shall find that the process of reflexion has put the light into a new condition. The light is no longer indifferent to the rotation of the Nicol; in one position of the Nicol the light passes as before, but as the instrument is turned round the light gradually fades, and when it is turned through a right angle the light is extinguished. Beyond this position the light reappears, and the same changes of fading and revival are observed in the light for every right angle through which the instrument is turned.

But these phenomena are susceptible of a very beautiful modification by the interposition of this plate of quartz between the reflecting surface and the Nicol. The changes in the light are no longer mere alterations of brightness, but exhibit a succession of colours resembling in their main features those of the rainbow or spectrum.

The peculiar condition to which light must be brought in order that these phenomena may be produced is called polarisation; and although an explanation of its nature must be reserved until later, I beg you to notice that it is effected in this instance by reflexion from a plate of glass. A similar effect is produced if light be reflected from many other substances, such as the leaves of trees, particularly ivy, mahogany furniture, windows, shutters, and often roofs of houses, oil paintings, &c., and last, but not least, the surface of water. In each of these cases the alternations of light and darkness are most strongly marked, and the colours (if a quartz plate be used) are most vivid, or, in technical language, the polarisation is most complete, when the light is reflected from each substance at a particular angle. In proportion as the inclination of the light deviates from this angle the colours become fainter, until, when it deviates very greatly, all trace of polarisation at last disappears Without occupying the time necessary to shift our apparatus so as to exhibit this with the glass plate, we may alter the reflecting surface from glass to water, and by projecting on the screen the beautiful phenomena of liquid waves, make visible the different degrees of polarisation produced at the variously inclined portions of the surfaces of those waves. A tea-tray will serve as well as anything else to form our little sea, and a periodic tap at one corner will cause ripple enough for our present purpose. The waves now appear bright on the screen, and although brighter in some parts than in others, they are nowhere entirely dark. But on turning round the Nicol the contrast of light and darkness becomes much stronger than before. Here and there the light is absolutely extinguished; in these parts the polarisation is complete, in others incomplete in various degrees. And if the quartz plate be again introduced we have the beautiful phenomena of iris-coloured rings playing over the surface of our miniature sea.

Now, that which you see here produced by our lamp and tea-tray, you may see any day under the bright sky of this southern coast. By using an apparatus such as we have here, or a simpler one which I will immediately describe, you may bring out for yourselves these phenomena of colour, and thereby detect the profusion of polarisation which Nature sheds around us. But before describing it, there is one peculiar feature of all these experiments which must be noticed—namely, that the same results would be produced if we changed the positions of the lamp and the screen. The light which is now polarised by the glass or the water, and examined by the Nicol, might equally well be polarised by the Nicol and examined by the glass or the water. And, therefore, if we find that any contrivance will serve for the one purpose, we may conclude that it will serve equally well for the other.

And now a word about that simpler apparatus. When light falls upon a transparent substance, part is reflected, part transmitted. If, therefore, the reflected part is polarised (and you have already seen that this is sometimes the case), it is not surprising that the transmitted part should be so also. And further, if the polarisation by a single reflexion or transmission is incomplete, it will become more and more complete by a repetition of the processes. This being so, if we take a pile of glass plates—say half-a-dozen, more or less, the thinner the better—and hold them obliquely before our eye at an angle of about 30° (say one-third of a right angle) to the direction in which we are looking, we shall have all that is necessary to detect the presence of polarisation; and if, further, we hold a piece of talc or mica, such as is commonly used as a cover to the globes of gas-burners, beyond the pile of plates, colour will be produced in the same general manner as with the quartz, although with some essential difference in detail.

Suppose that we now turn our attention from the sea to the sky, and that on a clear bright day we sweep the heavens with our apparatus, or polariscope, as it is called, we shall find traces of polarisation colours brought out in a great many directions. But if we observe more closely we shall find that the most marked effects are produced in directions at right angles to that of the sun, when, in fact, we are looking across the direction of the solar beams. Thus, if the sun were just rising in the east or setting in the west, the line of most vivid effect would lie on a circle traced over the heavens from north to south. If the sun were in the zenith, or immediately overhead, the most vivid effects would be found round the horizon; while at intermediate hours the circle would shift round at the same rate as the clock, so as always to retain its direction at right angles to that of the sun.

Now, what is it that can produce this effect—or what even produces the light from all parts of a clear sky? The firmament is not a solid sphere or canopy, as was once supposed; it is clear, pure space, with no contents, save a few miles of the atmosphere of our earth, and beyond that the impalpable fluid or ether, as it is called, which is supposed to pervade all space, and to transmit light from the further limits of the stellar universe. But, apart from this ether, which is certainly inoperative to produce the sky appearance as we see it, a very simple experiment will suffice to show that a diffusion, or, as it has been better called, a scattering of light, is due to the presence of small particles in the air. If a beam from the electric lamp, or from the sun if we had it, be allowed to pass the room, its track becomes visible, as is well known by its reflexion from the motes or floating bodies, in fact by the dust in the air. But if we clear the air of dust, as I now do by burning it with a spirit lamp placed underneath, the beam disappears from the parts so cleared, and the space becomes dark. If, therefore, the air were absolutely pure and devoid of matter foreign to it, the azure of the sky would be no longer seen, and the heavens would appear black; the illumination of objects would be strong and glaring on the one side, and on the other their shadows would be deep, and unrelieved by the diffused light to which we are accustomed.

Now, setting aside the dust, of which we may hope that there is but little on the downs behind your town, or out to sea in front, there are always minute particles of water floating in the atmosphere. These vary in size from the great rain drops which fall to earth on a sultry day, through the intermediate forms of mist and of fine fleecy cloud, to the absolutely invisible minuteness of pure aqueous vapour which is present in the brightest of skies. It is these particles which scatter the solar rays, and suffuse the heavens with light. And it is a curious fact, established by Prof. Tyndall while operating with minute traces of gaseous vapours (which I can only notice in passing, because it belongs only in part to our present subject), that while coarse particles scatter rays of every colour equally—in other words, scatter white light—finer particles scatter fewer rays from the red end of the spectrum, while the finest scatter only those from the blue end. And in accordance with this law, clouds are white, clear sky is blue.

But beside this fact, viz., that light scattered laterally from fine particles is blue, the same philosopher perceived that light so scattered is polarised; and by that observation he again connected the celestial phenomena described above with laboratory experiments.

By a slight modification of his experiment, due to Prof. Stokes, I hope to make this visible to the audience. It will probably be in your recollection that when polarised light passed through a Nicol, its intensity is unaltered when the Nicol is in one position, but it is destroyed when it is in another at right angles to the first. I now pass the beam from the electric lamp through a tube of water containing a few drops of mastic dissolved in alcohol. The mixture so formed holds fine particles of mastic in a state of suspension; these scatter the light laterally, so as to be visible, I hope, to the entire audience. And if we were to examine with a Nicol this scattered light, we should find the phenomena of polarisation. But, better still, we can cause the light to pass through the Nicol before being scattered, and produce the same effect, not only upon the particular part to which our eye is directed, but upon the whole body of scattered light. As the Nicol is turned, the light seen laterally begins to fade; and when the instrument has been turned through a right angle, the only parts remaining visible are those which are reflected from the larger impurities floating in the water independently of the mastic. An effect still more beautiful, and at the same time more instructive, can be produced by interposing, as was done in the case of reflexion, a plate of quartz between the Nicol and the medium which causes polarisation. The whole beam is now suffused with colour, the tint of which changes, as did the tints on the waves, while the Nicol is turned round. And not only so, but while the Nicol remains at rest, the tints are to be seen scattered in a regular and definite order in different directions about the sides of the beam. This may be shown by reflecting from a looking-glass a side of the beam not visible directly, and by comparing the tint seen by reflexion with that seen direct. But this radial distribution of colours may also be shown in a more striking manner, by putting together two half plates of quartz of the kinds which have the property of distributing the colours in opposite orders, and by observing the result along the line of junction. The compound plate here used is known by the name of a biquartz, and affords one of the most delicate tests of the presence of polarised light. In this case, when the Nicol is turned round, the colours of the two halves follow one another in opposite orders; and as each series is completed twice in a revolution of the Nicol, the halves of the quartz will be of the same colour four times in a revolution—twice of one colour and twice of its complementary.

The colours which we have here seen are those which would be observed, as before remarked, upon examining a clear sky in a position at right angles to that of the sun; and the exact tint visible will depend upon the position in which we hold the Nicol, as well as upon that of the sun. Suppose, therefore, we direct our apparatus to that part of the sky which is all day long at right angles to the sun, that is, to the region about the north pole of the heavens (accurately to the north pole at the vernal and autumnal equinox); then, if on the one hand we turn the Nicol round, say in a direction opposite to that of the sun's motion, the colours will change in a definite order; if, on the other, we hold it fixed, and allow the sun to move round, the colours will change in a similar manner. And thus, in the latter case, we might conclude the position of the sun, or, in other words, the time of day, by the colours so shown. This is the principle of Sir Charles Wheatstone's polar clock; one of the few practical applications which this branch of polarisation has yet found. The action of such a clock may be thus roughly shown. There is now projected upon the screen a dial plate, in which the hours are arranged in their usual order, but are crowded together into half their usual space, viz., twelve hours occupy half instead of the entire circle. The inner part of the disc is covered with a plate of selenite (mica would serve the purpose equally well), which is capable of revolving about its centre, and which, as you see, in a particular position shows colour more strongly than in any other. An hour hand is roughly drawn upon the plate. The apparatus here used is furnished with two Nicol's prisms, the hinder one of which imitates the polarising effect of the sun, while that in front is the instrument with which we should examine the north pole of the sky. The whole is now so arranged that when the plate shows brightest colour the hand points to XII., say noon. As the back Nicol is turned round, say as the sun begins to sink, the colour fades; and when the plate is turned so as to restore the colour, the hand points to I. Similarly, as the back Nicol is turned gradually further, representing the passage of the sun westward during the afternoon, the position of the plate giving the strongest colour, as indicated by the hand, corresponds to the successive hours of the dial; and when the Nicol has been turned through 90°, that is, when the sun has reached the horizon, the hand has moved from XII. to VI. In this way, as its inventor has remarked, a dial may be constructed which will work equally well in sunshine or in shade, or even when the sun itself is overcast, provided only that there be a patch of clear sky to the north.

Up to this point we have reproduced in an experimental fashion the general every-day phenomena, both celestial and terrestrial, which give rise to polarisation; and we have given such general account of them as will serve to connect them together, and to show that they all belong to one system of laws affecting the nature of light. I should, however, regret, and I feel confident that you would share in that regret, if we were to leave the subject with its surface as it were merely scratched, and without any attempt to penetrate deeper into its substance. With your permission, therefore, we will devote such time as you may be still willing to grant me to a few elementary experiments in polarisation, which, while certainly not less beautiful than those which you have already seen, will, perhaps, better illustrate the nature of the processes which we are now trying to investigate.

Polarised light, as indicated at the outset, is distinguished from common light by the presence of certain peculiarities not ordinarily found, and these peculiarities are to be detected only by means of special instruments. Light which has been reflected or transmitted at particular angles from various substances, light which has been scattered by small particles, is found to be in this peculiar condition. So likewise is light which has passed through this transparent piece of Iceland spar, or Nicol's prism, as it is called. Yet the light which has so passed through, and which is now projected on the screen, is to the unaided eye in no way different from the same light before its passage. Nevertheless, if we examine or analyse it by means of a second Nicol, we shall find the peculiarity of its condition revealed. For if either of the Nicols be turned gradually round (and remember that they are both transparent colourless blocks of crystal) the light gradually fades until, when it has been turned through a right angle, the light is absolutely extinguished. On turning the Nicol further the light revives, and afterwards again fades, in such a manner that in a complete revolution the light is twice at its brightest, and twice is extinguished. Now, light is due to extremely small and rapid vibrations of a very subtle medium, which is supposed to pervade all space. The fact that vibrations (*i.e.* motions to and fro) in one direction can produce waves advancing in another will be familiar to all of you who have watched the movement of a cork floating on the sea. You will have noticed that the cork has simply moved up and down, or nearly so, while the waves have passed, as it were, under it, along the surface of the water.

Now, in order to make clearer to our minds how this wave motion is produced, I will throw the electric light upon a machine devised for the purpose. You now see a horizontal row of knobs As the slider is pushed in the knobs at one end begin to rise in succession until each has in turn attained its greatest elevation. Immediately after reaching its highest position it begins to descend; so that the knobs first rise and then fall in regular succession, and continue to rise and fall in the same manner so long as the motion is continued. Each of the knobs, beginning from number one, is thus successively at the highest position, while at the same moment those immediately before and behind it are at lower positions. And as the knob which is at the highest position represents what we call the crest of the wave, the crest will pass successively along all the knobs, beginning from the first. Thus the waves are transmitted along the line, while the vibrations take place across it. If the line of knobs represent the direction of a ray, their motions will represent the vibrations and waves to which the light is supposed to be due. In ordinary light these vibrations may take place in any directions perpendicular to the ray; and the effect of the crystal of which the Nicol is made, is to restrict these vibrations to a particular direction. In the arrangement now before you the first Nicol causes the vibrations to be altogether horizontal. When the second Nicol is placed similarly to the first, it will obviously have no further effect upon the light; but if it be turned through an angle, it will transmit only vibrations inclined to the horizontal at that angle; that is, only such part of the original horizontal vibrations as can be brought into the inclined direction; in other words, it will transmit only part of the light. And as the inclination is increased the part of the light transmitted will diminish, until, when the second Nicol is in a position to transmit only vertical vibrations (*i.e.*, when it has turned through a right angle), the light will vanish. Such is an explanation of this fundamental experiment in polarisation on the principle of what is called the Wave Theory of Light; and I have ventured to give it in some detail, because it is the key to all others, and forms a starting point for any who may desire to go further in the subject; and it is a remarkable feature in this Wave Theory of Light that the results of many other experimental combinations, to some of which we will now proceed, might be predicted upon the principles already laid down.

If a plate of crystal, such as selenite, be placed between the two Nicols, and turned round in its own plane, it will be found that in certain positions at right angles to one another no effect is produced. These may be called neutral positions. In all other positions the field is tinted with colour, which is most brilliant when the plate has been turned through half a right angle from a neutral position. If one of the Nicols be turned, the selenite remaining still, the colour will fade and entirely vanish when the Nicol has turned through half a right angle. After this position the complementary colour will begin to appear, and will be brightest when the Nicol has completed a right angle.

The colours so produced depend upon the thickness of the plate; thus, if we take a plate of selenite merely split and not ground to a uniform thickness, we shall have a variety of tints indicating the thickness of each particular part; or we may, by a careful arrangement of suitable thicknesses, produced a coloured pattern of delicacy and variety dependent only upon the skill with which the pieces have been worked.

A plate of the same crystal worked into a concave form is interesting as showing not only that the colours are dependent upon the thickness, but also that when, with an increasing or diminishing thickness of crystal, they have run through their cycle, they begin again; in other words, that the phenomenon is periodic. The field is then covered with a series of concentric rings, each of which is tinted with colours in a regular order.

In all these instances it is clear, from the experiments themselves, as well as from other experiments which form no part of our present subject, that the modifications which light undergoes are due to the internal structure of the crystals used. And it becomes a question of interest whether it be not possible, by some mechanical process, performed upon a non-crystalline substance, such as glass, so far to imitate a crystalline structure as to reproduce some of the optical results already shown. For this purpose let us take a bar of glass. On interposing it in its natural state between the Nicols when crossed, we find that no effect is produced in the dark field upon the screen. If, however, I merely press it as though with the intention of bending or breaking it, there will be at once brought about a condition of strain capable of affecting the vibrations of the ray falling upon it, to such a degree that some of them will find their way through the screen. And this result may be explained on precisely the same mechanical principles as in the case of the crystal. The effect may be heightened by placing the piece of glass in a vice, and screwing it up so as to bend or compress it to a greater degree than was possible by the hand alone. When this is done the direction and even the relative amount of torsion or compression of the different parts will be noted down as it were by the forms and hues of the figures thrown upon the screen.

The same kind of effect is shown by a piece of glass unevenly heated; but better still by glass which has been rapidly and unevenly cooled,—unannealed glass, as it is called. In the pieces now before you, the outside, having become first cooled and solidified, has formed a rigid framework, to which all the interior has been obliged to conform. The interior parts have consequently undergone strains and pressures in different directions and in different degrees, in accordance with which each part has become the subject of a definite internal molecular arrangement; and these, by each in its own way, modifying the light which they transmit, give rise to the figures now before you.

I will conclude this series of experiments by one which, although not so beautiful or striking as those which you have already seen, is still interesting as bringing the subject home to us, and as the only application of polarisation to commercial life which has yet been made. You will recollect the brilliant sequence of colour shown by a quartz plate when submitted to polarised light. Well, the effects produced by that quartz plate are also produced by not only some other crystals, but, what is very remarkable, also by many of their solutions, *e.g.* by that of sugar. Into this tube I have put a solution of sugar; when it is placed before the lamp, polarisation colours are shown on the screen, while the liquid itself remains colourless. If the solution be strengthened by the addition of more sugar, the tints vary; and by accurate observation of the colours for different positions of the Nicol, the strength of the solution may be determined. An instrument constructed with proper means of registering these phenomena with accuracy is called a saccharometer.

These experiments might be multiplied almost indefinitely, and many a long winter evening might be spent in following polarisation into other branches of science upon which it has something to say. For example, on examining a variety of vegetable and animal tissues, slices of wood, fronds of fern, scales of fish, hair, horn, mother of pearl, &c., with a suitable polariscope, we should find that they exhibit, internally, definite structural characters, capable of affecting the light, which they transmit in the same general way as do crystals. Or again, if we were to apply the principles established in an early part of this lecture to the conditions of sky, aspect, and time of day under which the photographer notices that he can obtain the most perfect image

in his picture, we should find that they correspond with those which will furnish him with daylight in the most perfectly polarised condition.

Once more, among the many and curious phenomena which are visible during a solar eclipse, there is one which has longer than any other refused to lift its veil to the solicitations of science. I mean that halo of light, or corona as it is called, which extends beyond the dark disc of the moon, beyond those red flames of burning gas which the researches of Lockyer, of Janssen, and of others have brought almost home to us, far away for millions of miles into distant regions of space. It was pre-eminently to investigate this phenomenon that the last Eclipse Expedition, furnished with funds by Her Majesty's Government at the instance of this British Association, was sent out. And upon this investigation all the powers of the twin instruments of modern times, the spectroscope and the polariscope, were turned. The spectroscope could tell us the nature of the substances to the combustion of which the light is due, and even the conditions of temperature and of pressure under which the combustion is taking place; but it could not disentangle those parts of the phenomenon which are due to direct, from those which are due to reflected or to scattered light. It was for the polariscope to tell us whether the corona is a terrestrial effect,—a mere glare, in fact, from our own atmosphere,—or a true solar phenomenon; and in the latter issue, whether any of it is due to direct rays from incandescent matter, or all of it to rays originating in such incandescent matter below, but scattered laterally from gases which have cooled in the upper regions surrounding the sun. This question has not even yet received a definitive answer. But the brief account given within the last few days by Mr. Lockyer, in anticipation of his more complete digest of the voluminous reports from the various branches of the Expedition, seems to justify us in the conclusion that the corona is substantially a solar phenomenon due not to direct but to reflected or scattered rays.

The principle upon which the polariscope enables us to make these refined distinctions in such far off phenomena is after all very simple. If the corona were due wholly to the effect of our atmosphere on such light as reaches us during a total eclipse of the sun, the whole of that light would be similarly affected, because it comes very nearly from the same part of the heavens. In other words, its polarisation would be uniform, and the corona, when examined by a Nicol and quartz, would appear of a uniform colour. But if the phenomenon were wholly due to the sun and its surroundings, the light would be affected, if at all, differently in different directions drawn outwards (like spokes or radii of a wheel) from the sun as a centre. In other words, its polarisation would be arranged spoke-wise, or, to use the technical term, radially; and the corona, when examined as before, would vary in colour on different sides of the sun.

I have already drawn largely, perhaps too largely, upon your patience. But it will not have been without purpose that, besides witnessing the exhibition of a few experiments, you should have seen, at least in outline, what manner of thing a scientific investigation is. Well, whatever it is (and I will not weary you with a dry statement of its processes), the foundation of it must always be laid in careful, accurate, and intelligent observation of facts. And it is a consideration which may well stir the hearts of us outsiders of science, especially on an occasion when we come face to face with some of the greatest philosophers of our time, than any one of us, by practising his eye and riveting his attention, may contribute some natural fact, some fragment of knowledge, to the common stock. And surely has not this a particular significance and importance to us, at a period when, by shortening the hours of labour, more leisure, as we may hope, will be at the command of many? It will, I take it, be our own fault if we spend that leisure in walking through dry places seeking rest; for, to those who have the eyes to see and the spirit to discern, the world is neither dry nor barren; but rather, it is like the mountain as it appeared to the servant of the prophet when his eyes were opened, full of beauty and wonder, of mystery and power,—full of hosts from all nations, striving manfully onward to promised lands of knowledge and of truth, and waging ceaseless warfare against ignorance and prejudice, and the long train of evils which are consequent upon them. And if, as the eventide of life draws on, our eye wax dim, and our step grow weary, so that we can no longer follow, we may still lay us down to rest in some unknown spot, in the full confidence that others will not be wanting to fill our places and gain fresh ground, though we may not live to see it.

SECTION A

Sectional Proceedings

Ad interim Report on the Results Obtained by the British Association Eclipse Expedition of 1871, by J. Norman Lockyer, F.R.S.

I. New Instruments

These were as follows:—

1. A train of five prisms to view the corona.
2. A large prism of small angle placed before the object glass of a telescope.

On these instruments I may remark that the Royal Astronomical Society, in the first instance, invited me to take charge of an Expedition to India merely to conduct spectroscopic observations; but although this request did me infinite honour, I declined it, because the spectroscope alone, as it had been used before, was, in my opinion, not competent to deal with all the questions now under discussion. Thus some of the most eminent American observers had come to the conclusion that the spectrum of hydrogen observed in the last eclipse round the sun, to a height of 8 minutes, was a spectrum of hydrogen "far above any possible hydrogen" at the sun. Hence it was in some way reflected. Now with our ordinary spectroscopic methods it was extremely difficult, and one might say impossible, to determine whether the light which the spectroscope analysed was really reflected or not; and that was the whole question.

It became necessary, therefore, in order to give any approach to hopefulness, to proceed in a somewhat different way in the 1871 expedition, with regard to the spectroscope, and, to guard against failure, to supplement such observations with photographs.

To understand the method adopted, let us suppose a train of prisms. Take one prism out of the train, and consider what will happen if we illuminate a slit with a monochromatic light and observe it through the prism. If we render sodium vapour incandescent and illuminate the slit by means of it, we get a bright yellow image of the slit, due to the vapour of the metallic sodium only giving us yellow light. But why is it that we get a line? Because we employ a line slit. If, instead of a straight line, we have a crooked line for the slit, then we see a crooked line through the prism. Going one step further: Suppose that instead of a line, whether straight or crooked, we have a slit in the shape of a ring, we see a ring image through the prism. And then comes this point: If, when we work in the laboratory, we examine these various slits, illuminated by these various vapours, if we observe the corona in the same way, we shall get a ring built up by each ray of light which the corona gives to us; since we know, from the American observations, that there were bright lines in the spectrum of the corona, as observed by a line slit: in other words, the corona examined by means of a long train of prisms should give us an image of itself painted by each ray which the corona is competent to radiate towards us.*

These were the considerations which led to the adoption of this new attempt to investigate the nature of the corona now in question. It was, to use a train of prisms, pure and simple, using the corona as the slit, a large number of prisms being necessary to separate the various rings we hoped to see, by reason of their strong dispersion.

This principle, good for a train of prisms such as I have referred to, is good also for a single prism in front of the object-glass of a telescope. Such was the method adopted by Prof. Respighi, the distinguished Director of the Observatory of the Capitol of Rome, who accompanied the expedition.

This method, if it succeeded, would be superior to the ordinary one in this way. If we were dealing merely with scattered light, then all the rings formed by vapours of equal brilliancy at the base of the chromosphere would be of the same height, while, if such scattering were not at work, the rings would vary according to the actual height of the vapours in the sun's atmosphere.

3. Integrating spectroscopes *driven by clockwork.*
4. A self-registering integrating spectroscope, furnished with telescopes and collimators of large aperture and large prisms. (This instrument was lent by Lord Lindsay.)
5. A polariscope-telescope, so arranged that the same observer could almost simultaneously observe both with the Savart and the Biquartz.
6. A polariscope-telescope, arranged for rapid sweeping round the corona at a given distance from moon's limb.

* After I had thought of this arrangement, and had secured an instrument to carry it out, Prof Young, in a communication to NATURE, suggested the same method of observation.

II. *The Main Results—Spectroscopic Observations*

It has been established that the idea that we do not get hydrogen above 10 seconds above the sun is erroneous, for we obtained evidence that hydrogen exists to a height of 8 or 10 minutes at least above the sun.

Just as the sun disappeared Prof. Respighi employed the instrument to which I have already referred to determine the materials of which the prominences which were then being eclipsed were composed, and he got the prominences shaped out in red, yellow, and violet light; a background of impure spectrum filling the field; and then as the moon swept over those prominences they became invisible. He saw the impure spectrum and the yellow and violet rings gradually die out, and then three broad rings painted in red, green and blue gradually form in the field of view of his instrument; and as long as the more brilliant prominences on both sides of the sun were invisible he saw these magnificent rings.

These rings were formed by C and F, which show us that hydrogen extends at least 7 minutes high, for had we been dealing with mere glare, *had we not been dealing with hydrogen itself we should have got a yellow ring as well.* In addition to the red ring and the blue and violet, which indicate the spectrum of hydrogen, he saw a bright green ring, much more brilliant than the others due to 1474.

While Prof. Respighi was observing these rings by means of a single prism and a telescope of some four inches aperture, some 300 miles away from him—he was at Poodocottah and I was at Bekul—I had arranged the train of five prisms. My observation was made intermediately, as it were, between the two observations of Prof. Respighi's. The observations may be thus compared:—

Respighi ...	C D^3	F G	Prominence at beginning of eclipse.
Lockyer ...	C 1474	F G	Corona 80 seconds after beginning of totality.
Respighi ...	C 1474	F	Corona mid eclipse.

I had no object-glass to collect light, but I had more prisms to disperse it, so that with me the rings were not so high as those observed by Respighi, because I had not so much light to work with, but such as they were I saw them better because the continuous spectrum was more dispersed, and the rings—the images of the corona—therefore did not overlap. Hence doubtless Respighi missed the violet ring which I saw, but both that and 1474 were very dim, while C shot out with marvellous brilliancy, and D^3 was absent.

These observations thus tend to show, therefore, that instead of the element—the line of which corresponds with 1474—existing alone just above the prominences, the hydrogen accompanies it to what may be termed a great height above the more intensely heated lower levels of the chromosphere, including the prominences in which the lower vapours are thrown a greater height. With a spectroscrope of small dispersion attached to the largest mirror of smallest focus which I could obtain in England, the gaseous nature of the spectrum, as indicated by its *structure*, that is bands of light and darker intervals as distinguished from a continuous spectrum properly so called, was also rendered evident.

Photographs and Structure of Corona

The photographic operations (part of the expense of which was borne by Lord Lindsay) were most satisfactory, and the solar corona was photographed to a greater height than it was observed by the spectroscope, and with details which were not observed in the spectroscope. Mr. Davis was fortunate enough to obtain five photographs of great perfection at Bekul, and Captain Hogg obtained some at Jaffna, but the latter lack in detail. The solar nature of most, if not all, of the corona recorded on the plates is established by the fact that the plates, taken in different places, and both at the beginning and end of totality, closely resemble each other, and much of the exterior detailed structure is a continuation of that observed in the inner portion independently determined by the spectroscope to belong to the sun.

This structure I was also enabled to observe in my 6¼ in. equatorial, even three minutes after totality was over, and we may now say that we know all about the corona, so far as the structure of its lower brighter levels—that portion, namely, which time out of mind has been observed both before and after totality—is concerned. It may be defined as consisting of cool prominences, that is to say, in this region of the corona we will find the same appearances as in prominences, minus the brightness. We find the delicate thread-like filaments which all are now so familiar with in prominences,—the cloudy light masses, the mottling, the nebulous structure, all are absolutely produced in the corona; and I may add that the faintest portion of the ring, some 5 minutes round the sun, reminded me forcibly in parts of the nebula of Orion, and of that surrounding η Argus, as depicted by Sir John Herschel in his Cape observations.

While both in the prism and the 6¼-inch equatorial the corona seemed to form pretty regular rings round the dark moon, of different heights according to the amount of light utilised by the instrument, on the photographic plates the corona, which, as I have before stated, exceeds the limits actually seen in the instrument I have named, has a very irregular, somewhat stellate outline, most marked breaks or rifts *(ignored by the spectroscope)*, occurring near the sun's poles, a fact perhaps connected with the other fact that the most active and most brilliant prominences rarely occur there.

Sketches

From the photographs in which the corona is depicted actinically we pass to the drawings in which it is depicted visually. I would first call attention to two drawings made by Mr. Holiday, who formed part of the expedition, and in whose eye every one who knows him will have every confidence.

First there is a drawing made at the commencement of the totality, and then a drawing made at the end. There is a wonderful difference between these drawings; the corona is in them very much more extensive than it is represented actinically on our plates.

In another drawing, made by Captain Tupman, we have something absolutely different from the photographs and from Mr. Holiday's sketches, inasmuch as we get an infinite number of dark lines and a greater extension than in the photographs, though in the main the shape of the actinic corona is shown.

The corona, as it appeared to me, was nothing but an assemblage of such bright and dark lines; it lacked all the structure of the photographs, and appeared larger; and I have asked myself whether these lines do not in some way depend on the size of the telescope, or on the absence of a telescope. It seems as if observations of the corona with the naked eye, or with a telescope of small power, may give us such lines; but that when we use a telescope of large power, it will give, close to the moon, the structure to which I have referred, and abolish the exterior structure altogether, leaving a ring round the dark body of the moon such as Prof. Respighi and myself saw in our trains of prisms, and I in the 6-inch telescope, in which the light was reduced by high magnification so as to bring the corona to a definite ring some 5 minutes high, while Prof. Respighi, using a 4-in. telescope, brought the corona down to a ring something like 7 minutes high.

Many instances of changing rays, like those seen by Plantamour in 1860, were recorded by observers in whom I have every confidence. One observer noted that the rays revolved and disappeared over the rifts.

Polariscopic Observations

Mr. Lewis, in sweeping round the corona at a distance of some 6′ or 7′ from the sun's limb, using a pair of compensating quartz wedges as an analyser, which remained parallel to itself while the telescope swept round, observed the bands gradually to change in intensity, then disappear, bands of a complementary character afterwards appearing, thereby indicating radial polarisation.

Dr. Thomson at Bekul saw strong traces of atmospheric, but none of radial polarisation, with a Savart. With the same class of instrument the result obtained by myself was precisely similar, while on turning in the Biquartz, at the top and bottom of the image of the corona, *i.e.*, near the sun's equator, faint traces of radial polarisation were perceptible for a short distance from the moon's limb. Captain Tupman, who observed with the polariscope after totality, announces strong radial polarisation extending to a very considerable distance from the dark moon.

Reversal of Lines at beginning and end of Totality

Captain Maclear, who was observing with me at Bekul, for some time just before the commencement of totality, but when the light of our atmosphere was cut off by the interposition of the dark moon, saw a large number of very fine lines of different heights at the base of the chromosphere.

Mr. Pringle, also at Bekul, saw many lines flash into the field of an analysing spectroscope carried by clockwork at the end of totality.

Captain Fyers, the Surveyor-General of Ceylon, observing with an integrating spectroscope, saw somethinglike a reversal of all the lines at the beginning, but nothing of the kind at the end.

Mr. Fergusson, observing with an instrument of the same kind, saw reversal neither at the beginning nor the end, though during totality he saw more lines than Captain Fyers.

Mr. Moseley states that at the beginning of the eclipse he did not see this reversal of lines. Whether it was visible at the end he could not tell, because at the close the slit had travelled off the edge of the moon.

Prof. Respighi, using no slit whatever, and being under the best conditions for seeing the reversal of the lines, certainly did not see it at the beginning, but he considers he saw it at the end, though about this he is doubtful.

From the foregoing general statement of the observations made on the eclipse of last year, it will be seen that knowledge has been very greatly advanced, and that most important data have been obtained to aid in the discussion of former observations. Further, many of the questions raised by the recent observations make it imperatively necessary that future eclipses should be carefully observed, as periodic changes in the corona may then possibly be found to occur. In these observations the instruments above described should be considered normal, and they should be added to as much as possible.

SECTION D

SUB-SECTION ZOOLOGY AND BOTANY

Opening Address by the President, Sir John Lubbock, Bart., M.P., F.R.S.

Although this would not, perhaps, be a fitting opportunity for discussing the importance and best mode of introducing the study of Natural Science into our great public schools, and though the question is still in a far from satisfactory position, yet I think I may congratulate the Section that some progress has been made in that direction during the last few years. To this result the influence of the British Association has no doubt greatly conduced. As yet, indeed, Natural Science is generally taught but to some of the elder boys, and certainly is very far indeed from having its due share of attention in relation to other subjects. I am happy to say, however, that most of the regulations which are being drawn up under the Public Schools Act, by the new governing bodies of the public schools, contain a provision that Natural Science shall be taught to all boys in their passage through the school. As the Royal Society has a representative in the governing bodies of all the public schools, we may fairly hope that this clause will not be allowed to remain a dead letter. I have no reason to suppose that any head-master will oppose the change; but it will of course be necessary for the governing bodies to allot a sufficient amount of funds to this purpose, so as to enable the head-masters to carry out the clause in an efficient manner. In several cases, moreover, and eventually I hope in all public schools, special scholarships and exhibitions will be devoted to Natural Science. When these changes come into full operation, they will doubtless greatly influence the system of education pursued in our preparatory schools. At present, I regret to say, that I know of no private school in England where Natural Science receives the attention it deserves. I must, however, in fairness add, that private schoolmasters are almost compelled to give, not the kind of education which they would themselves prefer, but that which is the most effective preparation for the course of study pursued at the public schools.

The Association has also urged on Government the importance of introducing the elements of Science into the elementary schools of the country, and a deputation from the Council waited on Mr. Forster with this object. In the new code shortly afterwards promulgated, Mr. Forster has admitted the principle, and allotted certain payments to extra subjects, coupled, however, with conditions which, as stated in the report of the Royal Commission on Scientific Instruction, render the promise to a great extent illusory. The subject is no doubt one of great difficulty; but Mr. Forster has distinctly stated that the Government have discarded the idea that the educational functions of Government should be confined to the encouragement of reading, writing, and arithmetic. The experience of some of our best schools, such, for instance, as those of Dean Dawes and Prof. Henslow, show clearly that elementary science can be introduced with the most excellent results, and I rejoice to see that some of our most important School Boards, for instance, those of London and Liverpool, have determined that elementary instruction in science shall be given in all the schools under their control.

If it is said that in such cases but a smattering can be given, I might ask, who has more? Those who are the most advanced in knowledge will be the first to admit how slight that knowledge is.

Indeed, every fresh observation, every new discovery, opens up new lines of inquiry. Take, for instance, the results of Mr. Darwin's great work on the Origin of Species. Mr. Darwin, as almost all biologists would now admit, has thrown a great light on a very interesting and difficult problem; yet in doing so, it suggested various new lines of inquiry, and in removing to a certain extent the veil from our eyes, discovered to us fresh fields for research, which promise most interesting results to those who will study them with diligence.

It is surprising how much, in spite of all that has been written, Mr. Darwin's views are still misunderstood. Thus Browning in one of his recent poems says:—

> That mass man sprung from was a jelly lump
> Once on a time; he kept an after course
> Through fish and insect, reptile, bird, and beast,
> Till he attained to be an ape at last,
> Or last but one.*

Speaking to such an audience as the present, it is unnecessary for me to point out that this is a theory which Mr. Darwin would entirely repudiate, which is utterly inconsistent with his views. Whether fish and insect, reptile, bird, and beast are derived from one original stock or not, they are certainly not links in one sequence. I do not, however, propose on this occasion to discuss the question of Natural Selection. But I may observe that it is one thing to acknowledge that in Natural Selection or the Survival of the Fittest Mr. Darwin has called attention to a *vera causa*, has pointed out the true explanation of certain phenomena: it is quite another thing to assume, as is too often done, that all animals are descended from one primordial source. For my own part, I am quite satisfied that Natural Selection is a true cause. Whatever may be the final result of our present inquiries, whether animated nature is derived from our ancestral source, or from a number of successive creations, the publication of the Origin of Species will not the less have constituted an epoch in the History of Biology.

How far the present condition of living beings is due to Natural Selection; how far, on the other hand, the action of Natural Selection has been modified and checked by other natural laws, by the unalterability of types, by atavism, &c.; how many types of life originally came into being; whether they arose simultaneously or successively,—these and many other similar questions remain to be solved, even if we admit the theory of Natural Selection. All this has, indeed, been clearly pointed out by Mr. Darwin himself, and would not need repetition, but for the careless criticism by which in too many cases the true question has been obscured.

[The remainder of the President's Address was occupied by an enlargement of his views respecting the Origin of Insects,† which we hope to present to our readers at a future time in a complete form.]

SUB-SECTION ANATOMY AND PHYSIOLOGY

Opening Address by the President, Prof. Burdon Sanderson, F.R.S.

We are met here for the purpose of hearing papers on Anatomy and Physiology. It would not have been inappropriate to have given you some account of the limits of the two very distinct sciences which are so designated; but as I am anxious to occupy your time for as short a period as possible, I shall content myself with saying that the few observations I have to make will have reference only to the two sciences to which I am myself attached. I make this preliminary explanation; for the positions of the two sciences in England are so different that much that I may say about Physiology is not applicable to Anatomy.

I should have been glad if it had been possible to have occupied this time in giving you a retrospective account of the

* Prince Hohenstiel Schwangau, p. 68.

† See Sir John Lubbock's paper in Nature, vol. v. p. 27.

Progress of Physiological Research during the past year. I had intended to do so, but was led to abandon my intentions on the ground that although the work done has not been inconsiderable, we in England have taken very little part in it. If I had attempted the task, I should have been but chronicling the doings of our friends in Germany, who are now holding their own scientific assembly in Leipzig. As I do not wish to talk about German physiologists to-day, I find it more agreeable and more encouraging to look forward than to look back; for although we English physiologists (I say physiologists advisedly, because the anatomist is not in the same position) must admit with regret that we have had very little to do with the unprecedented development of our science during the last two decades, we do not intend to continue in the same inactive condition in future.

Considering that half the purpose of our meeting in this section is to promote the progress of physiology, I do not think I can more properly occupy your time than in endeavouring to show in what direction efforts must be made to improve its position, and particularly to secure a future more fruitful of substantial results than the past has been.

I shall begin by asserting a general principle, which, as I go on, I shall endeavour to justify—that one great reason why physiological research is less successfully pursued in England than we could wish it to be, lies in the general want of scientific education. In illustration of this position, I shall refer first to that higher training which is required for the production of scientific workers or investigators; secondly to what may be called the education of public opinion, by the popularising agency of books and lectures; and lastly to the introduction of Natural Science as an element of education in our great schools and universities.

Training of scientific workers.—If a man wants to be a physiologist, he must, as things at present stand, study medicine. There is no logical reason for this; for, although medicine ought to be built on physiology, there is no reason why a physiologist should know anything about the art of curing diseases. Practically, however, it is the case that the kind of education which a man requires in order to be a physiologist is best obtained through a course of medical study. I confess myself to be of the opinion that this close relation between medicine and physiology is likely to be a permanent one, on the general ground that any science is likely to be studied with more earnestness by those who have to practise an art founded upon it than by others. For example, in England there can be little doubt that it is to our pre-eminence over all countries in the mechanical arts that our exceptionally greater men in the physical sciences on which those arts are built, is due. The reason why the same sort of beneficial reaction of art upon science has not manifested itself in our own sphere is that the connection between the two, *i.e.*, between physiology and medicine, is much less substantial. We physiologists are not yet in a position to advise the doctors, and they, resting on the more reliable teaching of experience, are quite willing to do without us.

If I am right in supposing that the pursuit of physiological research will always be closely connected with medical study, it becomes a matter of interest to us to know in how far the existing institutions for teaching are fitted for the training of scientific men.

We, who are personally concerned in the teaching of medicine, must, I think, admit that, as regards English schools, an ordinary medical course is not a very good preparation for scientific work. The reason of this is that the "medical sciences" as they are called—chemistry, anatomy, and physiology—have developed far too fast for the resources of our schools. Physiology, which twenty years ago might (without very flagrant absurdity) have been called the handmaid of medicine, has become a great science quite independent of the art which brought her into existence. No longer learning from medicine as she used to do, but based entirely on experiment, she claims much closer relationship with the other experimental sciences, and particularly, of course, with physics and chemistry, than with her parent art.

Let us suppose ourselves carried back, say twenty years. Twenty years ago a lecture-room, with a gallery for showing preparations under the microscope, was all that was thought necessary for teaching physiology, even in the best appointed schools; but then how different was that time from the present as regards the position of the science. I can only refer to one or two of the directions in which progress has been made. All that we knew twenty years ago about the gases of the blood was founded on the Imperfect methods and erroneous results of Magnus. Take, for example, the exchange of gases in respiration. In 1852 all that we knew on this subject was founded on the imperfect methods and analyses of the physicist Magnus. Now Ludwig and his pupils have put us in possession of a knowledge which for exactitude may be compared with that of the fundamental facts of physics, with methods directly applicable to a number of most important questions. The same physiologist, Ludwig, had lately written his earliest papers on arterial pressure, and has thus by the introduction of new methods inaugurated a new era in the physiology of two mechanical functions. Du Bois Reymond has scarcely begun that series of researches by which he, like Ludwig, rather founded a new science than extended the limits of an old one. In France Brown-Séquard had discovered the functions of vasomotor nerves, and Bernard the glycogenic function of the liver.

Great as was the intrinsic value of all these investigations, it was surpassed by that of the influence which they exercised on the future progress of science. How rapid that progress has been may be readily judged of by any one who chooses to read any of the text-books of twenty years ago in the light of recent researches. With the exception of the somewhat obscure region of what is called animal chemistry, every chapter has been rewritten on the sure basis of direct observation and experiment, the mechanics of the circulation, the chemical changes in the blood and tissues in respiration, the relation between muscular movements and the central organs of the nervous system which preside over them, the electrical changes which go on in nerves and muscles when in and out of action, and in physiological histology, the mode of central and peripheral termination of nerve fibres, and the anatomy of the lymphatic glands and the mode of origin of the absorbent system in the tissues.

In this great progress one would rather not have to admit that Germany has done so large a proportion of the work; for France, notwithstanding her great leaders in science and her great scientific institutions, has accomplished much less than she ought to have done. In taking her part England has been represented by us, the teachers in her medical schools; but we, possessing neither space nor appliances for the prosecution of experimental inquiries, have contented ourselves only too readily to reap the fruits of other men's labours.

It would not be pleasant to make this admission, were it not possible to look forward with considerable confidence to something better. In the great medical schools of London, in the old Universities, and in one or two, at least, of the provincial schools, great efforts are now being made to provide adequate buildings and competent persons for the experimental teaching and study of physiology. It is, I think, a most encouraging sign of the times that the initiative in this movement has been taken by Trinity College, Cambridge. That wealthy corporation, whose very name recalls to our recollection the intellectual glories of our country, has condescended to provide a place for physiologists to study and labour in, from which (short though the time is for which it has existed) one or two valuable researches have already sprung. To what the University of London has done during the last twelve months in establishing a laboratory for inquiries into that most important though comparatively new branch of physiology which relates to the origin and nature of diseases, it is scarcely possible for me to refer, excepting in so far as to express my hope that its influence will eventually be felt in strengthening the hold of physiology on practical medicine.

Notwithstanding these efforts, it will take years to regain the position which we in England once had, and ought never to have lost. The appliances and places for work are now forthcoming, and can be extended as they are required. This is a great step forwards, but we still want the pecuniary resources requisite for carrying out systematic and continuous researches, and above all, we have still to educate workers.

Of the two wants I have mentioned, the want of money and the want of workers, the second is the most important. The difficulties which lie in our way in this respect are very great indeed. The obvious difficulty—the objection, I mean—which is always adduced by young men as a sufficient reason for not giving up their time to scientific research, is that it does not pay; but it need scarcely be said that the real difficulty is a more general one. It lies in that practical tendency of the national mind which leads us Englishmen to underrate or depreciate any kind of knowledge which does not minister directly to personal comfort or advantage, a tendency which was embodied in the

philosophy of Bacon, and has been thought by some to constitute its great weakness. I have no doubt there are as many in England as in Germany who would not be deterred by the prospect of comparative poverty, which in every country must be the part of those who devote themselves to abstract science, but very few who have the courage and resolution to follow this course in spite of a public opinion which estimates science on utilitarian principles.

This leads me naturally to my second position, which is that the most efficient means we can take to improve the position of our science in England are those which have for their object the enlightenment of public opinion, and that this is to be effected partly by diffusing this knowledge of our labours among the public, and so inducing them to take an interest in them, partly by introducing training in physical science into our schools.

In the art of exposition, *i.e.*, of making difficult subjects plain, we have one among us who is a master—whose powers in this respect have been acknowledged, not only in England, but in France, and still more emphatically in Germany. His work on elementary physiology has been presented to the German public by one of the leading German physiologists (who is himself a model of clearness of style), who tells his countrymen in his preface that no German writer could expound the experimental facts which are the basis of physiological knowledge as Huxley can.

In the existence of such a man as Huxley I find a great source of encouragement for the future of English physiology, not only on account of his own work, large though that has been (for no one builder can lay many bricks in an edifice where every brick requires such careful laying), but also for his influence on national life.

At one time I confess that I was disposed to underrate the value of popularising science;—now I see the power of exposition to be a great power for good. We have an example of the good that it effects in the history of this Association. We have another in that of the Royal Institution, which has lately been made familiar to us by the accounts which have been given of that great and good man who for so many years was its life. Faraday, the greatest physicist of his time, was equally master of the art of exposition. Of the influence which his mind thereby exercised on the minds of men, women, and children, there can be no doubt. Nor do I think that he lost by it himself, for although we cannot suppose that he taught without some exhaustion of his energies, I cannot believe that the effort was a useless one even to himself.

One would not venture to say of such a man that, in explaining to children the fundamental conceptions which in his mind were already so clear, these became still clearer; but I think it may be so.

I pass at once to the second part of my position, that which relates to the teaching of science, and particularly physiology, in schools. This I may deal with very shortly.

The teaching must necessarily be elementary. If it is thorough and genuine, it is good.

To wedge a little bit of Bowdlerised physiology, something about the structure and functions of the human body, into the ordinary course of a school education, may be an ornamental addition to it, but can scarcely be really useful. Our reform, if it is to be attempted at all, must be much more complete and radical. It must consist, not in adding natural science to the system of instruction in which we ourselves and our predecessors were brought up, but in substituting for some of the old drudgeries something better and more substantial.

As regards that higher education which may be defined as introductory to the studies of the University, most people are now disposed to recognise that there exists at the present day a tendency to increase its extent at the expense of its thoroughness. On the one hand, a powerful effort is made by the *laudatores temporis acti* to maintain the old discipline; while on the other a general though somewhat vague notion prevails that no system of education can be regarded as complete from which science is excluded. To reconcile these antagonistic tendencies, the only method which has been found is that of addition and accumulation. Instead of displacing some of the old requirements, an additional load of new subjects has been imposed on the unfortunate examinee in the form of chemistry, physics, animal physiology, &c. No wonder that to the victim who has just passed through one of our modern ordeals the very names of these sciences are sickening; for in addition to the disagreeable task of getting them up from text-books (text-books, however excellent, are at best but very poor reading), the competitor, whether successful or not, has the consoling reflection that he has been doing treadmill work after all—learning a number of facts and laws of great value to the man who is able to possess himself of them, but to him rendered absolutely useless from the mode of study to which the present system of examinations has compelled him.

The way to obviate this I have already hinted at. Let it be clearly understood that if natural science is to be made a part of our educational system, it cannot be introduced as an ornamental addition or accomplishment, but as part of the groundwork. To serve as a groundwork, we must admit that physiology and anatomy are not adapted.

The corner-stone must, of course, be mathematics. Side by side with mathematics the subjects which ought to claim preference are physics and chemistry. The latter, when taught and studied experimentally, is specially fitted to cultivate that certainty, that convincedness of mind, that clear realisation of facts seen not by the bodily but by the intellectual eye, which constitute the scientific spirit. A boy who has learnt to feel the certainty of the laws of chemical combination, of the relations between density and combining weight, and between both and specific heat, can never, so long as he retains his mental soundness, relapse into that state of vague indifference about facts which characterises many uneducated persons, or lose the habit of exactitude of conception and statement to which he is compelled by practice in chemical reasoning.

It is clear that anatomy and physiology cannot be recommended on the same ground, yet I believe that it may be wisely included in ordinary education, not as a discipline, and not as a subject of examination, but on the ground that it is so usefully applicable to the common affairs of life. It is undoubtedly useful that every one should know something of the structure and functions of his own body, and this for several reasons—first, because he is enabled thereby to take better care of himself, and to understand how to preserve himself by reasonable precautions against some of the well-recognised causes of disease. Another reason is, he would not be so likely as he would otherwise be to become the dupe of the many quackeries which are afloat—more ready to take the advice of the doctor as regards the regulation of his mode of life, less credulous about the efficacy of drugs.

Let us now, in conclusion, say one word as to the influences which the general adoption of a system based upon scientific training would exercise on scientific progress, and particularly on the progress of the science in which we are interested.

I can illustrate this best by taking the medical student as an example. We teachers of physiology to medical students know that when we begin first to talk to them about the principles of the subject, *e.g.*, about chemical change as the essential condition of all vital phenomena, about the relation between the production of heat and external motion, about the exchange of gases in respiration, and many other fundamental subjects, the great difficulty is that our auditors are utterly at fault for want of those conceptions about matter and its powers, which are expressed by the words we are constantly using, such as solid, liquid, gas, vapour, weight, density, volume, &c., all of which to the average finished schoolboy are perfectly meaningless. The result is that these fundamental conceptions, not having been mastered at first, are not mastered at all, and the student begins to build the superstructure without having had any opportunity of laying the foundation. If the *Vorbildung* were different, if students were to come to their work with the scientific habit of mind already formed, it would not only make them better students, but would retain its influence on him through life. The details might fade from the memory, but the spirit would remain.

I trust that it will not appear to the members of the Section that I have, in any of the observations I have made, forgotten that the object for which we are assembled here is the promotion of the science of anatomy and physiology. Although I cannot claim for our science a more direct interest in scientific training than for others, there are reasons (as I have endeavoured to show) why it suffers more from the want of it than others. The chief one being that, as compared with what we feel and know to be its real importance to the future welfare of humanity, the practical benefits which immediately arise from it are not so obvious.

I have said very little indeed of another pressing difficulty which we have now, and, I believe, will have for many years, to contend with—the want of pecuniary resources—because I know that in this country if educated public opinion can be interested on behalf of any scientific object, and particularly if

the intelligent classes of the community can be shown on good ground, that the furtherance of abstract science is a matter of vital importance to our national existence. no one believes that now the really trifling public expenditure which would be required to enable us to compete at least on equal terms with Germany, Austria, Bavaria, and Russia, would at once be forthcoming.

In the meantime it is the function and duty of all who have the means and are interested in scientific progress, and especially of us, the members of this section of the British Association, to afford such aid as we can to those who, supported by their own enthusiasm rather than by the prospect of honour or emolument, are willing to devote their lives to physiological and anatomical researches.

SUB-SECTION ANTHROPOLOGY

OPENING ADDRESS BY THE PRESIDENT, COLONEL A. LANE FOX

(*Concluded from page* 324)

AMONGST the earliest improvements upon the primitive arts of man would be the substitution of the throwing-stick by the bow as a means of accelerating the flight and force of the javelin. So decided an advance in the employment of missile force would lead to the discontinuance of the throwing-stick for ordinary purposes wherever the bow was introduced. The throwing-stick is now found only in distant and unconnected regions, viz., in Australia, and amongst the Esquimaux, and the Furus Furus Indians of South America; and it has been assumed, on account of the isolated positions in which it is found, that it must be indigenous. On the other hand, the use of the bow is almost universal; and it has equally been assumed, on account of its world-wide distribution, that it must be indigenous in different localities, and not derived from a common centre. Geographical distribution, however, although affording the best evidence obtainable, cannot be relied upon with certainty in the case of so early an invention as the bow appears to have been. I cannot concur in thinking that we have any sure evidence that the bow originated in different places; on the contrary, what evidence we have appears to me to be of a contrary tendency.

As by degrees the use of the bow spread over the world, that of the throwing-stick would tend to disappear. We have some grounds for supposing that the latter instrument was formerly in use in the Pelew Islands, and Mr. Franks has found it amongst some Mexican relics probably preserved in a tomb. May it not also have existed formerly in other localities where it has not been preserved in tombs, and where no trace of it now exists? If this were the case, where should we now expect to find it retained? In such localities as the Arctic Seas, where lack of suitable materials still renders the construction of the bow a work of great difficulty, as is shown by the manner in which several pieces of hard bone are sometimes fastened together to form one, or in Australia, where the knowledge of the use of the bow has never penetrated.

Closely connected with the bow, the harpoon may be instanced as an example of early origin and wide distribution. The harpoon is found in some of the French caves, amongst the earliest bone relics of human workmanship that have been brought to light. Its present distribution is almost universal, being found in Australia, North and South Africa, North and South America, and in all regions where its use has not been superseded by more suitable contrivances.

In proportion as our investigations are carried into the higher phases of civilisation, we find our areas of distribution more limited, and of more and more value to us in tracing the continuity of culture; and when we come to the distribution of the metallurgic arts we find them defined by marked geographical boundaries which are not the boundaries of the great primæval races of mankind.

If we draw a line across the globe from Behring Strait in a south-westerly direction through Wallace's line, leaving Australia on the east, and take for our period the date of the first discovery of America, we shall find that—putting aside the metallurgic culture of Mexico and Peru, which, it may be observed, is grouped round a single centre—this line separates the area of stone culture on the east from the area of metallurgic culture on the west, but it passes straight through the primæval racial boundaries.

If we take what we may call the metallurgic area more in detail, and endeavour to trace the distribution of the implements of the bronze period, we find that the same class of weapons and tools extends over a continuous area, including the whole of the northern, western, and central parts of Europe, as far as Siberia on the east; these implements, including palstaves, leaf-shaped swords, and socket celts, with the moulds for casting them, are of a character to prove that the diffusion of the bronze culture throughout this area must have been connected and continuous. In Egypt, Assyria, India, and China, we have also bronze, but the forms of the implements do not, as a rule, correspond to those of the area above mentioned; our knowledge of the bronze weapons of India and China is, however, extremely limited as yet. I have elsewhere given my reasons for believing that the knowledge of the use of iron in Africa must have been derived from a common centre; not only is the mode of working it the same throughout that continent and in India, but the forms of the weapons fabricated in this metal, and especially the corrugated blades, are the same in every part, and appear to have been copied and retained through habit, wherever the use of iron has penetrated. I have lately traced this peculiar form of blade in several parts of the Indian Peninsula and Burmah, and I have no doubt it will eventually be found further to the north, so as to connect the area of its distribution continuously with those of the same identical construction that are found in the Saxon and Frankish graves.

I have thus briefly alluded to the distribution of some of the arts associated with early culture, with the view of showing that as our knowledge increases we may expect to be able to trace many connections of which we are now ignorant, and that we should be careful how we too readily assume, in accordance with the theory which appears popular among anthropologists at the present time, that coincidences in the culture of people in distant regions must invariably have originated independently, because no evidence of communication is observable at the present time. Owing, perhaps, to a praiseworthy desire to refute the arguments of Archbishop Whately, and others who have erroneously, as I think, assumed that because no race of existing savages has been known to elevate itself in the scale of civilisation, therefore, the first steps in culture must have resulted from supernatural revelation, we have now had a run upon the theory of what may be called the spontaneous generation of culture, and the pages of travel have been ransacked to find examples of independent origin and progress in the arts and customs of savage tribes.

Owing to this cause we have, I think, lost sight in a great measure of the important fact which history reveals to us, that, account for it as we may—and it is one of the great problems of Anthropology to account for it if we can—the civilisation of the world has always advanced by means of a leading shoot, and though constantly shifting its area, it has within historic times invariably grouped itself round a single centre, from which the arts have been disseminated into distant lands, or handed down to posterity. In all cases a continuous development must be traced before the problem of origin can be considered solved; the development may have been slow, or it may have been rapid, but the sequence of ideas must have been continuous, and until that sequence is established our knowledge is at fault. As with the distribution of plants, certain soils are favourable to the growth of certain plants, but we do not on that account assume them to be spontaneous offspring of the soil; so certain arts and phases of culture may flourish amongst certain races, or under certain conditions of life. But it is as certain that each art, custom, and institution had its history of natural growth, as it is that each seed which sprouts in the soil once fell from a parent stem. The human intellect is the soil in which the arts and sciences may be said to grow; and this is the only condition of things compatible with the existence of minds capable of adapting external nature, but possessing no power of originality.

If I am right in supposing that it is one of the primary objects of Anthropological Science to trace out the history and sources of human culture, a consideration of the relative value of the various classes of evidence on which we rely for this purpose, will be admitted to be a question of no slight importance in connection with our subject. We must distinguish between those branches of study which we are apt to look upon as intrinsically the highest, and on that account the most attractive, and those which are of most value as evidence of man in a low condition of culture. To the religions, myths, institutions, and language of a people we are naturally drawn, as affording the best indications of their mental endowments; but it is evident that these carry us no farther back in time than the historic period, and however necessary to be studied as branches of our science, they

fail to afford us any direct evidence of those vast ages during which our species appears to have gradually taken upon itself the characteristics of humanity. Every age has, however, left us the relics of its material arts, which, when studied comprehensively in connection with the geological record, may be taken as evidence of mental development from the earliest period of time. Nor i it in point of time alone, but also by reason of their stability, that the material arts afford us the surest evidence on which to reconstruct our social edifice. The tendency to constant variation within narrow limits is a psychical characteristic of the uncultivated man; but the material arts are not subject to those comparatively abrupt changes to which, prior to the introduction of writing, all branches of culture are liable which are dependent for their transmission on the memory, and are communicated by word of mouth.

Few who have read the works of Prof. Max Müller or Mr. Farrar can fail to have been struck with the value of the evidence, as far as it goes; but, on the other hand, the very short distance to which it carries us back in investigating the origin of speech; nor is this surprising when it is considered how constant must have been the changes to which language was subject in prehistoric times. Amongst the one hundred islands occupied by the Melanesean race, the Bishop of Wellington informs us there are no less than two hundred languages differing from each other as much as Dutch and German, and this diversity of languages and dialects is confirmed by Mr. Turner in his account of his nineteen years' residence in Polynesia. Amongst the Penons, or savage tribes of Cambodia, Mr. Muhot speaks of the great number of dialects spoken by tribes whose manners and customs are the same. Amongst the Musgu of Central Africa, Barth tells us that, owing to the absence of friendly intercourse between the several tribes and families, such a number of dialects had sprung up as to render communication between them difficult. Upon the River Amazon Mr. Bates mentions that in a single canoe he found several individuals speaking languages so different as to be unintelligible to the others. In a state of culture in which such diversity of tongues existed, what could have been the chance of preserving unchanged the myths, religions, and all those manifestations of intellect which are dependent on tradition?

The greater stability of the material arts as compared with the fluctuations in the language of a people in a state of primæval savagery, is well shown by a consideration of the weapons of the Australians and the names by which they are known in the several parts of that continent. As I have already mentioned, these people, from the simplicity of their arts, afford us the only living examples of what we may presume to have been the characteristics of a primitive people. Their weapons, respecting the distribution of which we have more accurate information than we have of their vocabularies, are the same throughout the continent; the shield, the throwing-stick, the spear, the boomerang, and their other weapons, differ only in being thicker, broader, flatter, or longer in different localities, but whether seen on the east or the west coast, each of these classes of weapons is easily recognised by its form and uses. On the other hand, amongst the innumerable languages and dialects spoken by these people, it would appear that almost every tribe has a different name for the same weapon.

If, then, it is evident that much of the history of our prehistoric ancestors has been for ever lost to us, we may console ourselves with the reflection that in their tools and weapons and other relics of their material arts, the most reliable source of evidence as to their intellectual condition has continued to our time. As to the myths, religions, superstitions, and languages, with which they were associated, we may content ourselves by devoutly thanking Providence that they have not been preserved. As it is, anthropological studies are said to have their fair share in the creation of lunatics, and we can easily believe that no sane intellect would have survived the attempt to unravel such a complex and tangled web of difficulty as the study of these subjects would have presented to our minds.

The consideration of the value of evidence naturally leads us to the third part of my subject, namely, the mode of collecting it and of digesting it after it has been brought together; and as this is, I believe, the most defective part of our organisation—or to speak more properly, the part of our existing institutions in which our want of organisation is most conspicuous—I had intended to have spoken at greater length on this subject; but as I have already trespassed upon your time so long, I am under the necessity of curtailing what I had proposed to say on the subject of organisation. If I am wrong, as I have heard it suggested by some anthropologists, in supposing that the greatest difficulties under which we labour are attributable to the absence of reliable evidence, and if we already possess as much information about savages and about prehistoric men as we require—and we have nothing to do but to read the books in our libraries, and write papers calculated to promote discussions, and fill journals with interesting controversies and speculations—if, as I gravely heard it asserted not long ago at a public meeting, it would be a pity to explore Stonehenge for fear so remarkable a monument should be divested of that mystery which has always attached to it, owing to our entire ignorance as to its origin and uses, then to those who entertain such views the few remarks I shall venture to offer on this subject must appear not only superfluous but mischievous. But if, on the other hand, I am right in supposing that our existing evidence is lamentably deficient, and in many cases false; that it has been collected by travellers, many of whom have had but little knowledge what to look for and observe; and if, this being the state of our knowledge, the evidence which we desire to obtain is now rapidly disappearing from off the face of the earth. The Tasmanians have been swept away before we know anything about them; the New Zealanders and all the Polynesian Islanders are fast changing their habits; and it is now difficult to find a North American Indian in a state of unadulterated savagery; whilst at home our prehistoric monuments are broken up and ploughed down day by day in the construction of buildings and railroads; it is evident that a set of societies which provide no organisation whatever for promoting exploration at home or abroad can only be regarded as fulfilling very imperfectly the functions which institutions established for the purpose of anthropological investigation might reasonably be expected to serve. Beyond the limits of this Association, there is but one society in this country which has the funds necessary for promoting explorations, and that is the Geographical Society. Every expedition which goes out under the auspices of that Society is necessarily brought in contact with the races inhabiting the districts which are explored; but it can hardly be expected that the Geographical Society should do as much as could be desired in the way of promoting anthropological investigation, as long as Anthropology and Ethnology are excluded from the functions of that Society. A Geographical Society should be regarded as the eyes and ears of an Anthropological Society abroad, in the same way that the archæological societies should fulfil the functions of eyes and ears directed to the past history of man, and the most intimate alliance ought to exist between them. A step in the right direction has lately been taken, at the suggestion of Mr. Clements Markham, by the establishment of a joint committee of the Geographical Society and Anthropological Institute, to draw up questions for travellers whom it is proposed to send to the Arctic Seas; and this, it is to be hoped, will be the first step towards a more intimate alliance in the future. As to the Archæological Societies, whose name is legion, and the functions of which are necessarily anthropological in a great degree, they are, as a rule, the most impotent and unprogressive bodies; living from hand to mouth, with funds barely sufficient to maintain a secretary, and to produce a small volume of transactions annually; without the means of promoting exploration, they are dependent entirely upon the casual communications of members, the substance of which is sometimes repeated over and over again in the different societies. If we inquire what useful purpose is served by these divisions of the metropolitan societies, we are told that one is a society, another is an association, and a third is an institute; and yet it does not appear that any one of these societies, associations, or institutes, perform any special function which cannot equally well be served by the others. They constitute divisions of persons rather than divisions of subjects; instead of promoting division of labour they serve only to promote repetition of labour; and so ill do any of them answer the expectations of those who devote themselves to the close study of any one branch of archæology or anthropology, that it has lately become necessary to establish an additional metropolitan society for promoting protohistoric archæology under the title of the Society of Biblical Archæology, embracing subjects which fall mainly within in the domain of anthropology. Much as I should feel disposed to condemn the multiplication of societies under existing circumstances, I cannot but think that by promoting the close study of a particular branch, the establishment of this society is a step in the right direction; and I therefore trust that it may be found to flourish at the expense of those which appear to have no special function to perform. As a

prehistoric archæologist, I can only add my humble testimony to that of others who think that this branch of anthropology is very unsatisfactorily dealt with by the metropolitan societies in which it is discussed. Quite recently this happy family has been increased by the birth of a fine child under the title of an Historic Society, and I observe that by way of specialising the functions of this society, it commenced life with a paper on Prehistoric Man. But there are no signs of any limitation to this improvident childbearing; it is announced that a Psychological Society is confidently expected. No one would be more disposed than myself to welcome psychology as a special branch of study if this family of gutter children is to go on increasing *ad libitum*; but it will be admitted that a Psychological Society, of all others, is liable to grow up scatterbrained, if completely severed from the influence of its more experienced kinsfolk.

I trust that I have made it apparent that Anthropology in its various branches includes some of the most popular and widely-disseminated scientific interests of the country; that the loss of power is enormous; not only is there no means of organised exploration, but the information which is published is either repeated over and over again in the different societies, or it is so scattered as to be beyond the reach of the majority of the students. They labour also under the disadvantage of being supported chiefly by men of small means, for the well-to-do classes in this country do not, as a rule, take any interest in either scientific or anthropological investigations. During the past year, a single American has done more in the way of anthropological exploration than the whole of the English societies, institutes, and associations together.

I will now briefly state my views as to the remedies for the evils of which I have spoken. I am averse to the principle of amalgamation; narrow views are often the most pronounced, and if they become dominant are liable to bring down the standard of an amalgamated society instead of enlarging its sphere of usefulness; besides, this amalgamation necessarily entails a certain loss of income by the loss of double subscriptions.

If my experience as a member of the council of most of the societies of which I speak does not deceive me, it should be the object of those who have the progress of anthropological studies at heart to induce the metropolitan societies to specialise their functions. The following might then become the titles of the various societies included under the term Anthropology, and they would represent not only the natural divisions of the science, but practically the divisions which are most consonant with the organisation of the existing societies. Setting history and historic archæology aside as beyond our province, we should have (1) Protohistoric Archæology; I adopt the term proposed by Mr. Hyde Clarke for this branch, which practically includes all that comes under the head of Biblical Archæology at present; (2) Prehistoric Archæology; (3) Philology; (4) Biology, including Psychology and Comparative Anatomy, in so far as it relates to man; (5) Descriptive Ethnology, viz., original reports of travellers on the races of man, conducted in association with geographical exploration. Under these heads we should, I believe, include all the various classes of special workers. These should constitute independent but associated societies; that is to say, the members of one should be privileged to attend the meetings and take part in the discussions of the others, but not to receive the publications of any but their own society. By this means each would profit by the experience of the other societies, but the funds necessary for the maintenance of each would be secured. As branch sections of anthropology they would be under the control of a general elected council, only in so far as would be necessary to prevent their clashing with each other, and for the control of any measures which it might be necessary for the several sections to undertake in concert; under the auspices of the general council might also be held the anthropological meetings devoted to such general subjects as either embraced the whole, or were not included in the sections. By these means the standard of anthropological science as a comprehensive study of the science of man in all its branches would be secured, and the possibility of its becoming narrowed under the influence of any dominant party would be obviated. It is hardly necessary to say that the chief advantage of such an arrangement as I suggest would consist in the employment of a single theatre and library for these cognate societies; they would employ a single printer, and the arrangements might include one or more artists, lithographers, and map-drawers, by which a great increase, and at the same time economy, would be effected in the illustrations. The saving effected by the union of these societies in a single establishment might be applied to conducting explorations either at home or abroad in connection with the Geographical Society. The question of the utilisation of apartments is one which commends itself especially to the notice of Government in regard to those societies, for which apartments are provided at the public cost. It should be made a *sine quâ non* that the societies so favoured should fairly represent all the branches of their subject.

As regards the local societies, it has been proposed to republish a selection of their papers under the auspices of this association. It is to be hoped that some arrangement, such as that proposed by the committee of which Sir Waller Elliot is secretary, may be carried out. I have only one suggestion to make on this point: re-publication is simply a repetition of cost and labour, if the desired object of bringing the papers together can be accomplished by other means. As to selection, I have no faith in it. If local and metropolitan societies could be induced to adopt a uniform size for their publications—not necessarily a uniform type—the papers relating to the same subjects might be brought together without the cost of reprinting. It would only be necessary to establish a classification of papers under various headings, such as, for example, those which constitute the sections of this Association. The societies might then print additional copies of their papers under each heading, in the same manner that additional copies are now struck off for the use of authors. A single metropolitan society might be recognised as the representative of each branch, and under its auspices the whole of the papers of the local and metropolitan societies relating to its branch might be brought together and printed in a single volume. Time does not allow me to enter into the details of the arrangements which would be necessary to carry out such a measure. I believe the difficulties would not be so great as might at first sight appear, especially as the evils of the existing arrangements are much complained of; but it should be a primary object of any arrangement that may hereafter be made that the independence of the several branches should not be sacrificed unnecessarily; it should be endeavoured to stimulate them and train them into useful channels, rather than to bring them too much under central control.

SECTION E

GEOGRAPHY

Opening Address by the President, Francis Galton, F.R.S.

THE functions of the several Sections of the British Association differ from those of other Institutions which pursue corresponding branches of science. We, who compose this Section, are not simply a Geographical Society, meeting in a hospitable and important provincial town, but we have a distinct individuality of our own. We have purposes to fulfil which are not easily to be fulfilled elsewhere; and, on the other hand, there are many functions performed by Geographical Societies which we could not attempt without certain failure. Our peculiarities lie in the brief duration of our existence, combined with extraordinary opportunities for ventilating new ideas and plans, and of promoting the success of those that deserve to succeed. We are constituents of a great scientific organisation, which enables us to secure the attention of representatives of all branches of science to any projects in which we are engaged; and if those projects have enough merit to earn their deliberate approval, they are sure of the hearty and powerful support of the whole British Association.

These considerations indicate the class of subjects to which our brief existence may be devoted with most profit. They are such as may lead to a definite proposal being made by the Committee of our Section for the aid of the Association generally; and there are others, of high popular interest, which cannot be thoroughly discussed except by a mixed assemblage, which includes persons who are keen critics, though not pure geographers, and who have some wholesome irreverence to what Lord Bacon would have called "the idols of the Geographical den."

We may congratulate ourselves that many excellent memoirs will be submitted to us, which fulfil one or other of these conditions. They will come before us in due order, and it is needless that I should occupy your attention by imperfect anticipations of them. But I must say that their variety testifies to the abundance of the objects of geographical pursuit, other than explo-

ration. There is no reason to fear that the most interesting occupation of geographers will be gone, when the main features of all the world are known. On the contrary, it is to be desired, in the interests of the living pursuit of our science, that the primary facts should be well ascertained, in order that geographers may have adequate materials, and more leisure to devote themselves to principles and relations. I look forward with eagerness to the growth of Geography as a science, in the usually accepted sense of that word; for its problems are as numerous, as interesting, and as intricate as those of any other. The configuration of every land, its soil, its vegetable covering, its rivers, its climate, its animal and human inhabitants, act and re-act upon one another. It is the highest problem of Geography to analyse their correlations, and to sift the casual from the essential. The more accurately the crude facts are known, the more surely will induction proceed, the further will it go, and, as the analogy of other sciences assures us, the interest of its results will in no way diminish.

As a comparatively simple instance of this, I would mention the mutual effects of climate and vegetation, on which we are at present very imperfectly informed, though I hope we shall learn much that is new and valuable during this meeting. Certain general facts are familiar to us: namely, that rain falling upon a barren country drains away immediately. It ravages the hill-slopes, rushes in torrents over the plains, and rapidly finds its way to the sea, either by rivers or by subterranean water-courses, leaving the land unrefreshed and unproductive. On the other hand, if a mantle of forest be nursed into existence, the effects of each rainfall are far less sudden and transient. The water has to soak through much vegetation and humus before it is free to run over the surface; and, when it does so, the rapidity of its course is checked by the stems of the vegetation. Consequently, the rain-supplies are held back and stored by the action of the forest, and the climate among the trees becomes more equable and humid. We also are familiar with the large differences between the heat-radiating power of the forest and of the desert, also between the amount of their evaporation; but we have no accurate knowledge of any of these data. Still less do we know about the influences of forest and desert on the rate of passage, or upon the horizontality, of the water-laden winds from the sea over the surface of the land: indeed, I am not aware that this subject has ever been considered, although it is an essential element in our problem. If we were thoroughly well informed on the matters about which I have been speaking, we might attempt to calculate the precise difference of climate under such and such conditions of desert and of forest, and the class of experiences whence our data were derived would themselves furnish tests of the correctness of our computations. This will serve as an example of what I consider to be the geographical problems of the future; it is also an instance of the power of man over the phenomena of nature. He is not always a mere looker-on, and a passive recipient of her favours and slights; but he has power, in some degree, to control her processes, even when they are working on the largest scale. The effects of human agency on the aspect of the earth would be noticeable to an observer far removed from it. Even were he as distant as the moon is, he could see them; for the colour of the surface of the land would have greatly varied during historic times, and in some places the quantity and the drift of cloud would have perceptibly changed. It is no trifling fact in the physical geography of the globe, that vast regions to the east of the Mediterranean, and broad tracts to the south of it, should have been changed from a state of verdure to one of aridity, and that immense European forests should have been felled.

We are beginning to look on our heritage of the earth much as a youth might look upon a large ancestral possession, long allowed to run waste, visited recently by him for the first time, whose boundaries he was learning, and whose capabilities he was beginning to appreciate. There are tracts in Africa, Australia, and at the Poles, not yet accessible to geographers, and wonders may be contained in them; but the region of the absolutely unknown is narrowing, and the career of the explorer, though still brilliant, is inevitably coming to an end. The geographical work of the future is to obtain a truer knowledge of the world. I do not mean by accumulating masses of petty details, which subserve no common end, but by just and clear generalisations. We want to know all that constitutes the individuality, so to speak, of every geographical district, and to define and illustrate it in a way easily to be understood; and we have to use that knowledge to show how the efforts of our human race may best conform to the geographical conditions of the stage on which we live and labour.

I trust it will not be thought unprofitable, on an occasion like this, to have paused for a while, looking earnestly towards the future of our science, in order to refresh our eyes with a sight of the distant land to which we are bound, and to satisfy ourselves that our present efforts lead in a right direction.

The work immediately before us is full of details, and now claims your attention. There is much to be done and discussed in this room, and I am chary of wasting time by an address on general topics. It will be more profitable that I should lay before you two projects of my own about certain maps, which it is desirable that others than pure geographers should consider, and on which I shall hope to hear the opinions of my colleagues in the Committee-room of this Section.

They both refer to the Ordnance Maps of this country, and the first of them to the complete series well known to geographers, that are published on the scale of one inch to a mile. It is on these alone that I am about to speak; for, though many of my remarks will be applicable more or less to the other Government map publications, I think it better not to allude to them in direct terms, to avoid distracting attention by qualifications and exceptions.

English geographers are justly proud of these Ordnance Maps of their country, whose accuracy and hill-shading are unsurpassed elsewhere, though the maps do not fulfil, in all particulars, our legitimate desires. I shall not speak here of the absence from the coast-maps of the sea *data*, such as the depth and character of the bed of the sea, its currents and its tides (although these are determined and published by another Department of the Government—namely, the Admiralty), neither shall I speak of the want of a more frequent revision of the sheets, but shall confine myself to what appear to be serious, though easily remediable, defects in the form and manner of their publication. It is much to be regretted that these beautiful and cheap maps are not more accessible. They are rarely to be found even in the principal bookseller's shops of important country towns, and I have never observed one on the bookstall of a railway station. Many educated persons seldom, if ever, see them; they are almost unknown to the middle and lower classes; and thus an important work, made at the expense of the public, is practically unavailable to a large majority of those interested in it, who, when they want a local map, are driven to use a common and inferior one out of those which have the command of the market. I am bound to add that this evil is not peculiar to our country, but is felt almost as strongly abroad, especially in respect to the Government of France. I account for it by two principal reasons. The first is, that the maps are always printed on stiff paper, which makes them cumbrous and unfit for immediate use; it requires large portfolios or drawers to keep them smooth, clean, and in separate sets, and an unusually large table to lay them out side by side, to examine them comfortably, and to select what is wanted. These conditions do not exist on the crowded counter of an ordinary bookseller's shop, where it is impossible to handle them without risk of injury, and without the certainty of incommoding other customers. Moreover, their stiffness and size, even when published in quarter-sheets, make them most inconvenient to the purchaser. Either he has to send them to be mounted in a substantial and therefore costly manner, or he must carry a roll home with him, and cut off the broad ornamental borders, and divide the sheet into compartments suitable for the pocket, which, to say the least, is a troublesome operation to perform with neatness. The other of the two reasons why the maps are rarely offered for sale, is that the agents for their publication are themselves map-makers, and therefore competitors, and it is not to be expected of human nature that they should push the sale of maps adversely, in however small a degree, to their own interests.

The remedy I shall propose for the consideration of the Committee of this Section is, to memorialise Government to cause an issue of the maps to be made in quarter-sheets on thin paper, and to be sold, folded in a pocket-size, like the county maps seen at every railway station, each having a portion of an index-map impressed on its outside, to show its contents and those of the neighbouring sheets, as well as their distinguishing numbers. Also, I would ask that they should be sold at every "Head Post-office" in the United Kingdom. There are about seven hundred of these offices, and each might keep nine adjacent quarter-sheets in stock, the one in which it was situated being the centre of the nine. An index-map of the whole survey might be procurable

at each of these post-offices, and, by prepayment, any map not kept in stock might be ordered at any one of them, and received in the ordinary course of the post. This is no large undertaking that I have proposed. The price of a quarter-sheet in its present form, which is more costly than what I ask for, is only sixpence; therefore the single complete set of nine sheets for each office has a value of not more than four shillings and sixpence, and for all the seven hundred Head Post-offices, of not more than 160*l*.

I believe that these simple reforms would be an immense public boon, by enabling any one to buy a beautiful and accurate pocket-map of the district in which he resides, for only sixpence, and without any trouble. They would certainly increase the sale of Government maps to a great extent, and they would cause the sympathies of the people and of their representatives in Parliament to be enlisted on the side of the Survey, and they probably be imitated by Continental nations.

It has often been objected to any attempt to increase the sale of Government maps, that the State ought not to interfere with private enterprise. I confess myself unable to see the applicability of that saying. It would be an argument against making Ordnance maps at all; but the nation has deliberately chosen to undertake that work, on the ground that no private enterprise could accomplish it satisfactorily; and, having done so, I cannot understand why it should restrict the sale of its own work in order to give a fictitious protection to certain individuals, against the interests of the public. It seems to me to be a backward step in political economy, and one that has resulted in our getting, not the beautiful maps for which we, as taxpayers, have paid, but copies or reductions of them, not cheaper than the original, and of very inferior workmanship and accuracy.

So much for the first of the two projects which I propose to bring before the consideration of the committee of this section. It is convenient that I should preface my second one with a few remarks on colour-printing, its bearing on the so-called "bird's-eye views," and on its recent application to cartography. Colour-printing is an art which has made great advances in recent years, as may be seen by the specimens struck off in the presence of visitors to the present International Exhibition. One of these receives no less than twenty-four consecutive impressions, each of a different colour from a different stone. This facility of multiplying coloured drawing will probably lead to a closer union than heretofore between geography and art. There is no reason now why "bird's-eye views" of large tracts of country should not be delicately drawn, accurately coloured, and cheaply produced. We all know what a geographical revelation is contained in a clear view from a mountain top, and we also know that there was an immense demand for the curiously coarse bird's-eye views which were published during recent wars, because even such as they are capable of furnishing a more pictorial idea of the geography of a country than any map. It is therefore to be hoped that the art of designing the so-called "bird's-eye views" may become studied, and that real artists should engage in it. Such views of the environs of London would form very interesting, and it might be, very artistic pictures.

The advance of colour-printing has already influenced cartography in foreign countries, and it is right that it should do so, for a black and white map is but a symbol—it can never be a representation—of the many-coloured aspects of Nature. The Governments of Belgium, Russia, Austria, and many other countries, have already issued coloured maps; but none have made further advance than the Dutch, whose maps of Java are printed with apparently more than ten different colours, and succeed in giving a vivid idea of the state of cultivation in that country.

I now beg to direct your attention to the following point:—It is found that the practice of printing maps in more than one colour has an incidental advantage of a most welcome kind, namely, that it admits of easy revision, even of the most beautifully executed maps, for the following reason. The hill-work in which the delicacy of execution lies, is drawn on a separate plate, having perhaps been photographically reduced; this has never to be touched, because the hills are permanent. But it is in the plate which contains nothing else but the road-work where the corrections have to be made, and that is a very simple matter. I understand that the Ordnance Survey Office has favourably considered the propriety of printing at some future time an edition of the one-inch maps on this principle, and at least in two colours—the one for the hills and the other for the roads.

This being stated, I will now proceed to mention my second proposal

Recollecting what I have urged about the feasibility of largely increasing the accessibility and the sale of Government maps, by publishing them in a pocket form and selling them at the Head Post-offices, it seems to me a reasonable question for the committee of this section to consider whether Government might not be memoralised to consider the propriety of undertaking a reduced ordnance map of the country, to serve as an accurate route-map and to fulfil the demand to which the coarse country maps, which are so largely sold, are a sufficient testimony. The scale of the reduced Government map of France corresponds to what I have in view; it is one of five miles to an inch, within a trifle ($\frac{1}{320000}$ of Nature), which is just large enough to show every lane and footpath. Of course it would be a somewhat costly undertaking to make such a map, but much less so than it might, at first sight, appear. Its area would be only twenty-fifth that of the ordinary ordnance map, and the hill-work of the latter might perhaps be photographically reduced and rendered available at once. The desirability of maps such as these, accurately executed and periodically revised, is undoubted, while it seems impossible that private enterprise should supply them except at a prohibitive cost, because private publishers are necessarily saddled with the cost of re-obtaining much of what the Ordnance Survey Office has already in hand for existing purposes. A Government department has unrivalled facilities for obtaining a knowledge of every alteration in roads, paths, and boundaries of commons, and Government also possesses an organised system in the post-offices, fitted to undertake their sale. The production of an accurate route-map seems a natural corollary to that of the larger Ordnance maps, and has been considered so by many Continental Governments.

I therefore intend to propose to the committee of this section to consider the propriety of memorialising Government to cause inquiries to be made as to the cost of construction, and the probability of a remunerative sale, of maps such as those I have described; and, if the results are satisfactory, to undertake the construction of a reduced Ordnance Map, on the same scale as that of France, to be printed in colours, and frequently revised.

These, then, are the two projects to which I alluded—the one to secure the sale of one-inch Ordnance Maps, on paper folded into a pocket form, to be sold at the Head Post-offices of the United Kingdom—700 or thereabouts in number, each office keeping in stock the maps of the district in which it is situated; and the other to obtain a reduced Ordnance Map of the kingdom, on the scale of about five miles to an inch, to fulfil all the purposes of a road map, and to be sold throughout the country at the post-offices, in the way I have just described.

I will now conclude my Address, having sufficiently taxed your patience, and beg you to join with me in welcoming, with your best attention, the eminent geographers whose communications are about to be submitted to your notice.

SECTIONAL PROCEEDINGS—FRIDAY, AUGUST 16

Discoveries at the Northern End of Lake Tanganyika, by H. M. Stanley.

THE President, Mr. Galton, in announcing the programme of proceedings for the day, explained the circumstances connected with Dr. Livingstone's discoveries previous to Mr. Stanley's expedition.

Mr. Stanley then read his paper, in which the following are the most important items, omitting everything of merely personal interest:—

"If you will glance at the south eastern shore of the Tanganyika, you will find it a blank; but I must now be permitted to fill it with rivers and streams and marshes and mountain ranges. I must people it with powerful tribes, the Wafipa, Wakawendi, Wakonongo, and Wanyamwezi, more to the south with ferocious Watula and predatory Warori, and to the north with Mara, Msengi, Wangondo, and Waluriba. Before coming to the Ma'agarazi, I had to pass through Southern Wavinza. Crossing that river, and after a day's march north, I entered Ubha, a broad plain country, extending from Uvinza north to Urundi and the lands inhabited by the Northern Watuta. Three long marches through Ubha brought me to the beautiful country of Ukaranga, and a steady tramp of twenty miles farther westward brought me to the divisional line between Ukaranga and Ujiji, the Liuche Valley, or Ruche, as Burton has it. Five miles farther westward brought us to the summit of a smooth hilly ridge, and the town of Ujiji embowered in the palms lay at

our feet, and beyond was the silver lake, the Tanganyika, and beyond the broad belt of water towered the darkly-purpled mountains of Ugoma and Ukaramba.

"The connection between the Tanganyika and the Albert Nyanza was a subject of interest to all geographers before I went to Central Africa. Livingstone even was almost sure that the Albert Nyanza was no more than a lower Tanganyika, and indeed he had very good reason for believing so. He had perceived a constant flow northward. All the Arabs and natives persisted in declaring that the Rusizi ran out of the Lake Tanganyika. Before I arrived at Ujiji he had never been to the north end of the Tanganyika. As we hugged the coast of Ujiji and Urundi, looking sharply to every little inlet and creek for the outlet that was said to be somewhere in a day's pulling, we would pass by from fifteen to twenty miles of country. It took us ten days' hard pulling to reach the head of the lake, a distance of nearly 100 geographical miles from Ujiji. Two days sufficed for the coast of Ujiji, the remaining eight we were coasting along the bold shores of Urundi, which gradually inclined to the eastward, the western ranges, ever bold and high, looking like a huge blue-black barrier some thirty miles west of us, to all appearances impenetrable and impassable. Only two miles from shore I sounded, and though I let down 620 feet of line I found no bottom. Livingstone sounded when crossing the Tanganyika from the westward, and found no bottom with 1,800 feet of line. The evening before we saw the Rusizi a freedman of Zanzibar was asked which way the river ran—out of the lake or into it? The man swore that he had been on the river but the day before, and that it ran out of the lake. I thought the news too good to be true. I should certainly have preferred that the river ran out of the lake into either the Victoria or the Albert. Livingstone and I resolved, if it flowed into the Victoria Nyanza, to proceed with it to that lake, and then strike south to Unyamyembe, and, if it flowed into the Albert Lake, to proceed into the Albert and cruise all round it, in the hope of meeting Baker. Just after dark we started, and in the morning we arrived at Muighewa, and started for the mouth of the river. In about fifteen minutes we were entering a little bay about a mile wide, and saw before us to the north a dense brake of papyrus and matete cane. Until we were close to this brake we could not detect the slightest opening for a river such as we imagined the Rusizi to be. We followed some canoes which were disappearing mysteriously and suspiciously through some gaps in the dense brake. Pulling boldly up, we found ourselves in what afterwards proved to be the central mouth of the river. All doubt as to what the Rusizi was vanished at once and for ever before that strong brown flood, which tasked our exertions to the utmost as we pulled up. I once doubted, as I seized an oar, that we should ever be able to ascend; but, after a hard quarter of an hour's pulling, the river broadened, and a little higher up we saw it widen into lagoons on either side. The alluvial plain through which the river makes its exit into the lake is about twelve miles wide, and narrows into a point after a length of fifteen miles, or a narrow valley folded in by the eastern and western ranges, which here meet at a distance of a couple of miles. The western range, which inclines to the eastward, halts abruptly, and a portion of it runs sharply north-westward, while the eastern range inclines westward, and after over-lapping the western range shoots off north-westward, where it is lost amid a perfect jumble of mountains. The chief Rubinga, living at Mugihewa, said that the Rusizi rose from the Lake Kivo, a lake fifteen miles in length and about eight in breadth. Kwansibura was the chief of the district in North-eastern Urundi, which gives its name to the lake. Through a gap in a mountain the river Rusizi escaped out of Lake Kivo. On leaving Kivo Lake it is called Kwangeregere; it then runs through the district of Unyambungu, and becomes known as the Rusizi or Lusizi. A day's march from Mugihewa, or say twenty miles north of the mouth, it is joined by the Luanda, or Ruanda, flowing from a north-westerly direction, from which I gather that the river Luanda is called after the name of the country—Ruanda, said to be famous for its copper mines. Besides the Luanda, there are seventeen other streams which contributed to the Rusizi; these are the Mpanda, Karindwa, Wa Kanigi, Kaginissi, Kaburan, Mohira, Niamagana, Nya Kagunda, Ruviro, Rofuba, Kavimvira, Mujove, Ruhuhha, Mukinda, Sange, Rubirizi, Kiriba. Usige, a district of Urundi occupying the head of the lake, extends two marches into the north, or thirty miles; after which comes what is called Urundi Proper for another two days' march; and directly north of that is Ruanda, a very large country, almost equal in size to Urundi. Rubinga had been six days to the northward. There were some in his tribe who had gone farther; but from no one could we obtain any intelligence of a lake or a large body of water, such as the Albert Nyanza, being to the north. Sir Samuel Baker has sketched the lake as being within one degree north of the Tanganyika; but it is obvious that its length is not so great as it is represented, though it might extend thirty or forty miles south of Vacovia. Ruanda, as represented to us by Rubinga, Mokamba, chiefs of Usige, and their elders, is an exceedingly mountainous country with extensive copper mines. It occupies that whole district north of Urundi Proper between Mutumbi on the west and Urundi on the east, and Itara north-east. Of the countries lying north of Ruanda we could obtain no information. West of Urundi is the extreme frontier of Manyuema, which even here has been heard of. In returning to Ujiji, after the satisfactory solution of the river Rusizi, we coasted down the western shore of the Tanganyika, and came to Uvira at noon on the following day. We were shown the sandy beach on which the canoes of Burton and Speke had rested. Above, a little south of this, rises the lofty peak of Sumburizi, fully 4,500 feet above the level of the lake. Mruti, the chief of Uvira, still lives in the village he occupied when Burton and Speke visited his dominions. A day's march, or fifteen miles north of this, Uvira narrows down to the alluvial plains formed by the numerous streams which dash down the slopes of the western range; while the mountainous country is known as Uhembe, the land of the cannibals, who seldom visit the canoes of the traders. South of Uvira is Usansi, peopled by a race extremely cannibalistic in its taste. From Usansi we struck off across the lake, and, rowing all night, at dawn we arrived at a port in Southern Urundi. Three days afterwards we were welcomed by the Arab traders of Ujiji, as we once more set foot on the beach near that bunder. We have thus coasted around the northern half of the Tanganyika, and I might inform you of other tribes who dwell on its shores; but the principal subject of my paper was to show you how we settled that vexed question, "Was the Rusizi an effluent or an influent?" There is, then, nothing more to be said on that point.—In reply to a question from the President, Mr. Stanley said that Burton and Speke halted on a sandy beach just thirteen miles from the extreme end of Tanganyika. Had they gone but half way up the mountain, to the village where resided Amruta, the King of Uveri, they must have seen the northern head of Tanganyika plainly. But in drawing up at this point they simply took the point where the eastern and western ranges meet. The western range halts abruptly; the eastern ranges overlap it. I would not wish for sweeter water than the water of Lake Tanganyika.

Dr. Livingstone's Recent Discoveries, by Colonel J. A. Grant.

The two letters from Dr. Livingstone to Mr. Gordon Bennett, of the *New York Herald*, inform us that he had traced the southern waters from 11° to 5° south latitude, and he supposed they must flow on to the Nile by the Bahr Gazal, at 9° north latitude. I must say that this is an extravagant idea which cannot be entertained, for there are many circumstances precluding such a thing. The distance still unexplored by Dr. Livingstone may be roughly stated as nearly one thousand miles between his most advanced position and the mouth of the Gazal. In this distance we have Speke's Mountains of the Moon, and the great bend (to the west) of the Nile at 7° to 8° north latitude as the principal obstructions to Dr. Livingstone's theory. We also have three hundred miles of longitude between the two positions, but the crowning objection to Dr. Livingstone's waters reaching the Nile is the fact that we already know that the source of the Gazal was visited and determined only a few years ago by the eminent botanist Schweinfurth, who fully satisfied all geographers that the source of the Gazal is about 5° north of the Equator, and not, as Dr. Livingstone supposes, 11° south of it. My observations on the Gazal, made in March 1863, when descending the Nile from Gondokoro with my late companion, show that it is insignificant when compared with the Nile; it seems to be a swamp with little current, for the Nile branch, along which we were sailing, was not increased in width by the water from the Bahr Gazal, the Nile maintained its width of one hundred yards till after the Giraffe and Sooba joined it, then the stream was increased to a breadth of five hundred yards. The Gazal had no perceptible stream; at the junction its waters were still, and looked like a backwater, half a mile across, and surrounded by rushes. Our boatman and others told us that no boats were able to ascend it that year, 1863, as its channel was choked with

reeds and the ambatch tree. There is, therefore, no regular traffic on it by boats; some years it is completely blocked, a contrast to the Nile, which is navigable to large dahabieh, all the year round, between Gondokoro and Khartoom. If anything were wanted to prove that the Gazal has no connection with the southern waters of Livingstone, reference might be made to several men who have been in the Gazal country; but Dr. Schweinfurth, who is now in Europe, would be most able to give definite information. The narrative of Dr. Livingstone contains some curious incidents which are quite novel to me, for, in our journey from Zanzibar to Egypt, when travelling on the watershed of the Nile, we never saw any race of cannibals, any signs of gorilla—neither did we find that any race of natives ever kept pigs in a domesticated state; they eat one species of wild hog, but no race in the valley of the Nile was ever seen to keep pigs tame. Oysters must be a misprint. Taking into consideration these remarkable differences from the country we traversed, I cannot but think that Dr. Livingstone, having no chronometers to fix his longitude, has got farther to the west than he supposes, and that he had got amongst races similar in most respects to those on the west coast of Africa, described by M. Du Chaillu. In conclusion, this fresh discovery of lakes and rivers by Livingstone has defined a distinct new basin, and left clearer than ever the position given by Speke to the Nile in 1863. Besides the two despatches to Mr. Gordon Bennett, we have now seen Dr. Livingstone's letters to Lords Stanley, Clarendon, and Granville, dated between 1870 and 1872. It is much to be regretted that they contain so little mention of latitude, longitude, and altitude, for his vast discoveries of new country cannot be laid down by our map makers with any degree of certainty—indeed, no two men could make a similar map out of all the geography he has forwarded. He informs us that his drainage, from 12° south latitude, has been traced by him up to 4° south latitude, and that he believes these waters continue to flow north, and from the valley of the Nile by joining the Nile of Speke at 9° north latitude by the Bahr el Gazal. No such thing can happen, for we have ample evidence, from independent sources, against the doctor's theory, besides which there are curious circumstances in his letters forbidding any connection with the Valley of the Nile. Livingstone tells us that the natives keep pigs, and that he had met with the skull of a gorilla. This shows a region distinct from the Nile races and the Nile animals, for nowhere on our route did we meet with pigs domesticated, or gorilla in the forests. Though this is but circumstantial evidence, it appears strong to me, and it also appears that he must have been farther west in his longitude than he supposed.

Sir Samuel Baker states that the Nile receives the following rivers from the west, namely, "The Yé, third class, full from 15th April to 15th November, also another smaller river, third class, full from 15th April till 15th November," and "the Bahr el Gazal, little or no water supplied by this river." Having seen this river in March of the same year, I can testify to the correctness of Sir Samuel's description, from the notes made by me upon it. These notes state the Bahr Gazal gave little or no water to the Nile, which was not increased much in size after its junction. The Bahr Gazal was still water, and the Nile flowed past it at the rate of about two miles per hour. It must be remembered also that this was only one branch of the Nile; the other, the Bahr Giraffe, supplied half as much again of water, and flowed at the rate of four miles an hour where it joined the Nile. Another fact worth noting is, that the water of the Bahr Gazal is described as being clear by Sir Samuel—this implies that the water had settled, that it was still water, and that there can be no current, but if additional proof was necessary to show that Dr. Livingstone's waters from 12° south latitude do not join the Nile here, we have the crowning evidence—which Dr. Livingstone is not aware of—of the German traveller, Dr. Schweinfurth, who determined the source of this Bahr Gazal at 3° or 5° north latitude. Dr. Livingstone has been informed by natives that Speke's Victoria Nyanza consists of three or four lakes, the Okara, Kavirondo, the Naibash, and the Baringo; but we know from Speke's map and from his writings, that the Okaro is the Ukereweh lake, the Naibash is the Naivasha, on the east of his lake, and that the Baringo is to the north-east of his lake. Captain Speke tells us that he had seen quite half of the lake, as laid down by him, his longitudes and latitudes and altitudes gave him its general outline, and where he could not obtain those he had to content himself with native information. We, therefore, think that his information is perfectly reliable, and that Dr. Livingstone has been misinformed—at all events, the Victoria Nyanza discharges quite sufficient water to form a navigable river from the Ripon Falls to the Mediterranean, and no stream which joins it in its course can for a moment be compared to it in size. Dr. Livingstone makes a mistake as to its size; he calls it eighty to ninety yards wide, writes of it as the "little river," and I cannot conceive where he got his information. Speke's estimate makes it a width of 150 yards—not feet—across the actual waterfall, and immediately above this, he tells us that it is 300 yards wide. From this we turn to the Tanganyika Lake. Unfortunately, its altitude is not mentioned, so we must take it for granted that Speke's measurement of 1,800 feet was correct; but Dr. Livingstone tells us that it has some influence on the Nile. It is tantalising to be told this bare statement, which leads us to conclude that it runs into his line of drainage, and not into the Indian Ocean—as I suppose it does. However, if life and health be spared to the doctor he will determine this point when he has visited the southern end of this lake; and it is to be hoped that he will send us despatches with more frequency, as there is nothing to prevent his doing so by the hands of the numerous traders travelling between Zanzibar and Ujiji.

Consul Petherick was then called on by the President to give an account of the Bahr el Gazal river, the great tributary of the Nile discovered by him.

Dr. Beke then said it was by no means pleasant for him to have to recant the opinions which he had so long maintained, but he was perfectly convinced that Livingstone had not discovered the sources of the Nile. Capt. Speke made Tanganyika 1,700 ft., Baker made the Albert Nyanza 2,700 ft., or, as it had been corrected, 2,500 ft. Even making an allowance of 200 ft. or 300 ft., it seemed impossible, on account of the levels, that the river Lualaba should flow into either of those lakes. He concluded that the Lualaba must either go into the Ulle or into some lake, or turn round to the Congo. He did not, however, think it went to the Congo, owing to the ascertained levels. It was a mortifying thing to have to acknowledge that what he had so long contended for was wrong, but the facts which had previously been made known led to the inevitable conclusion that what Livingstone had discovered was not the source of the Nile.

Sir H. Rawlinson said he was glad to have this opportunity of bearing testimony to the great value which the Royal Geographical Society attached to Mr. Stanley's services, and also of expressing the high opinion they entertained of his merit as a traveller. Livingstone had, no doubt, achieved a great geographical success in discovering the great interior system of river beds, but from his letters it was evident that almost to the very last he had strong misgivings about his being upon the Nile basin. Over and over again he said it had occurred to him that he might have been on the Congo. What did really become of this great river system which he had discovered it was impossible to say authoritatively. All that could be said was, that it was a completely new discovery, but he trusted that Livingstone himself would be the discoverer of where those great central rivers run, for he should be sorry if he did not carry out to a successful issue the great work upon which he had been so long, and so honourably, and so conscientiously engaged. In a matter of this sort all must be conjecture, but putting all the arguments side by side, he confessed to the supposition that this great river system fell into a large central inland lake. He should very much doubt its ever reaching Lake Chad, but there was a very large space in the interior of the continent which might very well be occupied by such a river-stream draining all the surrounding mountains. The discovery of the lake (if there be such a lake) into which the central waters ran, would, he trusted, be the crowning success of Livingstone's African travels. He had announced that he was going to the source of those waters, and when he had satisfied himself of that, he would return northward, and with the supplies furnished him in a great measure by Mr. Stanley, he would be then in a position to follow the system beyond a point where he was previously arrested. His great difficulty on former occasions was owing to the incapacity and hostility of his attendants, but it was most gratifying to know that he had now at his command a faithful and efficient body of followers.

Mr. Clements Markham asked Mr. Stanley whether the country of Balegga, which Livingstone alluded to, was the same as that laid down in Sir Samuel Baker's map as Malegga. Baker gave the name of Malegga to a range of mountains, and Livingstone spoke of it as a mountainous country.

Mr. Stanley said he believed the two names referred to the

same region. No importance could be attached to difference in spelling, as it was purely a matter of hearing. To one traveller the word might appear to be pronounced one way, and to another traveller another. It was not even a difference of dialect. It was simply a difference in the spelling owing to the difference in the hearing.

The President, in closing the discussion, said that there was not the slightest doubt that Dr. Livingstone could only draw inferences as to where the waters he saw found an outlet. It was entirely a matter of theory. Geographers dealt with the facts that he had made known to them, and from those facts they drew their conclusions, just as Dr. Livingstone, from the same facts, drew his conclusions.

SCIENTIFIC SERIALS

THE *Monatsbericht der k. preussischen Akademie der Wissenschaften zu Berlin*, from January to March, 1872. The most numerous scientific papers in these three numbers of the Berlin *Monatsbericht* are of a chemical nature, consisting of notes by Prof. Hofmann on aromatic phosphines, on the products of oxidation of methylphosphine and elthylphosphine, and on derivatives of the ethylene-bases, and a paper by Prof. Rammelsberg on the chemical composition of ambygonite. Prof. von Rath gives an account of a meteorite which fell at Ibbenbiehren, in Westphalia, on June 17, 1870, and consists chiefly of silica, protoxide of iron, and magnesia, with small quantities of protoxide of manganese, lime, and allumina. Structurally it consists of a granular mass, containing imbedded crystaline grains, the composition of both being mainly identical. Prof. H. A. Schwarz, of Zurich, communicated a continuation of his investigations upon special mineral surfaces. Prof. Riess has a paper on the reaction of the induced currents in an unaltered circuit upon the main current of the Leyden battery. Prof. Helmholtz communicates a summary of the results obtained by Dr. W. Dolerowolsky, of St. Petersburg, by experiments upon the sensibility of the eye to differences in the luminous intensity of various spectral colours The natural history papers consist of a notice by Prof. Ehrenberg of Prof. Whitney's recent investigations of the Californian Bacillarian rocks, a paper by Dr. Roth on the geology of the Philippian islands, and two geographical memoirs by Prof. W. Peters, one giving the synonyms of the species of the chiropterous genus *Megaderma*, and describing a new form (*M. cor* Peters, from Abyssinia), the other discussing in considerable detail the species of Batrachia, collected by Spix in Brazil, after an inspection of the original specimens in the museum at Munich.

Journal of the Chemical Society, June 1872.—This number opens with a lecture on the "Chemistry of the Hydrocarbons" by C. Schorlemmer, which is a condensed summary of the history of this subject. In the opening part of this paper the definitions of organic chemistry are discussed, Mr. Schorlemmer preferring to define it as "the chemistry of the hydrocarbons and their derivatives." The lecturer then proceeds to show how far our knowledge of the constitution of the hydrocarbons has advanced. The chemistry of the paraffin series of hydrocarbons is first entered upon; these perhaps have been more completely studied than any of the succeeding series. All the paraffins of known structure may be divided into four groups; the first or normal paraffins have been to a great extent worked out by the author, and are those in which each carbon atom is directly combined with at least two other carbon atoms forming a symmetrical chain. The other three groups have not been studied completely, and are not here discussed. By abstracting two atoms of hydrogen from the paraffins a series of hydrocarbons is obtained called the olefines. The probable constitution is not, as was at one time supposed, that they have carbon atoms with free combining units, thus—$CH_2 - CH_2$—; but that one carbon atom is linked by two combining units to another carbon atom, thus $CH_2 = CH_2$. The hydrocarbons of the acetylene series were next introduced; these are formed by again abstracting two other atoms of hydrogen from the olefines; in acetylene, for instance, it is probable that the carbon atoms may be linked together by three combining units of each atom, thus $CH \equiv CH$. The aromatic hydrocarbons have been very much worked on during the last few years. The present theory of their constitution is due to Kekulé, who supposes that the six carbon atoms are united together in a sort of chain or hexagon by one and two combining units alternately, which would then leave six combining units unsaturated. These when combined or saturated with hydrogen will yield the hydrocarbon benzol, which may be considered as the starting point of the aromatic series. The differences observed in certain groups of isomeric aromatic compounds may be accounted for by the supposition that the different relative positions of certain elements or radicals as attached to the carbon nucleus cause a difference in the physical condition of the substance. The constitution of various other hydrocarbons, such as naphthaline, anthracene, &c., is discussed; but they are too complex to be here described in detail.—E. A. Letts has prepared benzyl isocyanate by the action of the benzyl chloride on argentic cyanate, benzyl isocyanurate being also formed during the reaction. By the action of ammonia on the former body monobenzyl urea is formed, which by treatment with water yields dibenzyl urea. By substituting aniline in the place of ammonia in the last-named reaction phenyl benzyl urea is produced.—T. E. Thorpe contributes some laboratory notes on various subjects and Prof. Himly a paper "On the estimation of carbonic acid in sea water," the method recommended is to precipitate the carbonic acid by baryta water, and to estimate the baric carbonate produced, it having been found that simply boiling the water is insufficient to drive off the whole of the carbonic anhydride. A detailed description of an apparatus for the collection of sea water below the surface is promised, which is also to be provided with the means of adding the reagent below the surface of the sea so as to avoid any loss of carbonic anhydride during and after the collection of the sample. The abstracts which follow the paper are as usual full of interest, containing as they do the pith and substance of many important papers.

SCHELLEN'S SPECTRUM ANALYSIS

Spectrum Analysis in its Application to Terrestrial Substances, and the Physical Constitution of the Heavenly Bodies. By Dr. H. Schellen, Director der Realschule, I.O. Cologne. Translated from the second enlarged and revised German edition by Jane and Caroline Lassell, edited, with notes, by W. Huggins, LL.D., D.C.L., F.R.S. (Longman and Co., 1872.)

IT is not difficult to deliver interesting lectures or to write an instructive book on spectrum analysis. The rapid succession of brilliant discoveries in this new branch of science, the amount of fundamental facts added by it to human knowledge, especially in the field of the cosmical world, assure the lecturer or writer appealing to the intelligent but not scientific public of useful and legitimate success. But what is not so easy to do is to interest at the same time the *gens du monde* and scientific men, by offering a selection of the most recent discoveries in a bright and literary form attractive to the former, and yet keeping for the latter the appearance of precision, and exactness of the numerical results.

All these conditions are very happily filled in "Schellen's Spectrum Analysis," edited by Mr. W. Huggins from the second German edition. I shall commence by giving a brief account of the chief points of the book.

The first part, introductory, is occupied by a description of the artificial sources of high degrees of heat and light, of which the study is so intimately connected with the chemical and astronomical phenomena embraced in the field of spectrum analysis; various apparatus, for instance, the gas-burner, the magnesium lamp, the Drummond lime-light, the electric spark of the induction coil, the Geissler's tube, and the electric light produced by voltaic batteries are described, and the practical adjustments are briefly but sufficiently referred to for a good understanding of the subject.

The second part is devoted to an elementary abstract of the geometrical and mechanical properties of light. The fundamental analogy between light and sound is developed, in order to explain to a reader unlearned in optics how the colour of a ray is the corresponding element of the pitch of a musical sound, and how it is possible to define a coloured ray by the time of its luminous vibrations. The description of refraction phenomena, especially the paths of rays through a prism, leads naturally to the separating process of the different colours on which spectrum analysis is founded.

Some examples of such an analysis of light by means of a prism are given, amongst which we may mention the screen-projections of the spectra of the electric, sun, or magnesium light; a sufficient number of illustrations enables every one easily to repeat the experiments.

A considerable number of chapters is devoted to the construction of the simple and compound spectroscope. The chief points of this construction, especially the contrivances for the simultaneous comparison of two spectra, the determination of the position of lines in the spectrum are carefully described. Afterwards a practical account of the methods for exhibiting spectra of terrestrial substances, for instance, metallic salts volatilised in a gas-burner, &c., will certainly interest chemists.

The beautiful appearance in the spectroscope of heated gases in Geissler's tubes, their bright lines, and also the important question concerning the change of spectra with temperature and pressure, all these subjects are sketched in general outlines; it is nevertheless to be regretted that an account of the beautiful experiments of MM. Frankland and Lockyer have not a place amongst these descriptions; the difficult problems raised by these experiments are not completely solved, and we by no means can accept every assertion developed in this interesting chapter.

The curious absorption phenomena to be observed in the spectrum analysis of light which has passed through certain liquids, especially of organic origin, deserved a peculiar notice; the author has not neglected to describe one of the most remarkable spectra—the absorption-bands of the blood, and to indicate what advantage natural history is able to derive from such observations even on microscopical objects.

An interesting chapter contains the theoretical and experimental explanation of the reversal of the spectra of gaseous substances. This phenomenon, studied independently by Foucault and Angström, and definitely generalised by Kirchhoff, is perhaps the chief point of the history of spectrum analysis, and certainly the beginning of its utilisation as a powerful method of investigation.

The only practical example of reversal given in the book is that of sodium vapour; but recent experiments have proved that nearly all metallic vapours heated conveniently in the voltaic arc show the reversal of a great number of bright lines into black ones.

The third part of the book, the most important in extent and results, is devoted to the application of the spectrum analysis to the heavenly bodies.

The sunlight, according to its brightness and to the peculiarities of its spectrum, is the best and easiest example to study. The dark lines in infinite number which it shows, called "Frauenhofer lines," from the discoverer, deserve special attention; therefore the author has illustrated the description of the sun-spectrum with two sets of maps. The first is a reduction of Kirchhoff's maps engraved on wood, representing in several tints the lines from A to G; the second series is a reduction to about half size of the admirable *normal solar spectrum* of Angström, in which the Frauenhofer lines from a to H_1H_2 are co-ordinated according to their wave-lengths. The accuracy of these lithographic plates is really wonderful; they will have the great merit of introducing amongst physicists and astronomers the wave-length scale for the designation of lines instead of Kirchhoff's scale, which is an arbitrary one; and in any case they will facilitate the transformation of the data from one to another. I must add that Angström's maps have been introduced into the present edition by the English editor, and that such an addition is certainly one of the greatest attractions of this book for scientific men.

A good abstract of Kirchhoff's and Angström's memoirs on the coincidence of the dark solar lines with the bright lines of metallic vapours leads to the hypothetical con-

stitution of the sun; this problem is so difficult, that it is necessary to leave to every one the responsibility of his own ideas on this subject. I ask, then, for permission to decline any critical notice of this part of the book.

I must mention also a useful description, illustrated with maps, of the telluric and atmospheric lines from the works of Brewster, Gladstone, Angström, and Janssen.

The remaining part of the book is entirely devoted to the most delicate applications of spectrum analysis to astronomy. A preliminary description of the sun-spots, faculæ, and other peculiarities of the surface of the sun, of the prominences round the disc, and so on, is given before the spectroscopic process for analysing these appearances is introduced, and enables the reader to understand very well the difficulties of the problem and the interest of its solution. I must mention especially the interesting account of the three total solar eclipses of 1868, 1869, 1870. A large series of drawings and photographic *fac similes* give the best idea of the phenomena, and show the improvements due to photography and spectroscopy; the relatively great extent devoted to this account is justified by the importance of the subject; the spectrum analysis of the prominences is in fact one of the most considerable results obtained for a long time in the sciences of cosmogony.

Now from this discovery of Janssen's it is easy to observe every day the solar prominences by utilising the bright lines of their spectrum. Janssen's method, discovered in India soon after the eclipse of 1868, was independently discovered again some weeks after by Lockyer, who has the real merit of announcing two years before the possibility of such an important observation, and would very likely have had the honour of priority if he had had beforehand the material means of carrying out his designs.

Schellen's book contains a complete account of the improved telespectroscopes of Lockyer, Respighi, Secchi, Huggins, Janssen, Young and Zöllner, and a beautiful series of coloured sketches, representing some daily observations of prominences all varying, but truly characteristic of their form. I must confess, however, that some of those beautiful pictures seem to me rather too much embellished by the imaginative fancy of one of the observers. The sun-spots and faculæ observed with a telespectroscope give a good number of new facts which have led Lockyer and Secchi to the most important inductions upon the constitution of the sun.

The spectroscope, as it is known, is able to give an exact measurement of the proper velocity of the luminous bodies. A German physicist, Doppler, deserves to be mentioned as the first who called the attention of astronomers to this subject, though a good number of his assertions may be incorrect. After him, Fizeau, a French physicist, to whom we are indebted for the first determinations of the velocity of light on the surface of the earth, showed the errors of Doppler in a little paper not very well known, published in 1849 ("Bulletin de la Société Philomatique de Paris"), and calculated the apparent change of refrangibility which would be produced by the proper motion of some heavenly bodies; but no direct experiment was made before the complete application of spectrum analysis to the sidereal phenomena. In this way Schellen's book gives a good abstract of the works of Huggins and Secchi. In these researches the velocity of rotation of the sun was to be tested as a verification of the general law of the phenomenon. I ought to say, that, the rather discordant results want a theoretical analysis, because the problem seems to me, in the case of the sun, more complicated than it appears at first sight. However, the influence of the velocity of the gas streams, especially of hydrogen, which constitute the greater part of the prominences, is unquestionably verified by Lockyer's observations. In the same way Huggins has proved and determined the proper motion of Sirius by the apparent change of refrangibility of the F line.

The remaining part of the book is devoted to stellar and meteoric spectrum analysis. It is impossible to give a superficial notice of the beautiful researches of Huggins and Secchi, researches which are always going on; the reader will find with interest various important results of these studies—for instance the existence in many stars of a good number of terrestrial substances—hydrogen, nitrogen, magnesium, sodium, &c.

One of the most interesting facts is the observation of the temporary star which appeared in May 1866; the great brightness of the star was due, as indicated by the spectroscope, to an immense mass of incandescent hydrogen.

At the end of the work the author gives some very important observations of Huggins and others on the spectrum of nebulæ; the chief result is the possibility, with the aid of the spectroscope, of distinguishing by the composition of their light the true nebulæ from the clusters of stars.

Finally, a description of the spectrum of the aurora borealis, the identification of its bright lines with some bright lines of the solar corona, a description of various meteors, lightnings, and their spectra, show into what difficult objects this new branch of science has pushed its investigations.

On the whole, this book must be considered as a good type of a "popular work;" it deserves the attention of the public, and the esteem of scientific men; and finally, it recommends itself by a gracious side. It was translated into English by two ladies, who have had the double merit of giving a proof of their good scientific taste, and of showing an example of the help which their sex is able to afford to science.

CORNU

OUR BOOK SHELF

Health and Comfort in House-building. By J. Drysdale, M.D., and J. W. Hayward, M.D. (London: E. and F. Spon, 1872.)

Sewer-gas, and how to keep it out of Houses. By Osborne Reynolds, M.A. (London: Macmillan and Co., 1872.)

THE first of these works supplies a want long felt by that section of the public who are desirous of obtaining a good supply of fresh air in their houses, without being subjected to the cold draughts usually associated with almost every system of ventilation. The book is most carefully written, and is evidently the result of much thought, time, and intelligent labour. After reviewing very fairly the systems of ventilation which have been proved to be ineffectual for supplying fresh warm air to the whole of a house, although perhaps very appropriate for single rooms, we are told that the key-note of this new

system consists in utilising the kitchen fire, which is almost constantly kept alight in summer and in winter. "Endeavour is made to prevent the air from entering the house at all except by the inlet provided in the lowest story of the house, with conditions available for the warming, cleaning, disinfecting, or otherwise improving the quality of the incoming fresh air, and regulating its quantity; the fresh air is then conducted into the central private hall, which is protected from smells, and all other means of pollution: it is from this private hall that the rooms draw their supply, even when the doors are shut. Having served its purpose in the rooms, the air is drawn off through the ceiling into the foul air chamber, and thence down and behind the kitchen fire, up the chimney-stack, and discharged high up in the open air, all possibility of back draught being prevented by the length and heat of the exhausting-syphon." It is a work which can be highly recommended to the officer of public health, the architect, and the householder, as a guide to the true principles of healthy ventilation. In "Sewer Gas; a Handbook on House-drainage," we have a very simple and original plan suggested for preventing noxious gases and exhalations from drains entering our houses. It is shown that these gases, being specifically lighter than atmospheric air, frequently ascend in pipes, and that they are also occasionally drawn in by the suction caused by the warmth of a house through accidental crevices in the drain pipes. It is proposed to remedy these evils by doing away with all traps except those connected with the pans of closets, and by placing a large trap in the pipe which connects the house drains with the sewer. A plan of this trap is given, showing that it is easily accessible, and can be cleaned at any time by even an inexperienced workman. The subject is one of even more importance than good ventilation. When we recollect that one of the most valued lives in Great Britain has been so recently imperilled from a mere defect in a system of drainage, we cannot too highly estimate the efforts of those who suggest, both by precept and experiment, the adoption of such measures as will ensure the safety of all sensible householders.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Hindrances to Students of Mathematics

It was the opinion of Dr. Samuel Johnson that everything ought to be persecuted in order that we may know whether it is worthy to live or not. There is, doubtless, a good deal of truth in this opinion, and the idea or the man that cannot endure and overcome a considerable amount of difficulty is of but little value. Still there must be a reasonable limit to persecutions and difficulties, and hence I hope that the praiseworthy efforts of the English mathematicians to improve their text-books of geometry will be successful. In considering such a matter as the improvement of text-books, an extensive knowledge of the experience of all classes of students will be valuable, and as many of the mathematical books profess to be written for those who are not fortunate enough to have a teacher, an account of the difficulties which such a one has experienced may be of some interest.

1. I place first among these difficulties the practice common to nearly all mathematical writers, of restricting the number of axioms or fundamental assumptions, making them fewer than they naturally are. It is worse than useless to attempt to prove something that is self-evident, or which is so nearly so that it is impossible to make any proof illustrate it. In all such cases it would be better to state frankly and clearly that we make an assumption, depending on observation to justify it. An example of this superfluous proof may be found in many of the books on rational mechanics, where we are told that a body cannot move out of the place of the forces, because we know of no reason why it should move to one side rather than the other; therefore, &c. Of useless definitions we have an example in a popular work on arithmetic, where we are told that "time is the measurement of duration," and a few pages further on that "duration is a portion of time." Allied to this is the contemptible habit of those who explain, with kind condescension and with great detail, all insignificant matters, while at the same time they cover up or dodge by some such phrase as "it is evident" the really difficult points.

2. I do not object to a frequent and thorough application of the differential calculus in a text-book, and such an application seems to me better than the coarse processes under which this calculus is sometimes concealed; but there is a habit, common to young writers, of introducing forced and difficult demonstrations where more simple ones would be better. An illustration may be found in one of our best books on astronomy. In the first edition of this book the author gave a long and difficult demonstration of the well-known formulæ for the transformation of rectangular co-ordinates in a plane. The demonstration was made to depend on the solution of functional equations by means of the differential calculus, and is an awkward thing to place at the beginning of a text-book. In the second edition, having removed this demonstration and supplied its place by a simple one, the author has made the first chapter of his book the best synopsis of spherical trigonometry that I know of.

3. An error of the English text-books written by Cambridge men is, I think, the great number of examples given at the close of each chapter. At least one-half of these should be omitted. It is a great mistake to keep the student lingering over the never-ending questions of conic sections, of maxima and minima, &c., and to give him the habit of solving petty problems, when he should be led forward as soon as possible to the study of the memoirs of those who have created the science. In this connection it seems to me a mistake in treating the differential calculus to confine ourselves rigorously to the notion of a limit. Although the doctrine of limits may be the only logical foundation of this calculus, the student as he advances must soon become familiar with differentials, and it is well that he should make their acquaintance in his text-book.

4. A defect, perhaps of teaching rather than of text-book, is the ignorance of all American students of numerical and logarithm calculations, and from my slight observation I infer that such is the case also with English students. It is not uncommon to hear such calculations spoken of with contempt, but there is nothing that gives one a clearer idea of the meaning of analytical formulæ than to make a numerical application of them. In this matter it seems to me that the assistance of a teacher is of much more importance than in dealing with theoretical difficulties, since with these a student must generally be left to himself, while a little advice from a skilful computor will save the beginner much time and trouble.

5. Finally I mention, as a source of some confusion and perplexity to the student, the changes of notation and the introduction of new names. Some such change and inventions will be necessary with the progress of science, but any which tend to mar the symmetry of analytical expressions, and render less easy the reading of the great mass of mathematical literature that we already possess, should be avoided. To call a well-known function a "wonnumetonomy," or a "subcontra-wonnumetonomy," does not of course endow it with any new properties, or make its discussion one whit easier, although we may gain a slight advantage in the way of brevity of reference. For my own part I hope that this introduction of words of thundering sound, and the calculation of almost interminable formulæ, for which no more ingenuity is required than for a numerical calculation, is only premonitory to the invention of a calculus of operations which shall furnish us with shorter and more powerful methods of investigation.

ASAPH HALL

Washington, August 16

Jeremiah Horrocks

In the course of research (for literary purposes) concerning Jeremiah Horrocks, the astronomer, born at Toxteth, near Liverpool, 1619, I have been unable to discover his parentage. Could any of your readers help me in this matter?

London, Aug. 12 E.

The "Mors Electrique"

With reference to your notice of M. Sidot's "Mors Electrique," I may mention that in India it has been proposed to use Magneto Electricity for the purpose of starting a jibbing horse,

by passing a spark between two points attached to the breeching. I believe this would be really practicable and useful.

August 9 J. F. TENNANT

MAGNETICAL AND METEOROLOGICAL WORK AT BOMBAY

WE have received from Mr. C. Chambers, F.R.S., the Director of the Colaba Observatory, Bombay, three memoirs, to appear eventually as appendices to the volume; observations dealing with (1) the Absolute Direction and Intensity of the Earth's Magnetic Force at Bombay, and its Secular and Annual Variation, (2) on the Lunar Variations of Magnetic Declination at Bombay, and (3) a description of a new Self-Registering Rain Gauge. In the first memoir Mr. Chambers refers to the diminution of terrestrial magnetic action with increase of height above the ground. He states, "I am aware that experiments have at times been made to determine the effect upon the terrestrial magnetic force, of change of elevation or depression, both upon mountains and in mines; and it may be that such have been made also upon high buildings; but excepting the observations made in the vaults of the Paris Observatory, which I have not seen any discussion of with reference to this point, I believe that no long series of observations—capable of detecting small differences of the kind now pointed out—have been made elsewhere than at Bombay; and that the facts so strongly brought to light by the Bombay observations have not previously been forcibly commented on. It has now been shown—by the discussion of independent observations in each case—that diminution of effect with increase of height extends to—(1) the Secular Variation of Declination, (2) the Secular Variation of Horizontal Force, and (3) the Diurnal Inequality of Horizontal Force. Consistent testimony of this kind—even allowing for the possibility of explaining the first case on a different hypothesis—gives probability to the supposition that the phenomenon of sensible diminution of terrestrial magnetic action with moderate and practically attainable elevations above the earth's surface is general."

The object of the new rain gauge is to produce a complete record of rain-fall by means of photography, with this additional advantage, that whenever a barometer is kept in continuous operation there need be no additional expense in working the rain gauge.

SCIENCE IN JAPAN *

PROF. W. E. GRIFFIS writes us a very encouraging letter from Fukuwi, Japan, where he is giving practical instruction in a chemical laboratory established a year ago. Sixty students attend his daily lectures on chemistry and physics, properly illustrated by experiments, and twelve students do actually practise in the chemical laboratory. What he says of Japan is equally true here in the United States, only that the rubbish of astrology and Chinese philosophy, which prevent rapid progress there, are here represented by notions not less common nor less obstinate. He says:—"In teaching physical science in Japan, one has need to begin at the lowest foundation, to demonstrate everything, and to clear away much rubbish of astrology, Chinese notions of philosophy, falsely so called, &c.; yet the students are fairly intelligent, and promise hopefully to fill, in some measure, the greatest educational need of the country—good teachers."

The following will also merit attention:—"It may please you to know that Japan, just entering upon her course of modern civilisation, has begun by not only assigning a foremost place to physical science in her schools, but has already established several laboratories, in which students receive practical instruction from German and American professors. The chief laboratory in Osaka is presided over by a German professor, having nearly one hundred students. Another laboratory, it is expected, will be established in Yeddo. There is one in the province of Kaga, in charge of a German professor; another, also under a German, is at Shidzoka, in the province of Suruga. The laboratory in Fukuwi, province of Echeyen, has been established nearly a year." This is the laboratory of Prof Griffis, above spoken of.

It gives us, indeed, great pleasure to record these significant evidences of progress in the far-off Japan. These facts, as well as many others, show that at length commerce, the arts, and physical science, have commenced their missionary career in Japan, and will soon introduce the blessings of civilisation in that great country leaving the Japanese and Chinese gods to take care of themselves, if they can.

* From the Iowa "School Laboratory of Physical Science."

THE "HASSLER" EXPEDITION

THE GALAPAGOS ISLANDS

THE numbers of NATURE for July 11 and 18 contain reports from Prof. Agassiz himself of his *Hassler* Expedition; we are glad to be able to furnish the following continuation of these reports from a writer in the *New York Tribune* who accompanies the Expedition:—

"About sundown on Thursday June 6 we bade good-bye to the Ossipee and to Payta, and, with a fair wind and smooth sea, started for the Galapagos. Darwin's account of this archipelago had excited our curiosity and interest to the highest degree. Of course our visit was all too short to settle the many interesting questions which his narrative suggests. We landed on Charles early Monday afternoon, June 10, and left early Wednesday morning. We landed at Tagus Cove, on Albemarle, Thursday morning, and remained until Friday afternoon. On Saturday at noon we anchored off James Island, and remained until Sunday at 10 o'clock, when we visited Jervis Island, and remained until sunrise on Monday. We anchored at Indefatigable Island on Monday by 9 o'clock A.M., and were detained repairing our engine until Wednesday afternoon, June 19, when we started for Panama. In so brief a visit to so remarkable an archipelago, no conclusions can properly be drawn from what we did not see, and yet one of the most interesting points of inquiry was precisely one that can be definitely settled by negative testimony only—the inquiry whether plants and animals found on one island are wanting on the other islands in the group. That this should be the case is not incredible; even on the continent we sometimes find plants and animals confined to very narrow localities. And although we had a very limited opportunity to examine the five islands on which we landed, our observations, as far as they go, tend to confirm the statements heretofore made that the Galapagos have a fauna and a flora decidedly of an American type, yet decidedly peculiar to themselves, and that even each island differs from the other islands; nay, that this difference extends, in some degree, to the fishes in the bays around their shores.

"The islands are to my eye much more recent in their formation than Juan Fernandez. Indeed, Narborough and Albemarle have so fresh a look that you could easily believe that there had been extensive eruptions there within the present century. Immense domes, 4,000 to 5,000 feet high, stand upon very flat truncated cones, twelve or fifteen miles in diameter. Over the whole surface of such mountains are scattered craters, chimneys, and small truncated cones. From many of these craters streams of lava have flowed toward the sea, some of them

spreading out to miles in breadth and miles in length, and this lava is so fresh and black that as you walk over it you scarce find even a lichen adhering to it; it is a rough field of hard black slags or clinkers. This crust of cooled lava is cracked into rude hexagonal blocks of from six inches to several feet in diameter, and between the blocks you may find cracks so fine that the rain will scarcely penetrate them, or you may find chasms a yard in width and many feet in depth. The thickness of this crust also greatly varies. Here may be a swelling in the ground, a little hillock bursting at the summit, and showing a lava-crust of unknown thickness, and a few yards off a similar hillock, or a black ridge, may show through its openings that it is a mere shell, from which the fluid, molten contents were drained; while the crust was barely thick enough to sustain itself. The general level of the field is thus diversified by innumerable pits, caves, small cones, and craters, which, especially in such hard, rough material, make it a very "hard road to travel." The remaining surface of the mountain is similar, but composed of older lava, in the cracks of which a few scattered trees and bushes find a foothold, and give a meagre clothing to the land. Occasionally a patch of volcanic sand, or sandstone, gives the vegetation a better chance. The more eastern islands of the group are simply like these better parts of the western. There were many indications that our visit was in a time of drouth—for example, an abundant growth of a delicate fern, *Adiantum*, on James Island, was withered to the roots. This drouth may have been one reason why the whole archipelago, with the exception of James, and small patches on Jervis and Indefatigable, had a blasted look. The trees and shrubs were nearly all leafless, and the bark of the two most abundant species was light gray, almost white. Two kinds of prickly pear—*Opuntia* and a cactus more like a *Cereus*—made a striking contrast to this white shrubbery, lifting their solid dark green masses high above the bushes and dwarf trees, particularly on Indefatigable, where all three kinds abounded. I saw in the short rambles which I had to take only one really fine kind of tree; it was a straight trunk, very smooth, glossy bark, vigorous branches, and grew on James Island. It was entirely leafless; but the dead leaves and fruit pods under it showed that it belonged to the great family in which our locusts and coffee bean are placed; it had large trifoliate leaves, and a bright scarlet bean. Another tree of the same family had a very singular appearance; the plant itself looked like a dwarf walnut or butternut; the pod was very thin and narrow, but carried four thin wings half an inch wide, thin as paper, standing at right angles, and extending the whole length of the pod.

"The geologists were quite successful in getting specimens of various animals. Over fifty different kind of fishes were obtained, and of these over three-fourths are peculiar to the Galapagos. Of the Galapagos, from which the islands are named, and in which they once so richly abounded, we only got a few specimens, and those very small compared with those of olden time. They have been so eagerly hunted for their flesh that they have been driven from the more accessible places, and stand a good chance of being altogether exterminated. Their brethren in the sea, the tortuga or sea-turtle, we saw in abundance, and got some very fine specimens. There are, as is tolerably well known, two other reptiles for which this archipelago is famous—two lizards of a genus not found elsewhere, and very peculiar in their habits. The Spaniards called them iguanas, from their resemblance to that reptile in the West Indies and Central America. But they differ so much from their American cousin that they ought to have a name of their own; and if the scientific *Amblyrhyncus* looks too formidable, let us translate it and call the creature a Bluntnose. On Charles Island we found abundance of the crested Bluntnose climbing with great agility over the rocks near Black Beach. The creature is about 30 in. long, nearly black, the old males having a deep red hue on the sides. It swims with great ease by its flat tail, and uses its long fingers and long nails for scrambling on the rocks, holding them while swimming close to the body. There is not a trace of web-footedness about them, and they make no use of the feet in swimming. They live on sea-weeds from the rocks in deep water, and their expression is mild and herbivorous, with a little clear, innocent eye. I was prepared for something hideous, and was agreeably disappointed. In another respect our experience differed from Darwin's, for we sometimes had no difficulty in frightening them into the water, and they came fearlessly swimming about the *Hassler* as she lay in Tagus Cove. These crested Bluntnoses we found upon all the islands. The slightly crested Bluntnose we found only on Albemarle and Indefatigable. Its scientific name might mislead one, for its head is just as much crested as its aquatic brother's. The only differences between them apparent at first sight are these:—The terrestrial animal is somewhat stouter, his nose is longer, his eye brighter, his tail less flattened and less crested, and his colour is a dusky orange, deepening into brown on the hindquarters. His habits of life are very different, as he does not go near the sea, but lives upon land plants, and makes a burrow for himself in the sand and among the fragments of lava. He spreads his hind legs flat on the ground, raises his chest to the height of his fore legs, and then nods and winks at you in a very odd way. It looked to me very much like swallowing, and I thought it possible that the creature, with his head in that position, swallowed air like a toad, as a means of breathing—swallowing into the lungs, not into the stomach.

"One of our most interesting adventures was landing in a little bay full of seals, so tame, or rather so little afraid of men, that we could tramp past groups of sleepers on the beach without awakening half of them, and without apparently frightening half of those that we did awake. They seemed to be fond of crawling under bushes just above high-water mark, and sleeping, two or three in a place, huddled close together. Under one bush lay a mother and her two cubs, so fearless that one of our officers held a piece of cracker to the old one, and she smelled it in his fingers as fearlessly as if she had been a pet dog. The cubs quarrelled with each other as to which should cuddle nearest the mother, and they all three snarled and snapped at the flies in the manner of a sleepy dog, and all this while a party of ladies and gentlemen, creatures as large as the seals, and which the seals could scarce have seen before, stood looking on within touching distance. These seals had much more length of arm, and used their arms more in the manner of a quadruped than I had supposed any seal could do. I saw them walk on the beach with the whole chest clear of the ground, and even jump upon the sand. Their favourite gymnastic exercise, however, was to lie upon their backs and roll in the manner of a horse. The tameness of these seals and of many of the land birds was very surprising; the Bluntnoses were more shy than we had expected. I repeatedly put my fingers within half an inch of little yellowbirds and phebes, and within six inches of mocking-birds. On James Island the birds were so numerous and so tame that while I was trying the experiment whether whistling to a yellowbird would divert his attention so much as to make him allow me to touch him, six other birds—including two mocking-birds—came up and alighted on twigs within two yards of the yellowbird, to see what was going on between us. As for the flies, their tameness and pertinacity of adhesion at the Galapagos goes far beyond all travellers' accounts. I knew a good housekeeper in New England who affirmed that house-flies could not be driven out of a room unless you struck and killed one or two, in order to show the others that you were in earnest. You cannot drive the Galapagos flies from you even with that

expedient. The birds and seals are not frightened by being stoned or shot; they don't know what stones and guns mean, and the flies are not frightened or discouraged by having any amount of their comrades killed. When a boat was coming off shore, the usual occupation, in order to prevent carrying the nuisances on board, was for everybody to be picking the flies off themselves (almost as they would burrs), killing them and throwing them into the water from the time of leaving the beach to the arrival on the deck of the ship; and the last fly slaughtered before you go into the cabin is no more afraid of you than the first one you slew at the beach. They are not biting flies—we have escaped trouble from mosquitoes and biting flies during the whole voyage—but they are crawling, tickling, adhesive, tantalising creatures. It was pleasant to find here at the Galapagos a species of penguin, smaller and more sober in dress than our old friends of the Straits of Magellan, but with the same winning, cunning manners that made the birds in the Straits such favourites with our party. And while speaking of the birds of these islands, I would not forget the splendid flamingoes, six feet high, of which we got many fine specimens. They sailed about in parties of twelve or twenty birds together, making long lines of scarlet flame floating through the air. We tried their flesh on the table, and found it the most delicious game, fully equal to the canvasback, as it seemed to us.

"One lesson I must confess to having learned at Indefatigable Island. I saw there indisputable proof that the surf of the sea is capable of rounding angular fragments of lava into pebbles, somewhat resembling in shape (but not at all in polish and grooving) glacial boulders. I had always from boyhood doubted the power of the sea to make angular fragments round: I had supposed that the action of the surf upon such fragments would be simply to pack them into a sort of McAdam's roadway. And even now, having had this proof that under peculiar circumstances the sea can make a tolerable imitation of drift, I am not a whit more ready to believe that the sea made the drift itself. You may prove to me experimentally that flour can be made from wheat with a pestle and mortar, but that will not convince me that the flour markets of the world are thus supplied. There are one or two little colonies on the island, but the colonists have a hard life, and there can hardly be any agriculture there for centuries to come. At present the two main products of the islands are terrapins (galapos), which are almost exhausted, and wild pigs, which are of little worth, and which are destroying the wild plants and animals. The archipelago offers at present a fine opportunity for a naturalist, who desires to make a residence here for several years, and thoroughly explore their structure and their productions, to throw a strong light upon the great modern question of the origin of species, and the doctrines of evolution. Younger than Juan Fernandez, purely volcanic, bringing no seeds with them from the bottom of the sea, not having had time to alter and amend species introduced from the mainland, how did these islands come in possession of their peculiarly organised beings—their Bluntnoses for example? This was the question constantly recurring to me during my visit to the Galapagos, as it had been at Juan Fernandez. Prof. Agassiz gave us a little talk one day on our way to Panama, and discussed the same point. Expressing his warm admiration for Darwin's moral and intellectual character, and earlier scientific labours, he said that he considered his present influence on science very pernicious as favouring the habit of 'filling up the wide gaps of knowledge by inaccurate and superficial hypothesis.' What we need in order to extend our knowledge of the origin of species, is not hypothesis and speculation, but a careful collation of facts, and a careful extension of our observation of facts. The hypothesis that the differences of species were produced by variations taking place in unlimited, in indefinitely long periods of time, is, at all events, strongly negatived by this occurrence of such marked peculiarities of difference from the surrounding world, in an archipelago that belongs wholly to the present geological epoch, and has not existed an indefinite time. It was very pleasant to us all to hear this greatest and most earnest opponent of Darwin rendering with such manifest sincerity his tribute of admiration for Darwin's genius and industry, and confessing with such evident pride his warm personal love toward him. As to the question of the origin of species, I think we were all willing to leave it a question. Darwin's hypothesis of gradual variation of species, and the natural selection for preservation of those whose variations were favourable to them in the struggle for life, seems to me to have few facts to sustain it, and very many to oppose it. At the same time it must be conceded that all the maxims of metaphysics and theology combine in assuring the man of science that he is always right in assuming the utmost paucity of original causes. The universe is certainly framed with infinite skill and wisdom, and there never will be found two different things, where one would answer. If the present existing forces of nature can bring an Amblyrhynchus and an Iguano out of one common parent, it would have been a waste of creative power to make two parents; that concession to the doctrine of evolution is demanded by philosophy and the principle of least action. But the facts of zoology seem to me to indicate clearly that the present acting forces of nature can do no such thing.

THE LATE PROF. DR. F. KAISER

ON July 28 last died Prof. Kaiser, Director of the Leyden Observatory.

Kaiser was born on June 10, 1808, at Amsterdam, where he was educated by his father, and, after the latter's death, by his uncle, J. F. Kaiser, himself a zealous promoter of astronomical research. In 1828 young Kaiser, whose love for astronomy had at an early period shown itself, was appointed assistant at the Leyden Observatory, which was then superintended by Prof. Wylenbrock. Till 1837 he remained in this position, improving himself by the study of all the best works in his department, when he was appointed Professor of Astronomy in Leyden University and Director of the Observatory. It is well known that this appointment marks the beginning of an epoch in the history of astronomy in the Netherlands. By unwearied exertions he soon collected some good instruments, and by means of his numerous and partly popular lectures he kindled such an interest in astronomy among the people that, in the year 1856, one of the items in the Budget was the cost of erecting a new Observatory. This he entered in 1860, furnished with many new instruments. This was followed in 1866 by permission, obtained through his never-tiring exertions, to publish "Annals." Notwithstanding that in the spring of this year he was seized with severe chest disease, which became a sad hindrance to his labours, he occupied himself with the editing of the "Annals," and with the improvement of the organisation and instruments of the Observatory. On the 4th of November last he set to work to perform some calculations necessary to complete a lecture for the third volume of the "Annals," on "The Measurement of the Diameters of Planets," and on the day after was seized with a hæmorrhage which made his illness assume a more critical character. Even from this attack he might have rallied with returning spring, had it not been for the death of his wife, with whom he had been happy for 41 years. From that blow he never recovered.

That astronomy has sustained a great loss in Kaiser, all who take an interest in the science must feel. It is to be hoped that ere long a worthy account of his life and labours will be given to the world.

NOTES

THE work of the French Association, which, as we have already announced, meets at Bordeaux from the 5th to the 13th September, comprehends—1st, At least two general meetings; 2nd, Meetings of divisions and lectures; 3rd, Scientific excursions; 4th, Public lectures. Of the last there will be four, the first of which was to have been by the late lamented M. Delaunay, on "The Constitution of the Sun;" his place will probably be filled by M. Cornu. The second public lecture is to be by M. Broca on "The Troglodytes of *Les Eysies*;" the third by M. Levasseur on "Commercial Geography;" and the fourth by Lieutenant F. Garnier, on "The Voyage of the *Cambodge* and the Political and Commercial *rôle* of France in the extreme East." There are to be seven excursions in all, one to the mouth of the Gironde for the purpose of observing the changes in the coast-line; another to the pre-historic remains and bone caverns of *Les Eysies*; the sixth is to Medoc for the purpose of visiting the great vineyards of Château-Margot and Château-Montrose.

THE International Congress of Scientific Archæology was opened at Brussels on August 22, with an attendance of 600 men of science of various nationalities, including Prof. Owen and M. Virchow. After being entertained to luncheon in the Hotel de Ville, the *savans* adjourned to the Ducal Palace, where, at two o'clock the Congress was opened under the presidency of M. d'Omalius d'Halloy, the Belgian senator and eminent geologist, who will soon be a nonagenarian. The opening address was given by M. Dupont, the distinguished director of the Brussels Natural History Museum, who gave a summary of the results of the researches relative to pre-historic times in Belgium. The Executive Committee, under the presidency of M. d'Omalius d'Halloy, was then constituted. The Belgian vice-presidents are MM. Hagemans, van Beneden, and Baron de Wit. The vice-presidents for foreign countries are M. Virchow, for Germany; M. de Quatrefages, for France; Mr. Franks, of the British Museum, for England; M. Nilsson, for Sweden; M. Steenstrup, for Denmark; and M. Conestabile, for Italy. M. Dupont, of the Belgian Museum, was installed as secretary-general. The excellent club known as the *Cercle Artistique et Littéraire* has thrown open its hospitable doors to the members of the Congress. On Saturday, Aug. 24, an excursion under the auspices of the Congress took place to the valley of the River Lesse, a tributary of the Meuse, which it joins not far from Dinant. The purpose of the excursion was to inspect the prehistoric remains which abound in the numerous caverns that exist along the banks of the Lesse. M. Dupont acted the part of guide, and his disquisitions at each particular spot of interest were followed by lively discussions among the geologists present. On returning across the Lesse from inspecting the *Trou de la Naulette*, one of the over-crowded boats had its balance disturbed and went down, happily with no worse result to the passengers than a thorough drenching. Among those on board was Mr. Franks, of the British Museum, who, with another gentleman, gallantly rescued Mme. Royer, Mr. Darwin's French translator. At Sunday's meeting it was decided to hold the meetings of the Congress biennially instead of annually. On Monday, 26th, an excursion was made to Mesvin and Spiennes. The latter place is supposed to have been a manufactory of flint implements, the ground visited being thickly covered with flint splinters and unfinished flints. After luncheon the railway cutting at Mesvin was visited, where some lively discussion ensued, the party subsequently inspecting some pits from which the flint for making tools had been extracted.

THE Government of New South Wales, following the lead of Europe and the United States, has introduced the system of telegraphing the anticipations of the weather, and has established certain stations on the coast for indicating the nature of any expected storm by means of signal masts. These signal masts support two yards, crossing each other at right angles in the direction of the cardinal points of the compass. A violent squall is to be represented by a conspicuous diamond-shaped signal; a heavy sea by a drum; a gale with clear weather is indicated by a diamond-shaped signal over a drum; and one with thick weather and rain by the same signal under a drum. The direction in which the wind is blowing is indicated by the particular yard-arm between which and the mast-head the geometrical signal is suspended. Gales that are general over a large portion of the coast are indicated without the mast-head flags, by the geometrical figures.

WE learn that Professor Nordenskjold, the originator and leader (under the direction of the Royal Swedish Academy) of the Swedish North Polar Expedition, contemplated since 1861 arrived on the 17th of last month at Tromsö, in Northern Norway, and sailed away again in the iron steamer *Polhem* on the 21st. Before leaving that port for the far north he sent a letter to Mr. Oscar Dickson, merchant, of Gothenburg (thanks to whose energetic and liberal support the expedition was enabled to start this year), giving a short description of the means at his disposal. The plan of the expedition is that of wintering on the northernmost islets of Spitzbergen (the Seven Isles), whence by the aid of reindeer sledges an over-ice journey northward will be attempted. The professor is accompanied by two physicians, a naturalist, an Italian naval officer, a first mate, two engineers, ten picked seamen, and four Lapps for attending the reindeer, from forty to fifty of which, with 3000 sacks of reindeer moss and other necessaries for wintering in the Arctic regions, have been taken by another (hired) steamer, the *Onkel Adam*, to the intended winter quarters. The Swedish Government has placed the brig *Gladan* at the professor's disposal till the beginning of winter. This vessel has also started from Tromsö, having on board a house, in which the exploring party is to winter in the Seven Isles; she will return to Tromsö, and hence take back a second cargo, consisting of coals. The expedition is in addition furnished with 1545lb. of paraffin, to serve as lighting and cooking material on the sledge journey. The house contains six living rooms, one of which is to be used as a workshop, a kitchen, pantry, bath-room, and frost-proof cellar. The expedition has also taken from Stockholm three "observation sheds." It is amply provisioned for two years, and well supplied with warm winter clothes, among which are complete suits of Lappish clothing for every person in the expedition. On the sledge journey, amongst other things, rum, paraffin, sleeping bags, tents of tarpaulin, a large sleeping carpet, &c., will be taken. Three boats, weighing respectively 300lb., 200lb., and 150lb., and specially adapted for ice travelling, with sledges, had been shipped at Copenhagen. To assist the Laplanders in the management and supervision of the reindeer, they have with them five reindeer dogs. Three live pigs form also part of the provisions. Finally, the expedition is well provided with all necessary scientific instruments.

PROF. C. H. F. PETERS, of Hamilton College, U.S., has discovered two more new planets of 11·5 and 12 magnitude respectively, provisionally numbered 123 and 122.

THE International Statistical Congress has opened at St. Petersburg its eighth session since it started its work in 1853, and is divided into five sections: the first on questions connected with the census of the population, the second on the movement of the people, the third on industry, the fourth on postal relations and commerce, the fifth on criminal statistics. The Congress is well attended by representatives of all countries, with a good sprinkling of English members. Dr. Farr, Mr. Hammick,

and Mr. Lock represent the official part of our members; Mr. Samuel Brown, Mr. Hamilton, Mr. Hendriks, Dr. Mount, M. Tayler, and Mr. Levi, represent the Statistical Society of London; and there are also Mr. Freeman, Mr. Heron, and Mr. Wethered as voluntary members. The Russian Government and the municipalities of St. Petersburg are most liberal in their arrangements for the reception of visitors. A free railway ticket over the Russian territory, and free lodgings in the best hotels, for every member of Congress, have been provided. The Princess Helena gives evening entertainments. The Hermitage and Museums are open, and there are to be excursions to the Exhibition at Moscow, and to the fair at Nijni Novogorod.

THE session of the Physical Science College of Newcastle-upon-Tyne will commence on Oct. 2, and will be divided into the Michaelmas, Epiphany, and Easter Terms. No preliminary examination is required, but students must be above the age of fifteen years. All particulars will be found in the college prospectus, to be had free on application to Mr. W. Bunning, secretary to the college.

THE twenty-seventh annual meeting of the Cambrian Archæological Association has been opened at Brecon, and the Congress will sit up to Friday evening. The President for the year is Sir James Russell Bailey, M.P., of Glamish Park, Cricklewell. The proceedings will be of the usual character, including the reading of papers on subjects of archæological interest, and daily excursions to places of note in the surrounding neighbourhood.

THE *Journal of the Franklin Institute* calls attention to the following interesting lecture experiment:—It is well known that a light ball, as of cork, is sustained for some time near the summit of a vertical jet of water, issuing from an orifice of such a nature that the steadiness of the jet is maintained. The experiment becomes more striking when a vertical blast of air issuing from a large bellows is substituted for the jet of water, as in this case there is no apparent support for the ball, which comports itself in a very amusing manner. When a strong blast cannot be obtained, if a slender wire, about four times the length of the diameter of the ball, be passed through its centre, so as to have one-fourth of its length projecting from one end, and one half from the other, the balancing is more readily obtained, as any considerable change in the relative positions of the centre of gravity and the point of support is prevented by the movements of the rod.

WE learn from the *Journal of the Society of Arts* that the directors of the telegraphic lines of France have recognised the absolute necessity of improving the theoretical and practical knowledge of its clerks, and with this view elementary courses of telegraphy have been arranged in all the chief towns, at which the attendance of the *employés* is obligatory. In addition to this, a superior course of instruction is to be opened in Paris, and those clerks who have most distinguished themselves in the provinces will be sent to the capital to complete their instruction. The courses are all to commence on the first of October.

Harper's Weekly, of August 17, announces the deaths of Mr. Sidney J. Lyon, a gentleman well known for his valuable geological and archæological researches while State geologist of Kentucky; and of Mr. Edmund Ravenal, of Charleston, S. Carolina, and Dr. Hubbard, of Long Island, both eminent conchologists.

WE notice from the *Field* that on September 3 and 4 a sale of the surplus animals of the Zoological Gardens of Antwerp is to t ke place. The collection to be disposed of includes many of the rarer species of mammals and birds. In the former figures a young Indian rhinoceros, several species of antelopes, moufflons, and a male markhare ("which," says the *Field*, "offers a chance for any one desirous of increasing the size of our Welsh goats"). The birds include ostriches, several species of rare and new pheasants, and a considerable number of the rarer water-fowl, serpents, pythons, &c.

WE learn from the *Times of India* of July 26 that Mr. Mark Fryar, the mining engineer who has been specially engaged to develop the mineraliferous resources of British Burmah, spent the last two months of 1871 in exploring the Mergui district of Tenasserim; and the results of his explorations have just been published by the Etcetera Department as an extra supplement to the *Gazette of India*. Of the coal which exists there Mr. Fryar does not speak at all hopefully. It is deficient in quality, and could not compete with English and Australian coal; besides which, there is no demand for it, the dense forests of Tenasserim being capable of supplying the whole country with fuel for generations to come. Summing up the results of his two months' tour, Mr. Fryar says the most remarkable feature of the districts is the wonderful extent of the distribution of staniferous detritus: "In rivers on the mainland and on islands of the sea, every small dishful of sandy gravel taken up contains palpable traces of black tin-stone;" and he thinks it exceedingly probable that a thorough examination of the hills whence the rivers flow would be rewarded by the discovery of rich veins of tin ore, which could be worked with the most profitable results.

A LETTER from Bucharest, given in the *Levant Times*, reports a curious atmospheric phenomenon which occurred there on the 25th of July, at a quarter past nine in the evening. During the day the heat was stifling, and the sky cloudless. Towards nine o'clock a small cloud appeared on the horizon, and a quarter of an hour afterwards rain began to fall, when, to the horror of everybody, it was found to consist of black worms of the size of an ordinary fly. All the streets were strewn with these curious animals. It is to be hoped that some were preserved, and will be examined by a competent naturalist.

THE International Congress on Weights and Measures meets at Paris on September 24.

THE cyclone which had been heard of from the Bay of Bengal, broke over Balasore early on the morning of the 1st July. There was a heavy gale from the N.W. at about 2 A.M., and at 4 A.M. the wind veered to the N.E., and blew with tremendous violence, subsequently passing to the E. and S.E, and dying away at one o'clock. The station, which was once one of the prettiest in Bengal, is said now to be a mass of ruins. The destruction of property has been very great. Several thousand people were rendered homeless, and many without food. The telegraph lines were carried clean away for several miles on both sides of Belasore.

THE *Honolulu Gazette* reports the following interesting fact which has recently been observed respecting the growth of coral, and which deserves very careful consideration:—Somewhat less than two years ago a buoy was moored in Kealakekua Bay. Last week the anchor was hoisted in order to examine the condition of the chain. "The latter, which is a heavy 2 in. cable, was found covered with corals and oyster-shells, some of which were as large as a man's hand. The large corals measure four-and-a-half inches in length, which thus represents their growth during the period of two years that the anchor and cable have been submerged. The specimens which we have seen show the nature of the formation of the coral by the coral animals very distinctly. When taken out of the water it had small crabs on it. A question arises whether these crabs live on the coral polypes, or whether they simply seek the branches of the coral for protection. The popular idea is that corals are of extremely slow growth, yet here we have a formation equal to over seventeen feet in a century."

THE BRITISH ASSOCIATION

BRIGHTON, *Thursday, Aug.* 22

THIS year's Congress of the British Association was formally brought to a close yesterday afternoon by a largely attended general meeting held in the Dome, the main purpose of which was to allot votes of thanks to those who had officially done their best to make the meeting successful. One of the best-deserved votes was that to the Mayor and Corporation of the town, who had done all that lay in their power to promote in every respect the comfort and convenience of visitors. If the meeting has not been in all respects a success, it has certainly been from no want of hospitality and courtesy on the part of the Brightonians. Prof. Fawcett proposed the vote of thanks to the distinguished president, Dr. Carpenter. The professor's praise of the president was hearty and well-deserved. In returning thanks Dr. Carpenter paid a well-merited compliment to Mr. Griffiths and Mr. Galton, "his right and left hands, the former his *fidus Achates*."

The following are the grants agreed to this year, with the names of the members entitled to them :—

MATHEMATICS AND PHYSICS	
*Cayley, Prof.—Mathematical Tables	£100
*Thomson, Sir W.—Tidal Observations	400
*Brooke, Mr.—British Rainfall	100
*Everett, Prof.—Underground Temperature (100*l*. renewed)	150
*Griffith, Mr. G.—Gaussian Constants (renewed)	10
*Glaisher, Mr. J.—Luminous Meteors	30
Glaisher, Mr. J.—Efficacy of Lightning Conductors	50
*Williamson, Prof. A. W.—Testing Siemens' New Pyrometer (renewed)	30
*Huggins, Dr. W.—Table of Inverse Wave-Lengths	150
*Tait, Prof.—Thermal Conductivity of Metals	50
CHEMISTRY	
*Williamson, Prof. A. W.—Records of the Progress of Chemistry (100*l*. renewed)	200
*Gladstone, Dr.—Chemical Constitution and Optical Properties of Essential Oils	30
Brown, Prof. Crum.—Temperature of Incandescent Bodies	50
Brown, Prof. Crum.—Electric Tensions of Batteries	25
GEOLOGY	
*Ramsay, Prof.—Mapping Positions of Erratic Blocks and Boulders (renewed)	10
*Lyell, Sir C., Bart.—Kent's-Cavern Exploration	150
Lubbock, Sir J.—Exploration of Settle Cave	50
*Busk, Mr.—Fossil Elephants of Malta	25
*Harkness, Prof.—Investigation of Fossil Corals	25
*Carruthers, Mr.—Fossil Flora of Ireland	20
*Harkness, Prof.—Collection of Fossils in the North-west of Scotland	10
*Bryce, Dr.—Earthquakes in Scotland	20
Willett, Mr. H.—The Sub-Wealden Exploration	25
BIOLOGY	
Lane Fox, Col. A.—Forms of Instructions for Travellers	25
*Stainton, Mr.—Record of the Progress of Zoology	100
*Christison, Sir R.—Antagonism of the Action of Poisons	20
*Balfour, Prof.—Effect of the Denudation of Timber on the Rainfall in North Britain (renewed)	20
MECHANICS	
*Grantham, Mr. R. B.—Treatment and Utilisation of Sewage	100
*Froude, Mr. W.—Experiments on Instruments for Measuring the Speed of Ships and Currents (30*l*. renewed)	50
Total	£2,025

Some of the grants, as the president remarked, were for large sums, but it is gratifying to learn that the sum realised by the sale of tickets this year will more than cover the whole amount. The total number of tickets sold has been 2,533, representing 2,649*l*.

* Reappointed.

Not the least successful, and doubtless to many of the 200 guests, not the least enjoyable of the numerous meetings which have within the last few days been held at Brighton, was the *déjeûner* given yesterday by the hospitable mayor in the banqueting-room of the Royal Pavilion.

The Press arrangements have received very general commendation. Special praise is due to the *Brighton Daily News*, whose reports of general and sectional meetings were unremitting until it came to Mr. J. F. Walker's paper, and what the *Pall Mall* calls the alarming polysyllable "Dinitrobrombenzene." The *News* might, however, have got over the word, which we shall not venture to repeat, "but," it says, "since the communication was full of such words as mononitromonobrombenzene and metamononitromonobrombenzene, we do not imagine a full report would be interesting to our general readers." Our spirited contemporary is probably right, as the *Pall Mall* remarks ; half-a-dozen such words might make a handsome day's wage even for the most diligent compositor.

In alluding to Dr. Carpenter's lecture on Chalk to be delivered to-night, the opportunity must be taken of supplying an omission which we unintentionally made last week. We should have mentioned that one of the three general lectures was by Mr. J. M. Duncan, on the "Metamorphoses of Insects."

SECTION A—MATHEMATICAL AND PHYSICAL SCIENCE

On a Periodicity in the Frequency of Cyclones in the Indian Ocean South of the Equator, by Mr. Meldrum.

One of the objects for which the Meteorological Society of Mauritius was established, in 1851, was to obtain extracts from the meteorological registers of vessels visiting the harbour of Port Louis, especially of such vessels as had experienced bad weather in the Indian Ocean.

Accordingly, clerks were employed to copy all the log-books that could be procured.

In 1853 the system of registration was remodelled. Instead of having the observations contained in each log-book recorded separately, all the observations in all the log-books for the same day were recorded on the same page.

As this system has been conducted without interruption to the present time, the Society has now a large collection of observations showing more or less the state of the winds and weather over the frequented parts of the Indian Ocean, in the form of a daily journal, during the last nineteen years ; so that a person may find at once what weather prevailed on any day or in any year during that period.

Together with the years 1851-2, therefore, during which the registers were differently kept, we have 21 years' continuous observation, from the meridian of Greenwich to 120° E., and from 23° N. to 45° S.

Adding to the information obtained by the Society throughout these 21 years numerous observations collected by several persons for the previous four years (1847-50), we have a more or less complete record of all, or of very nearly all, the cyclones which have taken place in the Southern Indian Ocean during the last 25 years ; for Mauritius is so much in the track of these cyclones, and so much visited by vessels in distress and by others trading between the colony and England, India, and Australia, that it is scarcely possible for any violent hurricane to pass without being noticed.

Taking now, for the present, the area comprised between the equator and the parallel of 25° S., and the meridians of 40° and 110° E., and examining a table of the cyclones that have occurred there from 1847 to 1872, it is found that some years have been remarkable for a frequency and others for a comparative absence of cyclones.

The five years, 1847-51, were characterised by cyclone frequency ; then came a period of comparative calm (1852-57), which was followed by six years (1858-63) remarkable for cyclones. The next five years (1864-68) showed a considerable ecrease ; and since 1869 there has been an increase, until, for

the present year (1872), the number of cyclones is already (28th June) greater than in any year since 1861.

What has now been said is not only borne out by the records of the Meteorological Society, which give detailed accounts of the hurricanes, but also, I have little doubt, by the books of the docks and marine establishments.

Especially in 1847-48, and again in 1860-63, the harbour of Port Louis was at times crowded with disabled ships; whereas in the years 1855-57 and 1866-68 there were very few.

It will be seen that these years correspond pretty closely with the maxima and minima epochs of sun-spots.

For the present I wish merely to call attention to the subject, in order that the connection which I think exists between sun-spot frequency and cyclone frequency may be either verified or refuted by past or future observation.

It appears to me that there is more than a mere coincidence as to time. There are three maxima and two minima epochs of cyclone frequency, corresponding nearly, if not entirely, with similar sun-spot epochs.

To examine the matter fully, it would be necessary not only to know the number of cyclones in each year, but also the extent and duration of each and the force of the wind. If we could thus get an expression for the annual amount of cyclonic energy, and could show that it varied directly as the amount of sun-spots, a connection would be established. One violent hurricane, which lasted ten days and passed over thousands of miles, might have more value than half a dozen smaller and short lived ones. However, having traced a large number of the cyclones in question, I have no doubt that the years of greatest cyclone frequency were generally, if not always, the years of greatest cyclone energy; and that the number of cyclones in a year is a fair expression of the cyclonic activity for that year.

Now, taking the maxima and minima epochs of the sun-spot period, and one year on each side of them, and comparing the number of cyclones in these three-year periods, we get the following results:—

	Years.	Number of Cyclones in each Year.	Total number of Cyclones.
Max.	1847	4	
	1848	6	15
	1849	5	
Min.	1855	4	
	1856	1	8
	1857	3	
Max.	1859	5	
	1860	8	21
	1861	8	
Min.	1866	5	
	1867	2	9
	1868	2	
Max.	1870	3	
	1871	4	14
	1872	7	

Taking two years on each side of the solar-spot epochs, we get:—

	Years.	Number of Cyclones.	Total number.
Min.	1854	3	
	1855	4	
	1856	1	15
	1857	3	
	1858	4	
Max.	1858	4	
	1859	5	
	1860	8	32
	1861	8	
	1862	7	
Min.	1865	3	
	1866	5	
	1867	2	15
	1868	2	
	1869	3	

Assuming that we have got a close approximation to the actual number of cyclones, and that the numbers fairly represent cyclonic energy, it is difficult to avoid the conclusion that the above tables point to a definite law; and that meteorology, magnetism, and solar physics are closely connected. For what holds good with regard to a large tract of the Indian Ocean probably holds good with regard to other portions of the earth's surface.

Is it not probable, also, that if there is such a connection as is here suggested between the sun-spots, or sun-cyclones (as they have sometimes been called), and earth-cyclones, there is a similar connection between the sun-spots and cyclones in the other planets?

On the Spectrum of Hydrogen, by Arthur Schuster, student of Owens College.

In a paper communicated to the Royal Society, I have shown that nitrogen has only one spectrum; the band spectrum usually obtained at low pressures being due to oxides of nitrogen. I have since subjected hydrogen to a similar investigation, and although my experiments may not seem to give an absolute proof of the correctness of the opinion advocated chiefly by Angström, they show clearly, I think, to what causes we have to ascribe the different results obtained by different observers. The changes through which the spectrum of hydrogen passes when the pressure is gradually diminished are, according to Wüllner,* as follows: the spark of the small induction coil begins to pass under a pressure of 135 mm.; the colour of the spark is white, but only under a pressure of 100 mm. it becomes sufficiently intense to be examined. The spectrum is a continuous one with shaded bands. This spectrum gradually increases in brilliancy down to a pressure of 30 mm. If the pressure is diminished still more the three lines $H\alpha$, $H\beta$, $H\gamma$, rise more and more from the continuous ground and the band spectrum gradually disappears. Under 3 mm. pressure only these three lines are seen, but if we continue to exhaust the tube, the continuous spectrum reappears in the green. Finally at the lowest pressure under which the spark passes a third spectrum of brilliant lines is seen. A short historical sketch will show in how far the above statement is in harmony with the results of Plücker, and will justify at the same time the course of experimenting which I have pursued.

The spectrum of hydrogen obtained by the passage of the induction current through vacuum tubes was first examined by Plucker in the year 1858, and described by him as follows:†—

Hydrogen gave a comparatively simple spectrum, in which five bands of about the same width are most prominent; a violet band A at the limit of the spectrum. Three bands in the green, B forms the limit towards the violet, and D towards the yellow. C is double the distance from D than from B. The fifth band E is in the yellow. The most intense of the three green bands is D, the colour of which is already yellowish. Next in intensity is C, and then comes B. The red is very prominent and extends over a wide space; a well-defined broad black line situated near its external limit; another broad black line separates it from the yellow band E.

The description of this spectrum agrees in its general features with the continuous spectrum described by Wüllner, and it is therefore important that already in August of the same year Plücker‡ publishes a second paper, in which he says that the above experiments had only been preliminary ones, and that the hydrogen had not been pure. Pure hydrogen, he says, shows only three lines, a red one, a greenish blue one, and a violet one which is less bright. Plücker makes repeatedly the remark that the purer the hydrogen the more concentrated is its light § on the above three lines, and he expresses the opinion that the bands seen in impure hydrogen are due to air. Later on, ‖ when he was looking out for different spectra of the same gas, he found that this spectrum cannot be due to air, and must therefore be a second spectrum of hydrogen. It must, however, be remarked, that Plücker never found this spectrum so well developed as Wüllner, and this cannot be due to the fact that he did not examine it under the same circumstances, for he describes ¶ the change which the spectrum of hydrogen gas undergoes when the pressure is increased, and only mentions the expansion of the lines. Although the Leyden jar was introduced in these experiments, and the second spectrum would not therefore have appeared, it is not to be expected that such a widely different spectrum which changes entirely the colour of the spark should have escaped the notice of such an observer as Plücker when he was looking out for different spectra. The most important recent contribution to the history of this spectrum has been made

by Angström,* who found that when the spark passing through a hydrogen vacuum giving the band spectrum, and at the same time, the three well.known lines (as is generally the case), is examined in a revolving mirror, two different images are obtained corresponding to the two spectra. Two different discharges must therefore take place in the tube, one of very short duration, which corresponds to the line-spectrum, and one which lasts much longer, and corresponds to the band spectrum. As this spectrum is, moreover, according to him, identical with the spectrum of acetylene obtained by Berthelot, Angström thinks himself justified in ascribing this band spectrum to acetylene.

My own experiments lead to the confirmation of Angström's supposition that the second spectrum of hydrogen is due to hydrocarbon. Generally two distinct causes, which we shall consider separately may introduce a hydrocarbon into the vacuum tube :—

1. The gas passing through india-rubber tubes will carry with it small pieces of india-rubber.

2. All the tubes are more or less greasy, and it is almost impossible to remove this greasiness entirely.

These two causes are sufficient to produce such effects as are observed by Plücker, but the spectrum obtained in consequence of these impurities will necessarily vary so much with different tubes, that the presence of impurities will soon be recognised as it was by Plücker. Such constant effects as those observed by Wüllner must, however, be due to a more constant cause, and we have not to look out long for such a cause. When Wüllner examined the spectrum of oxygen, he discovered two new spectra, and even before Angström had expressed his doubts as to the correctness of these spectra, Wüllner had found out that they were due to carbon or carbon compound, which were introduced into his vacuum tubes by the greased stop-cocks by which they were shut. Thus by the results obtained with oxygen it is proved that carbon compounds were introduced into his vacuum tubes, and we have only to consider whether these carbon compounds, which were sufficient to change entirely the spectrum of oxygen, are sufficient to make themselves perceptible in hydrogen. But Berthelot has shown that benzole mixed with a large quantity of hydrogen gives a spectrum of bands, and that acetylene when mixed with a sufficient quantity of hydrogen is not decomposed by the electric current.

It seems at first sight improbable that a gas passing through an india-rubber tube should carry with it a sufficient quantity of solid particles to change the appearance of the spectrum ; but Tyndall,† in his experiments on actinic clouds, mentions the effect produced by an india-rubber joint through which the gas subjected to examination had passed. The quantity of matter carried away by a current of air passing through an india-rubber tubing is not so small as might at first sight appear. The following experiment shows this. Take a piece of such tubing, and fix a small piece of glass tube to one of its ends. If the air is now sucked in through the glass tube the taste of india-rubber will make itself at once perceptible, although the mouth is not in direct contact with it. When I examined the spectrum of hydrogen, which had thus passed through an india-rubber tubing, the spectrum did not vary sensibly under different pressures. The colour of the spark was whitish, even under a pressure of 2 mm. The spectrum, evidently the band spectrum, described by Wüllner, did never show itself so well developed as is described by him, and resembled much more the spectrum as observed by Plücker. In different vacuum tubes the spectrum had the same appearance ; and I concluded therefore that the cause of impurity must lie in the tubing, which was therefore removed.

The vacuum tube was now fitted into the receiver containing the hydrogen, and sealed off at one end as soon as filled with the gas. This way of proceeding, however, presented many practical difficulties, and generally, therefore, another way was adopted. A drop of water was introduced in the vacuum tube, and after the vacuum had been made, the water was boiled, and the tube exhausted again, this being repeated until all the water had been evaporated and the air driven out. The spark decomposed the vapour, and the spectrum of hydrogen was thus obtained. Its appearance now varied much with the different vacuum tubes. One of them was carefully washed, first with sulphuric acid and then with distilled water. The spectrum obtained in this tube showed the continuous spectrum only so faintly that I think it would have escaped the notice of any observer who was not looking out for it. The influence on the colour of the spark was, however, much greater. The spark did not show that saturated red colour characteristic of hydrogen, but it was always somewhat whitish. This, however, is the nearest approach to the pure spectrum of lines which I could obtain. It is thus rendered at least highly probable that organic impurities are the cause of the observed spectrum of bands, and Angström's supposition that it is acetylene is very plausible. Wüllner examining the spectrum of acetylene, says that it is identical in the red and yellow with the second spectrum of hydrogen, but that it differs from it in the green and blue. He concludes that the acetylene is decomposed into hydrogen and carbon, that the hydrogen shows its yellow bands, and the carbon its green and blue bands. Now these green and blue bands are not at all due to carbon, but to carbonic acid, as stated by Wüllner himself, and only prove that carbonic acid was present. That the acetylene was decomposed is a supposition, which is in contradiction to Berthelot's results, mentioned above.

In order to ascertain whether the last traces of air remaining in the tube might not have an influence upon the spectrum of hydrogen, I tried to obtain the spectrum of ammonia, for this is the only compound which might possibly be formed, as aqueous vapour is always decomposed. Plucker says that ammonia also is decomposed into its elements, but I succeeded in obtaining its spectrum by the following arrangement :—A few drops of a strong solution of ammonia in water are introduced into the vacuum tubes, and the induction current is allowed to pass while the pump is being worked. Thus a vacuum is obtained sufficient to allow the passsage of the current, and at the same time the gas is constantly renewed. The spectrum of ammonia is very remarkable ; while nitrogen shows a spectrum of more than 70 lines, and the four lines of hydrogen are distributed over the whole spectrum ; a combination of these two gases when luminous gives out a perfectly homogeneous light. The colour of the spark is greenish yellow, and when examined by the spectroscope, it shows a broad band of exactly the same colour. The red and blue part of the spectrum is completely dark, while in the yellow and some parts of the green a faint continuous spectrum is seen. The wave-length of this band was determined by interpolation to be 5,686 to 5,627 x^{th} metres, and the band is therefore placed at the more refrangible end of the strong terrestrial absorption band called by Brewster δ. The spectrum of ammonia bears a strong resemblance to the spectrum of sodium, when at a high temperature its lines begin to widen.

Wüllner has discovered a third spectrum of hydrogen, which is a spectrum of lines, and appears under the lowest pressure which can be obtained. Not having a Sprengel's pump at my disposal, I could, unfortunately, not obtain this spectrum, and I merely mention here that it appears, from various remarks of Plücker, that he examined hydrogen under the precise circumstances under which this third spectrum ought to have come out. Thus, he says,* that hydrogen allows the induction spark to pass at a lower pressure than any other gas. At another place he says that when a tube filled with dry air is exhausted as far as possible, the lines of *hydrogen* and silicium appear, the lines of hydrogen being due to the hygroscopic condition of the glass. Angström believes this spectrum of lines to be due to sulphur. This is in harmony with the fact that small pieces of caoutchouc (containing sulphur) form part of the sources of error ; but Wüllner has shown that although all the lines of his spectrum of hydrogen seem to coincide with strong lines of sulphur, some strong lines of sulphur do not appear, and according to Wullner, the spectrum has in its general character no resemblance to that of sulphur. At any rate, it seems improbable that if this spectrum is really due to hydrogen, it should have escaped the notice of Plücker.

If we inquire now what bearing these results have on the general question of double spectra, we must remark that two different subjects have been mixed together. We have first bodies which are gases at the ordinary temperature, such as nitrogen, hydrogen, oxygen. The question, whether these bodies can give different spectra under different circumstances, must, I think, be answered in the negative. This was the opinion expressed by Angström from the beginning ; and although this physicist clearly obtained all the results mentioned by Plücker and Wüllner, they seem always to have left the conviction in his mind, that they are due to impurities. But there are other bodies, such as iodine, sulphur, and bromine. The existence of two spectra, in the case of iodine and sulphur, seems to be satisfactorily established by the researches of Mr. Salet. One of the

* Phil Trans. 1865.

† Tyndall, " Radiant Heat," p. 341.

* Phil. Trans. 1865.

spectra is the reversal of the absorption bands of the vapour of these bodies; while the others are spectra of lines. In the coloured vapours, the molecular constitution must be much more complex than in gases, and it is, therefore, not astonishing that such a coloured vapour should exert an absorptive influence resembling more that of a liquid than of a gaseous body. It would, therefore, show absorption bands, and if luminous, it will not show a spectrum of lines, but a spectrum of bands. At a higher temperature, however, when the vapour becomes a gas, the spectrum may change to one of lines. As a fact bearing upon the subject, I may mention the discovery made by Kundt, that nitrogen tetroxide gives the same absorption bands, whether in the form of a liquid, or in that of a vapour.

Preliminary Report of the Committee on Inverse Wave-Lengths.

The reference of spectral lines to a standard scale of wave-numbers, instead of to a scale of wave-lengths in air of a given pressure and temperature, or to any of the other scales in use, has very marked advantages. The scale of wave-numbers furnishes to the theoretical inquirer the ratios between wave-lengths,—which are what he chiefly wants—in the simplest and most conspicuous form; since a series of rays, of which the wave-lengths are in geometrical proportion, will be represented by equidistant lines upon the map. Accordingly the committee decided on reducing to wave-numbers all the wave-lengths, whether of solar lines or of the rays of incandescent vapours, which have been determined with sufficient precision. Mr. C. E. Barton has offered his services gratuitously for making the necessary reductions, and has made considerable progress with the solar spectrum. A specimen of the catalogue of solar lines was appended to this report, containing the lines from E to *b*. It is intended that this catalogue shall contain the most useful information available—namely, references to the position of each line on Kirchhoff's or Angström's maps, details of the processes by which the standard wave-numbers have been deduced, and indications of the intensity, width, and origin of each ray whenever these have been determined. The rays will, moreover, be bracketed into the groups that strike the eye in looking at the spectrum, and a number will be assigned to each group which will sufficiently indicate its position on the standard scale. It is estimated that the two catalogues—namely, the catalogue of the principal lines of the solar spectrum, and the catalogue of rays of incandescent vapours, will cost about 60*l*. The committee think that they could render the second catalogue more perfect if they were in a position to employ a competent person to revise and extend the determination of the rays of incandescent vapours, and they therefore suggest that this revision be made a part of their functions, and that an addition of 50*l*. be made to the grant for this purpose. This would increase the sum to be granted this year to 150*l*. The committee accordingly recommend that they be reappointed, and that this sum be placed at their disposal, in addition to the balance at present in their hands.

SECTION B—CHEMICAL SCIENCE

Thursday, Aug. 15.—At the close of the President's address, Dr. Wright read the *Report of the Committee for Investigating the Chemical Constitution and Optical Properties of the Essential Oils used for Perfumes*, which was followed by a short discussion, in which Mr. Hanbury pointed out the necessity of paying particular attention to the characters of the samples of the various oils taken for experiment, and he instanced several essential oils classed under the same name but of widely different origin and possessing wholly different properties. He was under the impression that sufficient care had not been taken in the selection of the samples with which experiments had hitherto been worked.

Prof. Mallett, of Virginia, U.S., exhibited some specimens of fused metallic arsenic which he had prepared by fusing the metal under great pressure. The fact that arsenic can thus be fused has already been determined by Landolt.

Prof. Mallett also gave an interesting *résumé* of his experiments on the nature of the gases occluded by meteoric iron. The method employed by him was essentially that of Graham, the meteorite being heated in a vacuum and the evolved gases removed by the Sprengel pump. The nature of the iron remaining was carefully examined, and it appeared that the heat modified the metal in a remarkable manner, principally as regards its capability of being forged. The original meteorite could be readily forged and beaten out into a tolerably perfect blade for a paper-knife, but on strongly heating the iron so as to drive off the occluded gases (principally hydrogen, carbonic acid, and carbonic oxide) it became cold-short, and could not be forged even with extreme care. The cause of the remarkable alteration in the tenacity of the metal gave rise to some discussion, from which it generally appeared that it was due to an alteration of the schreiberite in the meteorite.

Mr. W. L. Carpenter gave a short account of the methods employed in the recent dredging operations for collecting deep sea water. In the discussion which followed Prof. Crum-Brown described the method to be followed in the forthcoming expedition. The apparatus had been proved to work exceedingly well in shallow water, but it remained to be seen how far it could be used in the open ocean and under great pressure.

Prof. Thorpe exhibited a modification of the filter-pump recently described by Mendelejeff. It acts upon the principle of the hydraulic ram, and by means of a fall of water of less than a yard a vacuum of nearly 700' can be readily obtained. The modification consisted in the nature of the valve employed and in the method of determining the degree of exhaustion. The instrument has the advantage of portability and readiness of construction over the older form of Bunsen (which requires a fall of water upwards of 30 ft.), and is likely to come into general use.

Dr. Russell read a paper prepared by Dr. Moffatt on the tube ozonometer, which elicited some discussion as to the value of ozonometric observations conducted by means of iodide of potassium papers. The use of such papers was generally condemned by the members of the Section; but the meeting arrived at no definite conclusion respecting any other way in which the liberation of iodine may be utilised as a measure of ozone.

Mr. C. J. Woodward exhibited and described a very simple and cheap modification of Hofmann's Apparatus for the Electrolysis of Water.

Friday, Aug. 16.—Prof. G. C. Foster presented the *Report of the Committee appointed to investigate Siemen's Electrical Pyrometer*. The Committee had principally confined themselves to the determination of the constancy of the resistance of the platinum coil at high temperatures. Before the instrument can give perfectly concordant results it is absolutely necessary that the coil should be heated and cooled a great number of times. As some further alteration in the instrument was contemplated, the Committee recommended that a further application should be made to the Association in order to continue the investigations. In the discussion which followed, Mr. Dewar suggested the employment of a spectroscope with a compound prism of quartz and calc spar in the measurement of high temperatures.

Prof. Williamson read the *Report of the Committee for Superintending the Monthly Report on the Progress of Chemical Science*. The meeting cordially testified to its sense of the value of the Chemical Society's work in furthering the spread of chemical knowledge by the publication of its admirable series of abstracts of chemical memoirs published in the leading journals. Dr. Williamson assured the Section that the movement was rapidly becoming self-supporting, and that in a few years it would be no longer necessary to request the Association to supplement the funds at the disposal of the Chemical Society for the purpose.

Mr. Dewar described some experiments on the determination of the specific heat of carbon at high temperatures. The method of calorimetric measurement differed in no essential particulars from that usually employed. The temperatures employed were those of boiling zinc (1040°) and of the oxyhydrogen blowpipe which Mr. Dewar, by the method of Poullet and Deville and Troost, found to be about 2200° C. Between 0–1030 the mean specific heat of carbon was found to be 0·32, between 0–2000 upwards of 0·4. Mr. Dewar explained the variation in the temperature of the oxyhydrogen flame as obtained by Bunsen himself by the difference of pressure under which the combination of the two gases occurred in the two sets of experiments. His results on the specific heat of carbon in the main agree with those recently published by Weber. Starting from the difference in the heat of combination between carbon and oxygen to form respectively carbon dioxide, and monoxide, and making a certain assumption for the latent heat of carbon, Mr. Dewar arrives at the conclusion that the boiling point of carbon cannot possibly exceed 8000° C, and in all probability is somewhat near 7000° C.

Dr. Gladstone read a paper, prepared in conjunction with Mr. Tribe, *On the Mutual Helpfulness of Chemical Affinity, Heat, and Electricity in Producing the Decomposition of Water.* Dr. Gladstone commenced by describing the action of various metals upon water: some are able to eliminate the hydrogen from water, whilst others, and by far the larger number, are unable to do so. Zinc, if perfectly free from foreign metals, is without action on water; but if it be brought into contact with another metal even more stable in regard to its action on water, the electrical tension *plus* the chemical tension upsets the equilibrium between the atoms in the molecule, and hydrogen is eliminated. The effect of varying the distance between the plates was carefully measured, and it was found that the chemical action increased slowly up to a certain point, after which the action rapidly increases as the metals are brought into closer contact. Copper deposited on zinc foil is a very effective combination, and its action is materially accelerated by the meeting; thus, at 2° C. only 1 cb c of hydrogen was evolved per hour; 62 cbc were illuminated per hour at 55°, whereas at 93° C. as much as 528 cbc were produced. With magnesium and copper the action is even more marked. These re-actions afford methods of preparing exceedingly pure hydrogen, and they will doubtless be found useful in many operations of reduction.

Mr. Weldon described his process for the manufacture of chlorine by means of manganite of magnesium. The manganite is first produced by neutralising an acid solution of manganese chloride with Greek stone. By treatment with hydrochloric acid the manganite yields chlorine and magnesium and manganese chlorides. The solution is run out of the steel into an iron pot, and is afterwards boiled down until it reaches a temperature above 300° F., when it is run into a blind furnace and evaporated to dryness. On heating the dried residue chlorine and hydrochloric acid are evolved, and the manganite of magnesium is reproduced.

SECTION C.—GEOLOGY

The first paper was that by Prof. E. Hull, *On the Raised Beach of the North-east of Ireland.* All along the eastern coast of Ireland, from Dublin Bay northwards, there are to be found at intervals distinct evidence that the coast has been raised in recent times. This evidence is divisible into two kinds; first, the occurrence of a narrow fringe of varying elevation, forming a terrace extending for some distance inland from the coast, and composed of stratified sands and gravel, containing marine shells belonging to species now inhabiting the Irish Sea; and secondly, the existence of old sea-worn cliffs, forming the inland margin of these terraces, which are now beyond the reach of the highest tides. In the north of Ireland these cliffs are penetrated by caves, which have yielded bones of animals, some of which are extinct in that part of the country, while the gravels of the old beach contain amongst the sea shells worked flints in considerable quantity in County Antrim, which prove the elevation of the coast to have taken place since the human period.

The height attained by the beach above the present sea level is about 8 ft. in the south, but it rises gradually northwards, and there attains a height of 20 ft. The author considered this to be of the same age as the twenty-five feet beach of the west coast of Scotland, which falls somewhat in level towards the Solway; southwards this decrease in level continues, till the evidences of a raised beach almost disappear towards the estuary of the Mersey. The identity, therefore, of the phenomena on both shores is evident, and is a matter of some interest in the physical geology of these islands.

In the discussion which followed, Prof. Harkness, Mr. Pengelly, and the Rev. W. H. Crosskey took part, the last speaker insisting strongly upon the necessity of following these accumulations inland, and not confining our observations to the more attractive sections along the coast.

Mr. Jas. Howell then described the *Super-Cretaceous Formations of the Neighbourhood of Brighton*, in which the various deposits of the district were minutely described. Attention was called to the outlines of Tertiary beds on Furze Hill, and to the still smaller patches scattered over the Downs. The author, during the numerous excavations made in draining the town of Brighton, had observed that wherever brick-earth occurs with "Coombe rock" it is always the newer deposit of the two. From the deposits met with in the lower parts of the town, Mr. Howell concluded that the Brighton valley, at least as far up as the London and Lewes Road, was once covered by the tides.

Mr. W. Topley followed with an account of the *Sub-Wealden Exploration.* He first gave a brief description of the Weald and of the beds therein exposed, dwelling more particularly upon the lowest known rocks, the Ashburnham beds, in which the boring commences. He then described the older rocks as exposed in and around the coal-fields of Bristol and South Wales on the west, and the Belgian coal-fields and the Lower Boulonnais on the east. These rocks, it was stated, would certainly pass beneath the Weald, and along with them would probably occur workable coal measures, but the exact position of these last is a great uncertainty. The thickness of rock at the bore-hole, before reaching the Palæozoic beds, might be only 700ft. or it might amount to 1,600ft. The author drew special attention to the parts taken by Mr. Godwin-Austen and Mr. Henry Willett in this exploration. To the philosophic papers of the former we owe our knowledge of the underground range of the older rocks, and to the energy and perseverance of the latter is due the fact that speculation on this subject is about to give rise to actual experiment.

Mr. Godwin-Austen traced the area occupied by the old coal forests of Western Europe, and described the means by which this once united area had become broken up into separate basins. The axis of Artois and the coal-fields along its line were then more particularly noticed. He stated that carboniferous limestone had been found at a small depth in the Pays de Bray, beneath Kimmeridge clay, the whole of the lower members of the oolite series being there absent. In the area between the Pays de Bray and the Boulonnais, and under the Weald on the west of that, it was possible that coal-measures might be preserved. He protested against the sub-Wealden exploration being represented as a "search for coal;" its only object was to explore the rocks underlying the Weald.

Mr. Henry Willett gave an account of the origin and progress of the undertaking, stating that it was planned in honour of the first visit of the British Association to Sussex. He repeated Mr. Godwin-Austen's protest as to this being a search for coal, and said that this bore-hole was only the first of a series which would ultimately be necessary to complete our knowledge of the range of the Palæozoic rocks. He added that the subscriptions to the fund now amounted to 1,900*l*.

Mr. Harry Seeley entered at some length into his reasons for disbelieving that the coal-measures ever covered this area; but he, in common with other geologists, was very glad of the experiment now being made, as its results would have a very high scientific value, although commercially it would, he believed, prove a failure.

The remainder of the time was occupied by the reading of Mr. G. A. Lebour's paper *On the Geological Distribution of Goitre in England.* The author had by inquiries and correspondence collected a great amount of information upon the distribution of this disease, and his facts are of the more importance, as no information can be obtained upon the subject from Government statistical returns. He traced in detail the range of goitre over the various formations, and showed that the accepted beliefs on this subject were frequently erroneous. Thus, as regards magnesian limestone, which is commonly believed to be a very goitriferous rock, he showed that goitre was by no means so common there as in some other formations. Again, whilst on some regions occupied by carboniferous limestone the disease abounds, in others, where the general character of the rock is apparently the same, it is entirely absent. In searching for a general cause regulating the distribution of goitre, the author rejected as insufficient that generally given—the hardness of water. He showed it to be more probable that metallic impurities in the water were the cause. The carboniferous limestone was characterised by goitre almost in exact proportion to the metalliferous nature of the rock. Districts where ferruginous water occurs very commonly have goitre, particularly where the iron is derived from the decomposition of iron pyrites.

Friday, August 16.—The proceedings of this section opened with the reading by Mr. Pengelly of his *Report on Kent's Cavern, Torquay.* Specimens of bones and flint implements during the preceding year were exhibited to the meeting. Mr. Pengelly afterwards read a note *On the Occurrence of Machairodus latidens at Kent's Cavern.* This animal had been found there many years ago by Mr. M'Henry; but doubts had often been expressed as to the accuracy of this observation, and it was highly satisfactory to find that recent researches had confirmed M'Henry's discovery.

Mr. Evans made some remarks upon the flint implements found during the past year.

Prof. A. Gaudry described the various species of Machairodus, and Mr. W. Boyd Dawkins remarked upon the range of this animal, stating that the genus certainly occurred in the forest bed of Norfolk, although the species there was doubtful.

Dr. Carpenter followed with his paper *On the Temperature and other Physical Conditions of Inland Seas, considered in reference to Geology*. The general results obtained by recent deep-sea soundings were first described, the author afterwards passing to the special subject of the paper. Where seas were shut off by a narrow and comparatively shallow barrier from the great ocean it was found that the lowest bottom temperature of such seas was controlled by the lowest winter temperature of the surface. The bottom temperature of the Red Sea is about 71°, and since it appears that the distribution of reef-building corals depends not so much upon depth as upon temperature, we may expect to find them living at much greater depths in the Red Sea than anywhere else in the world. The great rivers flowing into the Mediterranean bring down a great quantity of organic matter, and the decomposition of this carries off much of the oxygen from the deeper water. Probably to this fact is owing the scarcity of life at great depths within that sea.

The author pointed out the bearing of these and similar facts upon geological speculation, and in these remarks he was followed by Prof. Phillips, who spoke of the great light which Dr. Carpenter's researches were throwing upon geology, explaining as they did how great areas of sea-bottom might be almost destitute of life, just as we find great deposits of rock to be.

SECTION D—DEPARTMENT OF ZOOLOGY AND BOTANY

Report of the Committee appointed for the purpose of promoting the Foundation of Zoological Stations in different parts of the world.

The Committee report that, as stated in the Report of the last meeting, the Zoological Station at Naples will be ready and in working order at the beginning of January 1873, the progress of the construction being such as to enable Dr. Dohrn to make this assertion.

This undertaking has received much official and private assistance, not only from public authorities, but in a very high degree from private persons. The Committee feel obliged to acknowledge especially the extraordinary services rendered by Mr. W. A. Lloyd of the Crystal Palace Aquarium in giving every assistance to Dr. Dohrn in so far as technical difficulties are concerned.

Special care has been taken to secure donations to the library of the Station. The eminent firm of Engelmann in Leipsig has presented all its works on Biology not previously possessed by Dr. Dohrn. Veweg in Brunswick has also sent all his publications on Biology. Theodor Fischer in Cassel has done the same. Important donations are promised by Dr. Alexander Agassiz of Cambridge, Mass., comprehending the publications both of his father and himself.

To secure the development of the library on a greater scale, it will be necessary to make general applications. For this purpose Dr. Dohrn, assisted by several of the greatest German publishing firms, is preparing an appeal to all German publishers, and he hopes also to succeed with a similar demand in Italy. The Committee hope that the British Association will lend its moral support to a similar demand in this country, not only by granting a complete set of its own publications, but by recommending a similar act to other Scientific Bodies and private persons.

The Committee are further glad to announce that some steam-navigation companies are prepared to grant a free passage to the naturalists and free transport for the goods to and from the station. As transactions are still pending between these Companies and Dr. Dohrn, the latter does not think it desirable to publish details on this point, or to mention the names of the Companies in question.

Dr. Dohrn contemplates a new step for the purpose of returning a larger income for the Naples Station. He is about to offer to several Governments, Universities, and Scientific Bodies, working tables in the laboratory of the Station for a certain annual sum. This sum would confer on the subscribing Government, University, or Society, the right of appointing a naturalist, who, on presenting a certificate to the administration of the Station, would be furnished with a working table, and admitted to a participation in all the very extensive advantages of the Station.

The Committee think well earnestly to advocate this new step of the administration of the Naples Station, the more as it lessens the burden of the single naturalist, enabling even such as are destitute of means to profit by the manifold advantages of the Station, while it secures a fixed income to the Station which would be employed in improving the technical and other means of investigation.

Mr. Lankester gave some additional account of the Zoological Station about to be established by Dr. Dohrn at Naples. During the present year he had personally had the opportunity of seeing the arrangements which were in progress.

"On the narrow strip of coast which separates the park of the Villa Reale from the sea, a large stone building is at present being erected at Naples, quietly and almost unnoticed—at least the Neapolitan press has paid no attention to it. The strength of the foundations—it has taken three months to lay them—shows that they are intended for an edifice of considerable size and durability; and on making inquiries I have learnt that this is the Zoological Station, which has been occasionally mentioned by Italian, German, and English journals during the last few months. It has been organised and is being built by a young German naturalist, Dr. Anton Dohrn, of Stettin, who, until a few years ago, was a *privat docent* at the University of Jena. He has paid nearly the whole of the expenses, which amount to about 50,000 thalers (7,500*l.*), out of his own pocket, the only assistance he has received having come from a few personal friends, who have lent several thousands of thalers for the purpose. The following is a short sketch of his plan:—The ground floor of the building, which covers an area of almost 8000 square feet, contains a great aquarium, which will be opened to the public. Dr. Dohrn hopes that the money thus obtained will not only suffice for all the expenses of the aquarium, but also afford a surplus to be employed in covering a part of the requirements of the upper story, which is to be exclusively devoted to scientific purposes. Besides the officials and servants employed in the aquarium, several young zoologists will be attached to the Station, and receive a regular salary from the director, Dr. Dohrn. Thus, a number of new positions will be opened up for young scientific men. But this is not all. As the only duty of these zoologists will be to devote themselves to certain branches of scientific work, and their exertions will be carefully directed and organised, as has long been the case in astronomical and meteorological observatories, there is every reason to hope that scientific research will be greatly facilitated and advanced by their labours. In the upper story of the Zoological Station laboratories will also be prepared for the use of naturalists coming from other parts of Italy and from abroad. For this purpose a large scientific library will be founded, Dr. Dohrn's very considerable private collection serving as a nucleus, and about twelve tables, fully furnished with the necessary appurtenances, established. Each of the latter will be provided with a number of tanks supplied with a constant stream of sea-water. Sea-fishing and dredging will be conducted on an extensive scale by means of several boats, to which, if the necessary means are forthcoming, a small steam-yacht will be added. The animals taken will be given to the zoologists for scientific treatment. It is more than doubtful whether all these rich and expensive conveniences can be furnished to zoological visitors without any pecuniary compensation; but I hear that Dr. Dohrn has drawn up a plan which will enable even naturalists of limited means to enjoy the advantages of the Station. He proposes to offer one or more tables to various governments and scientific societies for a fixed annual sum. These tables, and all the scientific resources of the Station, will at once be placed at the disposal of any naturalist who brings a certificate from the government, university, or scientific body to which the table has been let. This plan, among its many other advantages, seems to be a successful attempt to solve the difficult question as to how it is possible to unite a complete self-administration on the part of scientific bodies with the reception of pecuniary assistance from their governments.

"Dr. Dohrn speaks in the most grateful manner of the assistance rendered him by the German authorities in Italy, especially by Mr. Stolte, the consul-general at Naples, while at the same time he warmly acknowledges the interest in his undertaking displayed by the government of Italy, more particularly Signor Correnti and Signor Sella, the late and the present Ministers of Public Instruction. The difficulties in the way of the execution of his plan were neither few nor small, as may be gathered from the fact that, in spite of the readiness displayed by the municipal authorities of Naples, more than two years elapsed before a definitive contract could be concluded between the town and Dr

Dohrn with respect to the cession of a suitable site for the building."

Report of the "Close Time" Committee.

The Committee re-appointed at Edinburgh, for the purpose of continuing the investigation on the desirability of establishing a "Close Time," for the preservation of indigenous animals, report as follows:—

Believing the time had come for advantageously urging the Legislature to take further action whereby the object for which your Committee was appointed might be promoted, your Committee, after due consideration, prepared a bill, intituled an Act for the Protection of Wild Fowl, which being entrusted to the care of Mr. Andrew Johnston, M.P., was by him, Colonel Tomline, M.P., and Mr. Brown, M.P., brought into the House of Commons on February 15, and read a first time.

This bill was based on the "Sea-Birds Preservation Act of 1869," and *mutatis mutandis* only, strictly followed the provisions of this Act, which experience has shown to have fully effected the object for which it was passed, and to have given very general satisfaction to the country at large.

On the motion for the second reading of the bill in the House of Commons, June 12, the Hon. Auberon Herbert, M.P., proposed as an amendment that it was "desirable to provide for the protection of all wild birds during the breeding season;" but this amendment, which would have been fatal to the bill, was withdrawn, the bill was read a second time and ordered to be committed, June 21.

In the debate in the House of Commons on the notice for going into Committee, Mr. Herbert moved, according to notice, "That it be an instruction to the Committee that they have power to extend the protection, given under the bill to Wild fowl during the breeding season, to other wild birds." The House divided: Ayes 20, Noes 15; and thereupon Mr. Herbert moved a number of other amendments of which he had given notice, and these being accepted by the House, the bill, instead of being the moderate measure contemplated by your Committee, became one of general and indefinite scope.

By this means the fate of the bill, which had hitherto met with no serious opposition, was rendered very uncertain; and notice was given of a motion to throw it out; but on the report being taken, the bill on Mr. Johnston's proposal, was referred to a Select Committee, by whom it was still further modified; the objections urged against its sweeping clauses being overcome by limiting its effects to certain kinds of birds named in a Schedule, while the penalties for its infringement were diminished. In this form it went back to the House of Commons, and with a few other alterations finally passed that House, and was sent to the House of Lords.

In the Upper House, charge of the bill was taken by the Earl of Malmesbury, and, some fault being found with it, its provisions were further altered in committee, a person convicted of a first offence being rendered liable to a reprimand and the payment of costs and summons only. Thus modified it was returned to the House of Commons, and has since received Her Majesty's assent.

Your Committee cannot look with unmixed favour on this measure. It appears to them to attempt to do too much, and not to provide effectual means of doing it. In their former Reports they have hinted at, if not expressed, the difficulty or impossibility of passing any general measure, which without being oppressive to any class of persons, should be adequate to the purpose. Further consideration has strengthened their opinion on this point. They fear the New Act, though far from a general measure, will be a very inefficient check to the destruction of those birds, which, from their yearly decreasing numbers, most require protection, its restraining power having been weakened for the sake of protecting a number of birds which do not require protection at all. Your Committee have never succeeded in obtaining any satisfactory evidence, much less any convincing proof, that the numbers of small birds are generally decreasing in this country. On the contrary they believe that from various causes, many if not most species of small birds are actually on the increase. They are therefore of opinion that an Act of Parliament proposing to promote their preservation is a piece of mistaken legislation, and is mischievous in its effect, since it diverts public attention from those species which through neglect, indifference, custom, cupidity, or prejudice, are suffering a persecution that will in a few years ensure their complete extermination. At the same time your Committee are glad to state that such protection as is afforded by the new Act will be extended to the particular group of birds which in former Reports they have shown to require it most—all the wild fowl named in the bill prepared by your Committee, having being included in the schedule of the Act. It is also gratifying to your Committee to find that the principle of a "Close Time" for all birds has been admitted by the House of Commons, though the application of that principle may at present be inexpedient. Your Committee therefore trust that the Act will not be otherwise than beneficial in its results, and though greatly indebted to many noblemen and gentlemen for the assistance they have rendered, your Committee cannot refrain from especially thanking Mr. Andrew Johnston, for the skill and patience he has shown in the conduct of the bill introduced.

Your Committee respectfully suggest that they may be re-appointed.

Fourth Report on the Fauna of South Devon, by C. Spence Bate.

Attention had been principally directed to the development and habits of animals which had fallen under observation. This had been facilitated by the establishment at Plymouth of a marine pond as store for the Crystal Palace Aquarium. The observations had already proved interesting, and would become more so as the conditions of the pond became better adapted to Deep Sea species. It is formed out of a deep gulley in the limestone, partly extending back into a cave. At the entrance it is 11 ft. wide, and in other parts more than double; when the water is highest, its length is upwards of eighty feet. With the replacement of the original *Fucus* by green algæ, the water has become pellucid and clear. A list was given of the fish taken on the coast since the last report. Most of these have done well in the pond, the exceptions being fish of erratic habits, such as the mackerel. These, after restlessly roaming in search of an outlet, succumbed and died. Other fish thrive apparently unconscious of their confinement. The Blue Wrasse (*Labrus mixtus*) had exhibited marked sexual selection, a fact which had also been observed by Mr. Lloyd at Hamburgh. During the breeding time the male selects one out of many females, and afterwards regularly accompanies her. It had also been ascertained that the Blue Wrasse and the Spotted Wrasse were the same species. The male in confinement at Plymouth appears to be losing his fine colouration and approximating to that of the female; it seems, therefore, probable that the blue colour is more or less assumed at the breeding season.

With regard to the Crustacea, there are two subjects of interest. The first is the perceptible decrease in the numbers of the edible species, the decrease being more perceptible in the littoral than in the deep sea species. This arises from the custom of destroying the females as well as the males at all seasons of the year, and also from the preference given to the lobster for culinary purposes when laden with spawn. In the case of the crab (*Cancer pagurus*) there is not even this excuse. The marketable value of the female is at least one fifth that of the male. This arises from the smaller size, especially of the claws. Captured in greater numbers, they are wantonly destroyed, being hawked about the streets for a few pence. The capture of the lobster, he thought, should be interdicted from February until May, and that of the female crab altogether. To the assertion that the lobster and crab are so prolific as to render the destruction unimportant, there was the obvious reply, that in all those forms of life where the ova are most abundant, the development of the individuals is least quantitatively. In the case of the lobster, no one has ever seen that stage in its life which unites the animal as we know it with that which we have seen when it quits the egg, and, except the common littoral crab (*Carcinus mænas*), this is true of all the higher crustacea. Mr. Lloyd, of Hamburgh, has noticed that the male or soldier crab (*Pagurus*) in the spring takes hold of the shell containing the female, and carries it about for weeks together, and does not intercept its food as it would if a male were contained inside. He had found that crustacea might be preserved in a very superior way by keeping them in glycerine, and then drying them. Specimens preserved in this way two or three years ago were as flexible as if fresh. The soft parts should, if possible, be removed. He hoped to preserve fish in the same way. (Mr. Spence Bate subsequently remarked that after five or six years the structure of specimens preserved in glycerine appeared to become rotten. He suggested, therefore, the previous admixture with the glycerine of one-eighth of spirit of wine.)

Among the molluscs many species of *Aledone* had been captured. This was generally supposed to be a rare species, but

Octopus vulgaris proves to be the more difficult to obtain. Two specimens of *Sepia officinalis* were placed in the pond on the 8th of June, 1871. On the 12th July the female died, and was found to contain a large quantity of ova. Steps have been taken to have constructed in the cave behind the pond a case with a glass front for watching the habits of animals. The temperature of the water in the pond is several degrees below that in the tanks at the Crystal Palace.

The Mollusca of Europe compared with those of Eastern North America, by J. Gwyn Jeffreys, F.R.S.

After mentioning that he had dredged last autumn on the coast of New England in a steamer provided by the Government of the United States, and that he had inspected all the principal collections of Mollusca made in Eastern North America, the author compared the Mollusca of Europe with those of Massachusetts. He estimated the former to contain about 1000 species (viz. 200 land and fresh water, and 800 marine), and the latter to contain about 400 species (viz. 110 land and freshwater, and 290 marine); and he took Mr. Binney's edition of the late Professor Gould's Report on the Mollusca of Massachusetts as the standard of comparisons. That work gives 407 species, of which Mr. Jeffreys considered 40 to be varieties, leaving 367 apparently distinct species. About thirty species may be added to this number in consequence of the recent researches of Prof. Verrill and Mr. Whiteaves on the coast of New England and the Gulf of St. Lawrence. He identified 173 out of the 367 Massachusetts species as European, viz. land and freshwater 39 (out of 110), and marine 134 (out of 257), the proportion in the former case being 28 per cent. and in the latter 52 per cent.; and he produced tabulated lists of the species in support of his statement. He proposed to account for the distribution of the North American Mollusca thus identified by showing that the land and freshwater species had probably emigrated from Europe to Canada through northern Asia, and that most of the marine species must have been transported from the arctic seas by Davis's Strait current southward to Cape Cod, and the remainder from the Mediterranean and western coasts of the Atlantic, by the Gulf Stream in a northerly direction.

Dr. Sclater said that it had always been an interesting problem how the similarity of the Fauna of North Europe and North America had been brought about. It was formerly supposed that a continuous land area existed between the two continents in the neighbourhood of Greenland. He was quite disposed to agree, however, that the communication had been brought about through the northern parts of Asia. In fact the fauna of Western America and of Eastern Asia had greater points of similarity than those of Northern Europe and Eastern America. For example, *Ursus horribilis* of Western America was intrinsically connected with *U. Arctos* if not merely a form of it. There were also some peculiar mammals which were identical; for example, an Insectivore *Urotrichus* was common to Japan and North Western America. With regard to birds several European types have turned up also in North Western America, a true Bullfinch for example.

Prof. Allman said that the distribution of Hydroids hardly accorded with that of Molluscs. Amongst recently collected *Tubularida* which he had examined, and all of which were new, two species only were common to both sides of the Atlantic. Our own islands, the coasts of Norway, Iceland, and Greenland, and the northern shores of the Atlantic down to Southern Nova Scotia belonged to one large province. At Florida all Eastern forms die out. Amongst the West Indian islands not a single species was common to both sides of the Atlantic. Looking at the facilities for distribution afforded by the locomotive buds of these organisms, these facts were not easy to understand.

Prof. Thiselton Dyer said that plant distribution quite supported the theory of communication between Asia and America. Prof. Asa Gray had shown that the Flora of Japan had a strong affinity to the North West American. Grisebach had endeavoured to invalidate this, but as Mr. Bentham said in his recent address, with little success. It was remarkable to find in a case like this an accordance between the facts of animal and plant distribution, because in the case of the Malayan Archipelago plants of the Indo-Malayan type extended far to the east of the limits Mr. Wallace found to exist in the case of animals.

Mr. M'Lachlan as confirming Dr. Sclater's remarks concerning the similarity of the fauna of Siberia and Eastern Asia with North America, stated that several genera of Insects are common to the two districts, though absent in Europe. He instanced especially the neuropterous genus Pteronarcys which formed the subject of a well-known memoir by Newport on the occurrence of external breathing filaments in the perfect kind of insect.

Mr. Jeffreys in reply, instanced some cases of marine shells which are common to the western or Pacific, and eastern or Atlantic coasts of North America; one of these is *Verticordia acuticostata*, which was at first known only as a tertiary fossil, but has lately been found living not only in the European seas, but also in the Gulf of Mexico, Japan, and probably Davis's Straits.

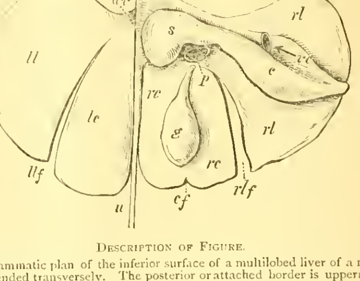
M. de Macklay had ascertained the existence of a species of sponge both in Japanese and Norwegian waters.

Department of Anatomy and Physiology

On the Arrangement and Nomenclature of the Lobes of the Liver in Mammalia, by Prof. W. H. Flower, F.R.S.

The description of the livers of various animals to be met with in treatises or memoirs on comparative anatomy are generally very difficult to understand for want of a uniform system of nomenclature. The present communication, which endeavours to supply such a system (and was illustrated at the meeting by a large series of coloured diagrams), is based upon an examination of the condition of the organ in examples of every important sub-division of the class. The difficulty usually met with arises from the circumstance of the liver being divided sometimes, as in man, ruminants, and the cetacea, into two main lobes, which have always been called respectively right and left; and in other cases, as the lower monkeys, carnivora, rodentia, &c., into a larger number of lobes. Among the latter, the primary division usually appears at first sight to be tripartite, the whole organ consisting of a middle, called "cystic," or "suspensory," lobe, and two lateral lobes, called respectively right and left lobes. This introduces confusion in describing livers by the same terms throughout the whole series of mammals, as the right and left lobes of the monkey, or dog, for instance, do not correspond with the parts designated by the same names in man and the sheep. There are, moreover, conditions in which neither the bipartite nor the tripartite system of nomenclature will answer, which we should have considerable difficulty in describing, without some more general system.

It appears desirable to consider all livers as primarily divided by the umbilical vein into two segments, right and left. This corresponds with its development, and with the condition characteristic of the organ in the inferior classes of vertebrates.



DESCRIPTION OF FIGURE.

Diagrammatic plan of the inferior surface of a multilobed liver of a mammal extended transversely. The posterior or attached border is uppermost. *u*, umbilical vein of the fœtus, represented by the round ligament in the adult, lying in the umbilical fissure; *d v*, the ductus venosus; *v c*, the inferior vena cava; *p*, the vena portæ entering the transverse fissure; *l l f*, the left lateral fissure; *r l f*, the right lateral fissure; *c f*, the cystic fissure; *l l*, the left lateral lobe; *l c*, the left central lobe; *r c*, the right central lobe; *r l*, the right lateral lobe; *s*, the Spigelian lobe; *c*, the caudate lobe; *g*, the gall bladder.

The position of this division can almost always be recognised in adult animals by the persistence of some traces of the umbilical vein in the form of the round ligament, and by the position of the suspensory ligament.

When the two main parts into which the liver is thus divided are entire, they may be spoken of as the right and left lobes;

when fissured as the right and left segments of the liver, reserving the term lobe for the subdivisions. This will involve no ambiguity, for the terms right and left lobes will no longer be used for divisions of the more complex form of liver.

In the large majority of mammals each segment is further divided by a fissure more or less deep, extending from the free towards the attached border, which I propose to call *right* and *left lateral* fissures (see Fig., *rlf*, and *llf*). When these are more deeply cut than the umbilical fissure, the organ has that tripartite or trefoil-like form just spoken of, the part between them being he so-called middle, cystic, or suspensory lobe. These terms I should propose to discontinue, and to institute *right central* (*rc*) and *left central* (*lc*) for the two regions included between the umbilical and the two lateral fissures, and to use *right lateral* (*rl*) and *left lateral* (*ll*) for the regions beyond the lateral fissures. The essentially bipartite character of the organ, and the uniformity of its construction throughout the class, is thus not lost sight of, even in the most complex forms.

The left segment of the liver is rarely complicated to any further extent, except in some cases by minor or secondary fissures marking off small lobules, generally inconstant and irregular, and never worthy of any special designation. The principal differences to be noted depend on the degree of completeness of the lateral fissure (which sometimes extends quite across the hepatic tissue completely severing the left lateral lobe), and the relative size of the two lobes.

On the other hand, the right segment is usually more complex. The right lateral fissure when fully developed passes into the right extremity of the portal fissure. The right central lobe, therefore, on its under surface does not reach to the attached border of the liver; but is always bounded in that direction by the portal fissure. Moreover, the gall-bladder when present is always in relation to its under surface. The position of this receptacle with respect to the lobe may vary—sometimes it is merely applied to its surface, loosely connected by connective tissue; in other cases it is deeply embedded in a fossa. Very often it is placed near the middle of the lobe—sometimes close to one or the other of its lateral boundaries. In many cases the fossa in which the gall-bladder is sunk is continued to the free margin of the liver as an indent, or even a tolerably deep fissure. This is called the cystic fissure (*cf*); but in consequence of its irregularity of position and frequent absence it is not of the same importance as the other fissures I have named, and does not mark off any distinct divisions of hepatic substance.

The right lateral lobe always has the great vena cava (*vc*) either grooving its surface or tunnelling through its substance near the inner or left end of its attached border, and a prolongation to the left, between the vein and the portal fissure, has long been known under the name of the *Spigelian lobe* (*s*). This is always a distinct hepatic region, sometimes a mere narrow, flat track, but more often a prominent tongue-shaped process. Whatever may be its form, it is bounded in front, or towards the free surface of the liver, by the portal fissure; on the left by the fissure of the ductus venosus (unless the vessel is bridged over by hepatic substance); posteriorly and partially on the right by the vena cava, but between this vessel and the right end of the portal fissure it is continued onwards into the adjoining part of the right lateral lobe.

The main body of the right lateral lobe is most commonly divided into two parts, not by a cleft, such as the lateral fissures, passing from the upper to the lower surface of the liver, but by one which severs a part off from the under surface. This is the *caudate lobe*, and the fissure which separates it from the right lateral lobe may be called the "fissure of the caudate lobe." In man it is almost obsolete, but in most Mammals it is of very considerable magnitude, and has very constant and characteristic relations. It is connected by an isthmus at the left (narrowest or attached end) to the spigelian lobe, behind which isthmus the vena cava is always in relation to it, channelling through or grooving its surface. It generally has a pointed apex, and is deeply hollowed to receive the right kidney, to the upper and inner side of which it is applied.

For ready comparison I have found it convenient to tint the diagrams of different livers with the following colours:—The left central lobe, dark blue; the left lateral, light blue. Where the left lateral fissure is not present, as in man, the ruminants, and cetacea, the colours will shade into each other, or the whole segment may be made of a medium shade. The right central lobe, dark red; the right lateral, light red; the spigelian, yellow; and the caudate brown. By this method the homologous parts of every liver, and the essential similarity of their construction, however diverse in appearance, may be seen at a glance.*

SECTION F—Economic Science and Statistics

Report of the Committee appointed on Uniformity of Weights, Measures, and Coins.

The Metric Committee of the British Association has much pleasure in reporting that another great stride has been made towards the uniformity in the weights, measures, and coins of all countries, by the passing of a law in Austria in June 1871, rendering the use of metric weights and measures permissive from January 1, 1873, and compulsory from January 1, 1876. The metric system is gradually diffusing itself all over Europe. At this moment fully two-thirds of that continent measured by population have adopted the metric system of weights and measures, and the other one-third has manifested sufficient interest in the question to justify the expectation of its early adhesion to the general agreement. But in this one-third there are comprised Russia and England, two countries which, by their population and commerce, exercise an enormous influence in the whole world.

The state of the question in Russia appears to be as follows:—In 1859 a Committee of the Imperial Academy of Russia, issued a report on the subject, which approved of the decimal division already incorporated in the Russian money system, and expressed an opinion in favour of extending such decimal divisions to weights and measures. In discussing, however, the possibility of even this moderate reform, the Academicians saw that such a considerable change would be required that they felt it would be far better for Russia at once to introduce the metric system, and this was the conclusion of their recommendations. Since the publication of the report, the Imperial Academy of Russia has taken an active part in advance of the system all over the world. In 1867 Mr. Jacobi was a member of the International Committee on weights, measures, and coins in connection with the Paris International Exhibition, and wrote the report which was agreed to by the representation of the nations who took part in the conference on the subject. And later still, in 1870, owing to the representations of the Imperial Academy of Russia to the French Government and to the scientific bodies of other nations of the need of preparing more accurate and metric standards for the use of countries which might adopt the metric system, an International Committee was appointed to prepare such standards. This Committee met in Paris, in June 1870, and will resume its labours in September next.

In the United Kingdom considerable progress has been made towards the introduction of the metric system, though much certainly remains to be done. In 1862 a Committee of the House of Commons was appointed to consider the practicability of adopting a simple and uniform system of weights and measures, with a view not only to the benefit of internal trade, but to facilitate our trade and intercourse with foreign countries. In discussing the question of the possible decimalisation of the existing system, the Committee of the British House of Commons, in the same manner as the Committee of the Imperial Academy of Russia, reported that it would involve almost as much difficulty to create a special decimal system of our own as simply to adopt the metric decimal system in common with other nations. And under the circumstances the Committee came to a unanimous recommendation in favour of the introduction of the metric system.

Nearly 200,000,000 of people in Europe have already recognised the metric system as the international system of weights and measures, 160,000,000 of whom have already adopted it in a compulsory manner. If once, therefore, Russia and England should finally place their legislation on the same footing, the other smaller states will certainly follow, and Europe will have attained perfect unity as regards weights and measures. But in other parts of the world also considerable progress has been made. In Asia the whole of India may be said to have adopted the weights and measures of capacity of the metric system, though some time may elapse before the Act passed by the Indian Government can be carried into operation.

In America the United States have introduced it permissively;

* The principal modifications from this common plan are described in "Lectures on the Organs of Digestion in the Mammalia," in course of publication in the *Medical Times and Gazette*.

whilst Brazil, Chili, Mexico, Grenada, and other American Republics have adopted the metric system absolutely.

Nor has there been less done as regards the coinage. If we compare the coins now in use all over the world with those in use some twenty years ago it will be seen what advance we have already made everywhere towards unity. Some countries, such as France, Italy, Switzerland, Belgium, Greece, and Roumania, have already an identical system of coinage secured to them by the Coinage Convention of December 23, 1865. The Austro-Hungarian Empire issues gold pieces marked 20 florins and 8 florins, equal to 25fr. and 10fr. respectively. Spain issues gold pieces of 25 pecates, equal to the 25fr. pieces, and Sweden the Caroline, equal to 10fr.

The Committee much regret that the German Empire, which had recently a most favourable opportunity for extending the desired uniformity, an object to which she has shown her adherence by the adoption of the metric system, has issued a new gold coinage, having nothing in common either with the money of the Convention of France, Switzerland, Italy, and Belgium, or with the monetary systems of England or the United States.

During the last year the Committee have had communications with the Indian Government on the question of introducing the metric system of weights and measures into India, the original Act by which all the weights and measures of the system were introduced having been vetoed by the Home Government, and another, limited to the weights and measures of capacity, having been passed in its stead.

The ramification of the weights, measures, and coins all over the world will be fraught with immense benefit to science, commerce, and civilisation; and scientific and philosophical bodies of all nations have given their adhesion to it; the commercial classes look for it as an essential element in the economy of time and the performance of international work, and travellers all over the world regard it as the greatest boon that could be conferred. Towards the attainment of this important object the Metric Committee of the British Association for the Advancement of Science have exercised an important influence.

SECTION G—Mechanical Science

Opening Address by the President, Frederick J. Bramwell, C.E.

The point which I have to determine is what shall my one subject be—on what shall I address you? I have thought over many subjects connected with mechanical science, but I cannot discover anything more practically important than "Coal." Very few matters are of greater real interest at all times to the nation at large, and very few are more prominently before the minds of the public at the present time, and certainly no subject can be more appropriate for a mechanical engineer, if for no other reason than this, that the steam engine is still the very crowning glory of mechanical engineering, and that coal is the staff of life, and, so to speak, the breath of the nostrils of the steam engine. The raisings of coal, which in 1855 were only 64 millions of tons in Great Britain, rose to 80 millions in 1860, and to 108 millions in 1869; and I will also advert to the fact that the price of all kinds of coal has in the colliery districts risen, speaking in round numbers, about 100 per cent. within the last twelve months, and is still rising. Let us now see how we do deal with coal in those cases where coal must be used; how we might deal with it in such cases; and how we might in certain instances substitute other sources of power for the coal which we now consume. And let us first of all consider this question of finding sources other than coal for our motive power. Before the steam engine was so extensively used as it now is, the wind, the force of the streams, and the force of the tide were all employed to give motive power. With respect to the power of the wind, it is to be feared it is too irregular to enable any manufacturer to rely upon it in competition with the steam engine. With respect to the power of our streams, the altered condition of the soil due to increased drainage and cultivation has so materially interfered with the regularity of their flow, that their efficiency as sources of constant power is seriously diminished, while competition with them by steam has become much greater than it was when the water mills themselves were better off. This state of things, however, might be cured, and, in fact, has been cured in certain districts, by the union of a large number of mill proprietors to form storage reservoirs, from which the water can be delivered with regularity so as to give an uniform supply to the mills. But the third source of water power, the tide mill, which at one time was used to a considerable extent, is almost wholly discontinued. The causes of this discontinuance are sufficiently obvious. The tide mill as formerly constructed could work for only a limited period in each ebb, and to obtain the full effect it had to utilise both the night and the day tides. But while the tide mills laboured under these disadvantages, they possessed the great merit that their power, such as it was, was one that could be depended on, and one which, although it fluctuated, fluctuated regularly and within known and definite limits. I would suggest that, in those cases where there are large manufacturing districts within a few miles of the sea, and where there is a rise and fall of the tide, coupled, in the outset at all events, with natural indentations of the coast which might be comparatively readily dammed up for the storage of the water, there such storage should be made that the water should be set to work turbines of the best kind (turbines which will work with very nearly the same per-centage of the total power given out by the water at any particular moment, whether they are immersed or whether they are not); that these turbines should be employed in pumping water at a high pressure into Armstrong accumulators; and that pipes should be laid on from those accumulators to the neighbouring manufacturing town, and should there deliver their power to the consumers requiring it, to be used by them in water-pressure engines. Suppose a beginning were made with the city of Bristol, which is no doubt a very favourable instance for the application of this suggestion. Here the rise and fall of the tide might safely be taken at 24 ft. Half a square mile of water enclosed would, after the most lavish deductions for loss, yield, in Bristol at least, 5,000 horse-power, probably sufficient to replace the whole of the power of the stationary engines now at work in Bristol. I will now consider the question how coal is wasted in its use, but before doing so I will say a few words upon the loss that occurs in the coal mine itself. Happily, this loss has for some years past been greatly reduced. More economic systems of working have prevailed, plans of dealing with small coal by washing away its impurities, so as to render it fit for cokeing, have been largely adopted, and thus a great deal of that coal which a few years since would have remained buried in the mine, as not justifying the expense of raising it to the surface and of paying royalty upon it, is now brought to light and is utilised. Nevertheless we know that at ordinary prices of coal it is to the advantage of the colliery proprietor in many instances to leave a considerable per-centage of the seams that are worked rather than to endeavour to lessen that percentage by the use of a more expensive system of artificial support for the roof, and further that it also pays him to leave altogether unworked very thin seams of coal. Hereafter, when coal becomes scarce, there can be no question that the inhabitants of these islands would be glad to make use of the now despised unworked seams, and also to recover the buried coal of the worked seams; but such seams and such savings, although they can be worked and made at present, when the mines are open, if not at profit, yet with little loss, will then only be capable of being reached by a reopening and pumping out of abandoned mines, a process so expensive that great indeed must be the need of our successors if they are compelled to resort to it. I now come to the question of the way in which waste occurs in the use of the coals that are brought to the surface. This use may be divided into two great branches—the domestic and the manufacturing. I will consider first the domestic use. This is a highly important branch of the subject. It is believed that out of the total of ninety-eight or ninety-nine millions of tons of coal which in 1869 were retained for home use, eighteen and a-half millions of tons, about one-fifth of that quantity, were consumed for domestic purposes (about ten millions being exported). We all of us know intimately the way in which coals are burnt for domestic purposes. The other way in which we use coal is for purposes of manufacture, and this, again, may be divided into two branches at least—namely, the coal that is employed for obtaining power, and the coal that is employed in metallurgical and other operations not immediately connected with the production of power. To treat of those latter cases first, they are far too numerous to be dealt with in detail, and, therefore, only a few of the principal must be considered. Take the subject of coke making. How much coal is heated in clamps and in kilns to be converted into coke, and in how few instances is any use made of the whole of the heat residing in the

gaseous parts of the coal which are driven off. This heat frequently amounts to 30 per cent. of the whole of that which is in the coal. We come next to the smelting of iron. Take the preliminary process of calcining the ore. In those cases where the ore is "black band," the ore so common in Scotland, the calcining is done by the combustion of the carbonaceous matter mixed with the ore. Far more than the quantity of fuel requisite for the calcination is associated with this ore, but the whole of it is burnt off, and no effort whatever is made to utilise the surplus heat. Then with regard to the blast furnaces for smelting iron. Here, still almost universally in Scotland, that large seat of the iron manufacture, and to a considerable extent in England, the waste gases are suffered to issue from the furnace top, illuminating the country for miles round, and bearing testimony to the indifference of the owner of the furnaces to a waste of our store of fuel. Upwards of sixty years ago—viz., in 1811—the utilisation of these gases was suggested in France, but not much was done for thirty years. About 1840, however, their use became not infrequent in that country, and French manufacturers and chemists taught us that the gas thus recklessly wasted might be collected and utilised, and made to replace the fuel expended in heating the hot blast stoves and in raising steam for the blowing engines. But, for the cause which has been and will be alluded to, the adoption of this plan was very slow indeed in England. It has now been in use, however, for many years in our best conducted works, but as a proof of the slowness of its introduction, the furnaces of Scotland, as I have already said, are even to this day almost universally worked upon the wickedly wasteful principle of allowing these gases to burn idly away. Take again the melting of steel in crucibles where the heat issues from the furnace, of necessity hotter than the heat of the melted steel (for were it not so it would cool it), and of this issuing heat, as a rule, no use whatever is made. Take again the heating furnace and puddling furnace of our iron works, very commonly from these heat at a greater temperature than that of welding iron escapes up the chimneys, disregarded as though it had cost nothing for its generation.

Next let us consider how we are dealing with coal when we use it for obtaining motive power in our steam engines. Steam engines may be divided into the four great heads of marine, locomotive, portable, and fixed. Including within the term steam engine the boiler as well as the engine, the waste may arise in a steam engine in two ways, in either one of them, or in both combined. It may arise from an imperfect utilisation of fuel in the production of steam—that is, a waste due to the boiler and to the firing; or it may arise in an improper use by the engine of the steam provided for it by the boiler. There can be no question that the boiler waste is, as a rule, very large indeed. I am perfectly certain there is hardly any subject more worthy the attention of the engineer than the replacing the stoker by some mechanical arrangement which shall afford absolute uniformity of firing, and therefore absolute uniformity of the conditions of the fire, and this is a subject not only worthy of attention on account of the saving of coal, but also on the ground of putting an end to a most laborious, exhausting, and, it is to be feared, unhealthy occupation, viz., that of the steamboat fireman, more particularly when he is working in a hot climate. If perfect combustion were obtained in the fire, I do not think there would be much difficulty in properly utilising by the boiler the heat evolved.

I have now laid before you some of the points in which the boilers and engines of the present day are below the standard to which engineering science has already reached, and in which, therefore, there is known opportunity for immediate improvement. There is a perpetual bugbear in the way of improvements, and that bugbear is the so-called "practical man," and he was in my mind when, in previous parts of this address, I have hinted at the existence of an obstacle to the adoption of improvement. I do not wish the section for one moment to suppose that I, brought up as an apprentice in a workshop, and who all my life have practised my profession, intend to say one word against the practical man. On the contrary, he is the man, of all others, that I admire, and by whom I would wish persons to be guided; because the truly practical man is one who knows the reason of that which he practises, who can give an account of the faith that is in him, and who, while he possesses the readiness of mind and the dexterity of action which arise from the long-continued and daily intercourse with the subject of his profession, possesses also that necessary amount of theoretical and scientific knowledge which justifies him in pursuing any process he adopts, which in many cases enables him to devise new processes, or which, at all events, if he be not of an inventive quality of mind, will enable him to appreciate and value the new processes devised by others. This is the truly practical man, about whom I have nothing to say except that which is most laudatory. But the practical man, as commonly understood, means the man who knows the practice of his trade, and knows nothing else concerning it; the man whose wisdom consists in standing by seeing, but not investigating, the new discoveries which are taking place around him, in decrying those discoveries, in applying to those who invent improvements, even the very greatest, the epithet of "schemers," and then when he finds that beyond all dispute some new matter is good and has come into general practice, taking to it grumblingly, but still taking to it, because if he did not he could not compete with his co-manufacturers. The aim and object of such a man, indeed, is to ensure that he should never make a mistake by embarking his capital or his time in that which has not been proved by men of large hearts and large intelligence. It is such a practical man as this who delays all improvement. For years he delayed the development in England of the utilisation of the waste gases of blast furnaces, and he has done it so successfully that, as I have already had occasion to remark, this utilisation is by no means universal in this kingdom. It was such men as these who kept back surface condensation for twenty years. It is such a man as this who, when semaphores were invented, would have said, "Don't suggest such a mode to me of transmitting messages; I am a practical man, sir, and I believe that the way to transmit a message is to write it on paper, deliver it to a messenger, and put him on horseback." In the next generation his successor would be a believer in semaphores, and when the electrical telegraphist came to him and said, "Do you know that I can transmit movement by an invisible electrical power, through a wire however long, and it seems to me that if one were to make a code out of this movement, I could speak to you at Portsmouth at one end of the wire, while I was in London at the other," what would have been the answer of this practical man? "Sir, I don't believe in transmitting messages by an invisible agency; I am a practical man, and I believe in semaphores, which I can see working." In like manner, when the Siemens' regenerative gas furnace was introduced, what said the practical man: "Turn your coals into gas, and burn the gas, and then talk of regeneration. I don't know what you mean by regeneration, except in a spiritual sense. I am a practical man, and if I want heat out of coals I put coals on to a fire and burn them," and for fifteen years the practical man has been the bar to this most enormous improvement in metallurgical operations. The practical man is beginning slowly to yield with respect to these furnaces, because he finds, as I have already said, that men of greater intelligence have now in sufficiently large numbers adopted the invention to make it a formidable competition with the persons who stolidly refuse to be improved. The same practical man for years stood in the way of the development of Bessemer steel; now he has been compelled to become a convert. It may be said that employers and the heads of manufactories are, as a rule, in these days, educated gentlemen, and that, therefore, it is wrong to impute to them the narrow mindedness of the practical man. I agree that in numerous instances this would be wrong; but the fact is that in many cases, I think I may say in most cases, the head of the establishment, the moneyed man, the man who by his commercial ability (that most necessary element in all establishments) keeps the concern going by finding lucrative orders, is not intimately acquainted with the practice of the business carried on by his firm. He relies upon some manager or foreman who too commonly is not the real but the so-called practical man. It is to such men as those who simply practise that which they have seen, without knowing why they practise it, that the title of practical man has most improperly been attributed, and it is on the advice of such men that the true heads of the firm too commonly regulate their conduct as to the management of their business, and as to the necessary changes to be made in the way of improvement. As I have said, the practical man derides those who bring forward new inventions and calls them schemers. No doubt whatever they do scheme, and well it is for the country that there are men who do so. It also may be true that the majority of schemes prove abortive; but it must be recollected that the whole progress of art and manufacture has depended, and will depend, upon successful discoveries, which in their inception were and will be schemes, just as much as were those discoveries that have been and will be unfruitful

But the successful discoveries, because they are successful, are taken out of the category of schemes when years of untiring application on the part of the inventors have, so to speak, thrust them down the throat of the unwilling practical man. Take the instance of Mr. Bessemer, who was beset for years by difficulties of detail in his great scheme of improvement in the manufacture of steel. As long as he was so beset, the practical men chorused, "He is a schemer; he is one of the schemers; it is a scheme." Supposing that these practical difficulties had beaten Mr. Bessemer, and that they had not been overcome to this day, the practical man would have derided him still as a schemer, although the theory and groundwork of his invention would have been as true under these circumstances as it now is. Fortunately for the world, and happily for him, he was able to overcome these most vexatious hindrances and make his invention that which it is. No one now dares to apply the term "schemer" to Mr. Bessemer or "scheme" to his invention; but it is as true now that he is a "schemer," and his invention a "scheme," as it would have been had he failed up to the present to conquer the minor difficulties. It is a species of profanation to suggest, but I must suggest it, for it is true, that Watt, Stephenson, Faraday, and almost every other name among the honoured dead, to whose inventive genius we owe the development that has taken place within the last century in all the luxuries, the comforts, and even the bare necessities of our daily existence, would, in their day, and while struggling for success, have been spoken of as schemers even in respect of those very inventions of which we are now enjoying the fruits. But I feel I need not labour this point further at a meeting of the Mechanical Section of the British Association—an Association established for the advancement of science. I know I shall be accused of decrying the practical man, and of upholding the schemers. I say most emphatically that I do not decry the practical man. I plead guilty to the charge of decrying the miscalled practical man, and I glory in my guilt; while I readily accept that which I consider the praise of upholding "schemers," and I do so for this simple reason that if there were no schemers there would be no improvement. I think it becomes a scientific body like the British Association to laud the generous effort of the unsuccessful inventor rather than to encourage the cold selfishness of the man who stands by and sees others endeavour to raise the structure of improvement without lending a hand to help, and even sneers at the builders, but when the structure is fully raised and solidly established, claims to come in to inhabit, and being in probably essays, cuckoo like, to oust the builders, and to take possession for his own benefit. One word in conclusion. Can we not devise some means by which consumers of coal may be instructed in, shamed into, or tempted to the economical use of that most valuable material? The Royal Agricultural Society of England, by its judicious efforts for many years past by the institution of trials and the giving of prizes for the best engines, has brought the consumption of coal down from 10 lbs. per horse-power to a little over a quarter of that quantity. Could we not institute a Society which should devote itself to the recording and the rewarding of the performances of steamboats and of fixed engines for land purposes? I am aware it is supposed that there is a difficulty in these cases which does not obtain in the case of portable engines that can be brought for trial upon a dynamometer, and that is, that the power exerted by marine engines varies during the voyage, and is not that which is developed at the measured mile, while in a manufactory it varies according to the conditions of the trade, and to the extent to which the British workman condescends to attend to his work. But there are implements which record the horse-power exerted from moment to moment, and register it on indices as readable as those of an ordinary counter of an engine, or as those of a gas meter. I believe that one of the very greatest incentives to economical working which the owners of steamboats could offer to their engine builders and engineers would be the application of such implements as these. Were they employed, the shipowner would know at the end of the voyage so much horse-power had been exerted as a whole, and that so much coal had been burnt, and that the result, therefore, was a consumption of so many pounds per horse-power per hour. All excuses of head-winds, and all the aid of canvas to the engine-power, would be eliminated from the calculation. The continual indicator would register truly the work the engine had to do, whether that work was made excessive by contending with head winds, or was rendered light by favourable breezes and the assistance of canvas. In the same way the proprietor of the engine for manufacturing purposes, the cotton mill, the woollen mill, the corn mill, and even the highly irregularly working rolling mills and saw mills, would be able at the end of the quarter to say: "Notwithstanding all the variations of my trade and rate of manufacture, I know that my engines have exerted so much power, I know that I have burnt so much coal, and that therefore such and such have been the economic results." Assuming that steamboat proprietors and the owners of fixed land engines would go to the expense of applying such continuous recording implements as these to their engines, and would become members of an association for the purpose of visiting and inspecting and of reporting upon their machinery, and of giving prizes to the men in charge for careful attention; prizes to the manufacturers for original good design and workmanship of the engines; and prizes to the proprietors for their public spirit in having bought that which was good instead of that which was bad and cheap, and for having employed intelligent and careful workmen instead of ignorant and careless ones,—I believe within a few years as great an improvement might be seen among the marine and manufacturing class of engines as has been effected by the laudable exertions of the Royal Agricultural Society of England among the portable ones. I think the initiation of some such society as this would be a practically useful result from the meeting of Section G.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, July 29.—Mr. Cayley presented the continuation of his memoir on the condition enabling a family of given surfaces to form part of an orthogonal system.—M. de Saint-Venant communicated a note by M. J. Boussinesq on a simple mode of determining experimentally the maximum resistance to sliding in a ductile, homogeneous, and isotropic solid.—M. Yvon Villarceau presented a note on a new theorem in general mechanics.—M. W. de Fonvielle read a notice of the results of observations on recent thunderstorms.—A note from M. P. Volpicelli on the theory of Nicholson's duplicates was read.—M. E. Becquerel presented a note by M. A. Cazin on the quantity of magnetism of electro-magnets.—M. C. Sainte-Claire Deville communicated a note by M. de Tastes on the fall of an aerolite in the commune of Lancé (Loir-et-Cher) on July 23. This fall took place about half-past 5 P.M., with a clear sky and bright sun; it was accompanied by a violent explosion heard over a great extent of country. The course of the meteor was from S.W. to N.E., and it appeared to be double, or to consist of two meteors following a parallel course. A large portion fell and buried itself in the ground to the depth of 1·50 metre.—M. Boussingault read a memoir in continuation of his researches upon the presence of iron in the organism; it related to the distribution of iron in the materials of the blood. The greatest portion is contained in the globules.—M. Daubrée presented an investigation of the meteorites of Ovifak, with regard to the amount of carbon and of soluble salts which they contain.—M. Berthelot presented a note on the constitution of acid salts in solution; M. J. A. Le Bel a note on the pyrogenated carburets of Pechelbroun; and MM. Girard and De Laire a note on the colouring matters derived from aniline, in reply to a recent communication by M. Lauth.—M. C. Sainte-Claire Deville presented a note of an examination by M. Gorceix of the gaseous emanations of Santorin during the close of the eruption of 1866.

THURSDAY, SEPTEMBER 5, 1872

NAVAL SCIENCE*

MR. REED, who has hitherto been known to the naval world principally as a successful shipbuilder, and as the writer of two valuable works on shipbuilding, comes before it now in the additional character of editor of a magazine, which, under the title of *Naval Science*, professes to embrace all branches of science relating to naval affairs. How far this profession will be fulfilled, as the magazine, advancing from number to number, gathers strength with increasing age, remains to be seen; but at present it is impossible to avoid the remark that a very disproportionate part of the two numbers now before us, and more especially of the first, is occupied with articles devoted to the study of naval architecture. The superabundance of papers relating to this subject is one which, from Mr. Reed's antecedents, might fairly have been expected, and is to be expected in the earlier numbers, until the editor gathers round him a staff competent to write on the many other scientific topics which present, or should present, equal interest to, and as directly concern, our naval officers. Such subjects as the stability or the rolling of ships, ably and in most respects agreeably as they are treated, have, from their theoretical point of view, absolutely no connection with the duties of a naval officer, however much they may appeal to his desire to be fully acquainted with whatever bears, even remotely, on his profession. It is, of course, important that, with these new ships which have points of maximum and vanishing stability, the commanding officer, and not only he, but every executive officer, should familiarly know the limit of inclination which his ship must never be allowed to exceed; but, practically speaking, it is of no more consequence to him to know the mathematical reason of this than it is to know the geological formation of a submerged rock ahead. The relation between the period of a ship in the trough of the sea and the period of the waves amid which she would be rolling, has even still less to do with the practical duties of a seaman who is unable, under any circumstances or in any degree, to alter either "the metacentric height," "the radius of gyration," or "the period of oscillation" (p. 199); but who is able, so long as the ship is not a helpless wreck, to keep her out of the trough of the sea, the position to which these experiments and calculations refer. We by no means wish to imply that the study of such questions as these is of no importance to the naval officer; on the contrary, we are very decidedly of opinion that whatever gives him a clearer insight into the meaning of the rules by which his conduct has to be guided, renders him a more intelligent, and therefore a more capable officer; what we would say is, merely, that they have not such paramount interest as to render it desirable to devote to them at least half the space in a magazine of Naval Science. Saying this, we must also add that we are fortunate in having in Mr. Reed one who represents for one scientific branch what should be represented in all branches.

The remaining space has been allotted to more varied papers, some of which are of considerable ability. Amongst these we would specially mention one on "Naval Tactics," which contains a very interesting *résumé* of the subject, and permits us to hope that in a future number the writer will enter more fully into a discussion of the probable and possible effects of the several formations; for though no certain result can be arrived at till war has actually tested them, it seems to us that much knowledge may be gained by a consideration of the different methods of attack and defence, as opposed to each other.

We have, again, a valuable contribution to navigation in an article on "Rhumb and Great Circle Charts," which illustrates the important application of the Great Circle principle to windward sailing, in a manner more lucid and satisfactory than we remember to have seen in print before. But in treating of its more general relations to navigation and to the conduct of a long passage, the writer would seem to have momentarily overlooked the geographical as well as the meteorological constraints which are everywhere put on it; thus, for instance, in the outward passage to Australia, the great circle route leads through latitudes dangerous or impassable from ice, whilst the steadiest streak of westerly winds is to the north rather than to the south of the 45th parallel. A previous article from, if we mistake not, the same pen, enters on the long-vexed question of "The Rational Method of Teaching Navigation." There can be little doubt that the author is right as to the rationality of the method;—as to the utter irrationality of the method which has been hitherto generally adopted, the difficulty which has stood in its way has been the absolute impossibility of adapting it to the necessities of the service, and of giving very young boys the requisite grounding in elementary mathematics, in the given time and amid the bustle and disturbance of a sea life. We may fairly hope that this difficulty is about to vanish, now that Mr. Goschen recognises the advisability of materially increasing the age for the entry of naval cadets. It is on this that the hope of any real improvement in the state of naval education must principally depend. When a youngster at the age of fourteen is thrust into a world of peculiar hardship and excitement, he must have an extraordinary aptitude if he follows up book-learning one step more than he is obliged to do. It appears in the evidence before Admiral Shadwell's Committee that about seven hours a week is a good average amount of study under instruction; it does not appear in the evidence, but it is none the less true, that a young boy's attendance at study in the forenoon, after he has kept the morning or middle watch, is for the most part corporeal rather than mental, from which he derives little or no profit. When the present system has been entirely done away with, and been replaced by some other, such, perhaps, as that recently proposed by Captain Goodenough, we may hope that our young naval officers, as they grow into manhood, may possess a fair groundwork of the more essential parts of an exact education. But until some such radical alteration has been made, until a real, however moderate, amount of accurate grounding becomes the rule and not the exception amongst our young officers,

* "Naval Science: a Quarterly Magazine for Promoting the Improvement of Naval Architecture, Marine Engineering, Steam Navigation, and Seamanship." Edited by E. J. Reed, C.B., &c. Nos. I. and II., 8vo. (Lockwood & Co.)

we confess that we can scarcely look with confidence to the now loudly vaunted schemes for "the higher education of the navy," whether it is to be carried on at Greenwich or elsewhere.

It is, however, a mistake to speak, as is so commonly done, of the navy as a scientific profession. As a profession, the regular line of the service is practical amongst the practical; it requires and cultivates a quick eye, a restrained temper, a cool courage, a ready judgment of men and things; it calls for a minute and thorough knowledge, not only of all that relates to the management of ships and men, but of the extensive "literature" issued and demanded by the Admiralty; few have the time, even if they had the disposition, to go deep into scientific study, to which there is no inducement, for which there is no reward. One of the earlier articles in the magazine before us, "On the Necessity of forming a Naval Staff," pointedly calls attention to this. We believe that the writer has under rather than overstated his case. That beyond the regular line of the service there are duties which call for a higher and more extended knowledge, is freely admitted by all; and we are convinced that these duties will be more efficiently performed by officers specially educated for them, than by others nominated indiscriminately or by roster, after a vain endeavour to bring the whole body of officers to one universal high standard. There are few men, worth anything at all, who have not a distinct speciality, and we conceive that it is by allowing, nay, encouraging these specialities to develop themselves to the utmost, that the greatest perfection in the aggregate is to be attained. To force a man of an essentially practical turn of mind, with a judgment in the handling of a ship, or with an insight into the character of men, which seems instinctive rather than acquired, to go through a distasteful course of high mathematics, or of foreign languages, or, on the other hand, to pin a man of unusual taste and aptitude for the study of more advanced science down to the routine of the service, appears to us a most erroneous system. Yet, so far as we understand, this is what is seriously proposed. The formation of a Naval Staff, and the abolition of the existing segregation of navigating officers, would, we believe, be a radical and immediate cure. It is in evidence before the committee already referred to, that the special training of officers whom interest or taste attracts to gunnery duties, has been found to work exceedingly well; we believe that a similar system with regard to navigating duties would be as successful; nor can we admit that a small body of men, chosen by the mere accidents of birth or family connection, is likely to furnish such a number of first-rate navigators and surveyors as could be got together by special selection from the whole service;—to use a geographical simile, we would drain a larger area. Roughly speaking, about one-sixth of the lieutenants on the list have taken out gunnery certificates; the proportion of those who would take out advanced certificates in navigation would probably be considerably greater; whilst, indirectly, a large number would follow up some course of study with a view to turning it to future account. If appointments as flag-lieutenants were made in a similar way, we believe that the impetus given to study amongst the officers of our navy would lead to results quite equal to those wished for. But it is not in human nature to pursue a course of study wearisome in its beginnings, amidst the worry and turmoil of an active profession, without encouragement, without hope of reward.

We have no space to notice, in a manner proportionate to its merits, Mr. Mallet's article on the Action of Torpedoes; this, after all, is, so far as the navy is concerned, the question of the day, and any discussion that leads to a closer acquaintance with it ought to be carefully studied. Every one acknowledges, first, that the navy, at present, is in a transition state; and secondly, that more Science is wanted. We consider it a fortunate thing, therefore, that what is destined to be a high-class journal of Naval Science, under the editorship of such a distinguished man as Mr. Reed, has made its appearance at this time, and we wish it every success—a success, moreover, which is certain, so long as the stated point of view is steadily kept in mind.

OUR BOOK SHELF

Die Echinoiden der oesterreichisch-ungarischen oberen Tertiärablagerungen. Von Dr. Gustav C. Laube. Mit vier lithographirten Tafeln. (Wien, 1871.)

AGASSIZ, Desor, E. Forbes, Desmoulins, and Wright have written elaborate monographs and descriptions of Miocene Echinodermata. Prof. Ed. Forbes described (Proc. Geol. Soc., vol. iv. pp. 230-232, 1843) a large series from the miocene beds of Malta and Gozo, collected by Capt. Spratt, R.N., of H.M. surveying vessel *Beacon*; Dr. Wright in 1855 (Ann. Mag. Nat. Hist., vol. xv.) described many species from collections made by the Earl of Ducie, from the same islands; and again, in 1864 (Q. Jour. Geol. Soc., vol. xx. p. 470), through the series collected by Dr. Leith Adams at Malta, he described new miocene forms. These were all important additions to the then little known echinodermata of the miocene rocks of southern Europe. In the present monograph, which is reprinted from the "Abhandlungen der k. k. Geologischen Reichsanstalt," Dr. Gustav C. Laube also carefully describes fourteen new or previously unknown species of echinoderms from the Austro-Hungarian miocene (upper tertiary) deposits, and adds a new genus (*Brissomorpha*) to receive those forms possessing non-depressed ambulacral grooves, and an attenuated posterior border. Many of the species described by Laube are peculiar to the miocene rocks of the Austro-Hungarian area, whilst others have a much wider distribution, several being identical with the Maltese forms described by Dr. Wright. Of the fourteen genera and thirty-seven species included in Dr. G. Laube's monograph, seven species occur in Malta, seven in Corsica, and eleven in France; while the remaining twelve species are peculiar to the Austro-Hungarian beds. The following new species have been described and figured by the author in the memoir before us, viz., *Cidaris Schwabenarii*, *Echinus dux*, *E. hungaricus*, *Echinocyamus transylvanicus*, *Scutella Vindobonensis*, *Echinolampas angustistellatus*, *Pericosmus affinis*, *Hemiaster rotundus*, *H. kalksburgensis*, *Schizaster leithanus*, *S. Karreri*, *Brissomorpha Fuchsi*, *Spatangus euglyphus*, and *S. austriacus*. The monograph contains a very valuable table showing the distribution of those species which occur elsewhere, such as Malta, Corsica, Italy, and France, with a general column for other localities (*andere Länder*); it is accompanied by four quarto lithographic plates devoted to the local and new species, which are carefully figured. The whole is an important contribution to this division of the *Annuloida*. R. E.

Fishes of New Zealand. Catalogue, with Diagnoses of the Species. By F. W. Hutton, F.G.S., Assistant Geologist. *Notes on the Edible Fishes.* By James Hector, M.D., F.R.S., Director. With 12 plates. (New Zealand, Wellington, 1872.)

THE geologists of New Zealand are of opinion that, in order to acquire a knowledge of the inhabitants of their country in past epochs, it is necessary first to know what its present inhabitants are. This will appear rather strange to some of their European brethren, who do not seem to consider that the subjects have anything to do with one another, and who usually keep them as far apart as possible. But there can be no doubt, we believe, that our Antipodal friends are right, and that a knowledge of the extinct fauna of any country must be preceded by a study of its existent fauna.

We have lately given our readers an account of two lately-published works on the Birds of New Zealand. We have now the pleasure of introducing to their notice an excellent *résumé* of the present state of our knowledge of the fishes of the same country. This has been prepared by Captain Hutton, author of one of the previously mentioned treatises, under the direction of the enlightened Chief of the Geological Survey of New Zealand, who himself contributes additional information to the volume of a highly important nature, in shape of Notes on the Edible Fishes of the Colony.

The arrangements and nomenclature adopted by Capt. Hutton are that of Dr. Günther's "Catalogue of Fishes," the most recent and by far the best authority on the subject. A few new species are introduced, discovered since the issue of Dr. Günther's work, and some imperfectly known fishes mentioned, which Dr. Günther does not appear to have noticed. Thus the total number of New Zealand fishes included in Captain Hutton's work amounts to 141. There can be no doubt, however, that this number will be considerably augmented when more attention has been devoted to the subject. Indeed, we believe that even within the past few months Dr. Günther has described some rather remarkable additions to the Ichthyological Fauna of New Zealand, which are not included in the present synopsis.

The greater number of New Zealand fishes are marine species. The freshwater fish fauna is poor in the extreme, although it included two remarkable forms belonging, one to the true *Salmonidæ*, and the other to a nearly allied group, which are the "Smelt" and "Grayling" of the native fishermen. The former fish, Dr. Hector tells us, is "delicious food," but does not attain sufficient dimensions to make it of great importance as an article of diet. But the native "grayling," which probably reaches 6 lbs. or 8 lbs. in weight, ought to be valuable, and we cannot quite understand why, with such a fish available, it was thought necessary to spend large sums in the endeavour to introduce European *Salmonidæ* into the freshwater of New Zealand.

In concluding the brief notice of a most useful work, we should add that the twelve plates which accompany it, and which give the outline of about fifty of the most characteristic species, even if not of great scientific value, will, we are sure, be of great assistance to the unlearned colonist in his attempt to make out the correct names of the native fishes.

LETTERS TO THE EDITOR

Radial Polarisation of the Corona

DURING the recent meeting of the British Association at Brighton, it was casually remarked by Sir William Thomson that during the eclipse of last December, it had been observed that the radial polarisation of the corona was greater at a small distance from the sun than close to it. This observation he thought was a very important one.

My observations on this subject were published in the *Philosophical Magazine* for last March, but I think Sir William Thomson's opinion may be taken as sufficient reason for thinking that they would not be uninteresting to the readers of NATURE.

I have twice accompanied Mr. Pogson, the Government Astronomer at Madras, as polariscopic observer, in his eclipse expeditions; first, in August 1868, and secondly, last December.

In August 1868 I used simply a Savart's polariscope, attached to a telescope, employing a diaphragm to limit the field of view. On this occasion I found that the corona was radially polarised. I shall enter, however, more fully into a description of the method adopted last December, as the results then obtained, while confirming those obtained in 1868, are, I think, of much greater importance.

The Savart was so adjusted as to show a white central band between two dark ones, when the bands corresponded in direction with the plane of polarisation. This polariscope was, last December, converted into a polarimeter, by causing the light to be examined to pass first through four plates of crown glass, mounted in a frame, moveable on an axis at right angles to the direction of the bands. This instrument was fixed in front of the eye-piece of a small equatorially-mounted telescope.

When the glass plates were perpendicular to the optical axis of the instrument, they had, of course, no effect whatever upon the polarisation of the light passing through them; but if the frame carrying the plates were turned on its axis, the light passing through them would be polarised in a plane parallel with the axis, and hence at right angles to the direction of the bands, and the amount of polarisation so caused may be calculated for any angle the glass plates may make with their normal or zero position by means of formulæ in Prof. W. G. Adams's paper, published in the *Philosophical Magazine* for April 1871.

It is evident that if we are examining common light by this instrument, turning the glass plates will cause black centred bands to appear; that is, the central band will be dark, and between two white ones, exactly the reverse of what takes place when light polarised in the plane of the bands is examined by the polariscope. If then while examining light polarised in the plane of the bands, we turn the glass plates, we prevent that polarised light from passing to the polariscope, and the bands gradually disappear as the angle of the plates increases, and they completely disappear when the plates are at such an angle as would produce on ordinary light the same amount of polarisation as that existing in the light under examination.

By knowing the angle through which the plates have to be turned in order to extinguish the bands, we are able to measure the amount of polarisation in any polarised light; the instrument forming what may be called a differential polarimeter. Further, it is evident that if we place our bands at right angles to the plane of polarisation, we shall get black centred bands, which would only be increased in intensity by turning the glass plates; hence we can only measure the polarisation of light with this instrument when the direction of the bands coincides with the plane of polarisation.

My own observations of the eclipse of 1868 led me to expect to find radial polarisation.

Prof. Pickering thought that the polarisation he observed in 1869 was caused by the reflection of sunlight from the unobserved portions of the earth into the atmosphere, and thence back to the eye. The plane of polarisation would, in that case, be vertical near the sun. I took the portion of the limb at about 90° from the vertex, towards the south (that is near the southern limb) for my observations, and carefully placed my instrument so that the bands were radial to the sun before totality. The bands were therefore horizontal, or nearly so. This was then a crucial experiment as to the accuracy of Prof. Pickering's view on the one hand, or of my own previous determination on the other.

Directly totality commenced the bands appeared, and they were white centred. The plane of polarisation was, therefore, horizontal and not vertical; it was radial, and could not be caused in the way imagined by Prof. Pickering.

I next turned the glass plates till the bands disappeared, and by this means measured the amount of polarisation, which as I have before explained, could not be done had the plane of polarisation been at right angles to the plane of the bands.

On examining the light from a portion of the corona at about ten minutes distance from the limb, I found the polarisation

greater, in about the ratio of ·275 to ·158, than it was close to the limb; these figures representing approximately the amount of polarisation respectively at ten minutes from the limb, and close to it, the total light being unity.

We may therefore conclude that

1. The corona is radially polarised.
2. This polarisation increases as we recede from the limb.

The bright lines seen in the spectrum of the corona inform us that *part* of the light we receive from it is intrinsic, that is, that the gases composing it are incandescent, and from their proximity to the sun we should scarcely expect anything else; yet this fact in no way renders it impossible that much of the light we receive from the corona should be reflected or scattered by minute particles of, perhaps, denser matter, probably incipient cloud, suspended within it, as such particles are supposed to exist in the earth's atmosphere, in order to account for the polarisation and blue colour of the sky. This supposition, when we remember that the temperature, and hence the amount of intrinsic light, must decrease as we recede from the sun, would amply account for the increase of polarisation with distance from the limb. There are, however, two other causes which may be named as adequate to produce this effect. Probably in reality the increase is due to the three causes combined.

When the plates were inclined so as to neutralise the corona polarisation, I saw faint dark centred bands on the portion of the moon's disc in the field. I did not observe any when the plates were at right angles to the axis of the telescope, but I think I should have noticed them had they existed; so that although there was a sensible amount of light on the moon's disc sufficient to show bands when polarised by the glass plates, I do not think it was perceptibly polarised itself. This would tend to show that the light was reflected from the moon itself, and not from the intervening atmosphere.

G. K. WINTER

Erratum of the Errata, or, "A Few Millions"

I AM indebted to Mr. A. Cowper Ranyard, of London, for calling public attention to errors existing in the illustrative appendix to a research entitled Acoustical Experiments, &c., which article of mine the Editor of NATURE honoured with a republication in his journal on May 9, 1872.

The existence of these errors has been known to me since a few weeks after the original publication of my paper; but as they did not affect in the least the subject proper of the research, and would be apparent to any one who might take the trouble to review the calculations, I allowed them to pass unnoticed, and even now would not pursue the subject further had Mr. Ranyard really corrected my errors; but he has *himself* committed the error of "A Few Millions" (the title of his communication*) which he would attribute to *me* when, in these words, he undertakes the correction of my figures. "Taking the velocity of light as 185,300 miles per second, and the wave-length of D_1, as given by Angström, at 0·00058950 millimetres, gives 5,058,700,000,000,000 vibrations per second, or a little more than *five thousand millions of millions*, instead of a little less than *six hundred millions of millions* vibrations per second, as given by Dr. Mayer." The following is the correct calculation:—

$$185,300 \text{ miles} = \frac{298,212,000.000 \text{ mm.}}{\cdot 0005895 \text{ mm.}} = 505,870,000,000,000$$

and 5,058,700,000,000,000 (Mr. A. C. Ranyard's result) minus 505,870,000,000,000 (Mr. Mayer's result) gives Mr. Ranyard 4,552,830,000,000,000 tremors.

Thus it appears that both Mr. Ranyard and myself commit errors in simple arithmetic, but I am sure that our mutual friends will not attribute them to want of sufficient mathematical culture to accomplish "a simple rule of-three sum." (A. C. R.) He that is without sin let him first cast a stone. I, however, do not wish Mr Ranyard's errors in any way to extenuate my own greater negligence which has disfigured the appendix of my paper, containing, as it does, "some strange numerical errors, which perhaps it will be well to point out, lest some of your readers should make use of the numbers given at the end of the paper without previously testing them." (A. C. R.) I will therefore ask my readers to substitute for the last paragraph under the heading of "Quantitative Relations in the Experiments and Analogical Facts in the Phenomena of Light," the following:—

"We will now examine the analogical phenomena in the case of light. Let fork No. 1, giving 256 vibrations a second stand for 508,730,000,000,000 vibrations a second, which will be the number of vibrations made by the ray D_1 of the spectrum, if we adopt 300,000 kilometres per second as the velocity of light. Then fork No. 3 will represent 504,750,000,000,000 vibrations per second, which latter give a wave-length ·0000048 millimetre longer than that of D_1, and belongs to a ray removed from D_1, towards the red end of the spec rum, by eight times the distance which separates D_1 from D_2. We saw that fork No. 3, giving 254 vibrations a second, had to move towards the ear with a velocity of 8·734 feet to give the note produced by 256 vibrations per second, emanating from a fixed fork; so, if a star, which only sends forth those rays which vibrate 504,750,000,000,000 times a second, should move towards the eye with a velocity of 2,442 kilometres, or 1,517 miles, its colour would change to that given when D_1 emanates from a stationary soda-flame."

ALFRED M. MAYER

* See NATURE, June 20.

Rev. John Ward on Atmospheric Germs

THIS worthy was Vicar of Stratford-upon-Avon, from 1662 till his death in 1681. He was a man of general knowledge, and was specially skilled in the diseases of women and children. It is not known that he obtained the archiepiscopal licence to practise physic, but he certainly practised the healing art, and he records his intention "to inquire whether a man may get of the archbishop a licence to practise *per totam Angliam!*" His diary, 1648-1679, is sensible and entertaining. It is chiefly known as containing a notice of Shakespeare, with the only extant account of the cause of his death, viz., "a feavour" caused by a carouse with Drayton and Ben Jonson. The Diary is in the Library of the Medical Society of London. It was edited by Dr. Charles Severn, and published by Colburn, in 1839.

The following extract is remarkable:—

"Venenum pestilens est congeries minimarum animalcularum per aerem volitantium, quæ corpora humana per respirationem aut poros subeuntes, eorum partes corrodunt et corrumpunt, ex iisque ad alia corpora volitantes, seu ad alia quocunque modo delatæ, et quasi contagio propagatæ, etram illa inficiunt, corrodunt, corrumpunt, sicut priora, e quibus evenerunt. . . . Supra fœnum cubare noxium multis fecit, non solum in peste, sed etiam in aliis morbis."

Of course *in peste* means "in the case of the plague."

C. M. INGLEBY

Coefficients of the Linear Expansion of Solids

AT the British Association which met last year in Edinburgh I suggested a *thermometer of translation* which should record the amount of the successive rises of temperature during the year. For this purpose a body possessing great expansibility with a fine needle point at its upper end, was proposed to be placed on a sloping frame, and made of a material possessing small expansibility, and protected from the changes of temperature, and having its upper surface finely serrated. When the body expanded, its upper end bearing the needle point would extend higher up on the frame, and when contraction commenced the projecting needle point would continue its hold of the teeth on the frame, preventing shortening at its upper end, so that the centre of gravity of the mass would be raised. In this way the successive increments of heat would be registered by successive *creeps* of the body upwards on the frame.

It has occurred to me that the same principle might be advantageously adopted for measuring the linear expansion of different solids.

In order to double the readings for expansion, clamping screws attached to upright rods fixed at the ends of the body would be better than the needle point for detention during contraction, which was proposed for the thermometer of translation. The bar to be experimented on would be placed on rollers in a vessel containing water or steam of different temperatures. The screws would be tightened at the lower end of the bar, and slackened at the upper before expansion, and tightened at the upper and slackened at the lower before contraction. After the contraction had fully taken place, the bar would be again heated and again cooled, and this process would be repeated until the total amount of translation became easily measurable. Although the amount of translation produced in any case by a single experiment might be scarcely appreciable, yet we can by cumulative repetition increase the amount of translation to any extent without increasing the errors of observation, for a single final reading is sufficient for the whole series of expansions however numerous

they may be. This single reading of the total amount of *creep* being divided by the number of times the experiment was repeated, and by the given number of degrees of heat through which it had been each time successively raised, and by the original length of the bar, will give the desired coefficient of expansion.

I think that results obtained by this mode of translation will, for minute expansions, be more reliable than those obtained either by Lavoisier and Laplace's method, or by that of Roy and Ramsden.

THOMAS STEVENSON

Baden-Baden, August 26

Origin of Insects

IN NATURE of December 7, 1871, there is an interesting letter from Mr. B. T. Lowne, on the Origin of Insects, in which the writer refers to Fritz Müller's "Facts for Darwin" in favour of the opinion that "the larval forms of insects are probably derived from imaginal" or perfect forms. I have not at present any opinion to offer on this subject; but, though I estimate very highly indeed the light which Fritz Müller has thrown on the Crustacea, I think nothing can be more unsatisfactory than his remarks on insects. He concludes that the earliest insects resembled the wingless Blattidæ, overlooking, what is obvious enough, that any theory of the origin of insects ought to account for, or at least show the origin of, those most characteristic organs of the class, the wings. I quite agree with Mr. Lowne that "it is extremely probable that insects first emerged from the water with fully-formed wings." I think it scarcely possible to doubt that the wings were originally organs of aquatic respiration. But this does not answer the question of the origin of insect metamorphoses, which, though an evolutionist, I think one of the greatest difficulties of the theory of evolution; it does not answer the question whether the perfect forms with wings and legs have been derived from the larval forms without either, or the converse.

Mr. Lowne goes on to say, "We have still relics of an aquatic winged insect fauna in the hymenopterous genus, discovered by Sir John Lubbock." I cannot think this brings us any nearer to the origin of insects. It could not do so unless the Hymenoptera were at or near the origin of the class, and this will scarcely be maintained. The Hymenoptera are probably the highest of all insects—certainly so if instinct is the criterion. The aquatic Hymenopteron (I do not know its name) is no more a relic of the origin of insects than are the water-beetles; and no one will say that the Coleoptera are near the origin of the class. It is true that the water-beetles are wingless, while the Hymenopteron in question is winged; but the beetles are a winged order, and those which have no wings have lost them. Indeed, it is only in a functional sense that any beetle is wingless, for they all retain the wing-covers, which are modified wings. It is probably true that the origin of all animals whatever was aquatic, but it does not follow that the aquatic members of any class denote the origin of the class. The aquatic habits and structure may be only adaptive. No one would look to the seal or the hippopotamus for the origin of the Mammalia.

JOSEPH JOHN MURPHY

THE LAW WHICH REGULATES THE FREQUENCY OF THE PULSE

FROM a pamphlet on this subject, recently published by Mr. A. H. Garrod, we extract the following summary of the main features of the circulation :—

"The circulation of the blood is maintained by the repeated contraction of the heart. Each cardiac revolution is divided into three parts—the systole, the diaspasis, and the diastole. The following laws hold with regard to the length of these intervals :—

"I. The systole, together with the diaspasis—or, in other words, the first cardiac interval—varies as the square root of the whole revolution.

"II. The systole varies as the square root of the diastole.

"III. The diaspasis is constant.

"The amount of work that the heart has to perform in maintaining the circulation depends on two sets of changes which may occur in the system: 1. Variations in the blood pressure; 2. Variations in the resistance to the outflow of that fluid from the arteries.

"As the capacity of the arteries, including the ventricles, varies directly as the blood pressure, and as the flow of blood from the capillaries does the same, the frequency of the heart's beats is dependent on the resistance to the capillary outflow, and not at all on the blood pressure; in other words, the heart always recommences to beat when the blood pressure in the systematic arteries has fallen a certain invariable proportion.

"Variations in blood pressure result from: 1. Absorption into, and excretion from, the vascular system of fluids; 2. Changes in the capacity of the arterial system, which occur on the contraction or relaxation of the muscular arteries; 3. Changes in the amount of available blood, which result from the hæmastatic dilitation of some of the yielding vessels on altering the position of the body. As changes in the first of these cannot be very sudden, and those in the latter are never very considerable, the mean blood pressure in health varies but little during short intervals.

"Variations in peripheral resistance result from: 1. Different degrees of tonicity or patency of the muscular arteries; 2. Different resistances in the venous system. The former may occur independently in one or other system of vessels, as the cutaneous or the alimentary; also mechanically from pressure on a part of the body. The latter are insignificant in health.

"The heart depends for its power of doing work on chemical properties in the blood it pumps into the systemic vessels, and as the blood reaches it direct from those vessels, the cardiac intramural circulation varies with the changes in the former; and the length of the systole varying only as the square root of the time of diastole, the degree of cardiac nutrition varies directly as the systematic blood pressure, and as the square root of the diastolic time. The coronary arteries supplying the whole heart, the work done by the right ventricle is governed by that done in the left; thus the supply of blood in the left auricle is always rendered sufficient for the requirements of the systemic circulation; though, as there is no reason for believing that the resistance in the pulmonary vessels varies with that of the systemic, there must be some peculiarities in the former circulation (which may explain the variations in the ratio of the number of pulse beats to respirations in some cases).

"The auricular contraction is a very small force, and its function is most probably to close the tricuspid and mitral valve.

"The heart commencing its systole as a whole, it is highly probable that the impulse for action is given by a force which affects both ventricles; such is found in the coronary circulation and the active diastole produced by means of it."

THE CONGRESS OF PREHISTORIC ARCHÆOLOGY

THE meeting of the International Congress of Archæology at Brussels was brought to a close last Friday, August 30. On the previous Tuesday General Faidherbe spoke on the Dolmens, of which he had made a special study in Algeria. He believes them to be the work of some people whose traces can be found from Pomerania to the coast of Africa, and of whose migrations they indicate the halts. Mr. Franks, of the British Museum, presided on the afternoon of the same day, when the discussion turned chiefly on the primitive races of Belgium. On Wednesday the last expedition of the Congress took place, Namur and the Camp of Hastedon, distant about two kilometres from Namur, being the places selected. The establishment of this camp, covering an area of from eleven to twelve hectares, is attributed to the men of the Polished-Stone period. It is situated on a high plateau, and the cuttings made through the ancient enclosure were explained by M. Dupont, Director of the Brussels Museum.

M. Dupont dwelt chiefly on the fact that at the epoch of the Mammoth there were two perfectly distinct populations in Belgium, one using the flint cut at Spiennes, near Mons, and the other that of the Somme. The highly interesting Museum of Archæology belonging to the town of Namur was afterwards examined by the Congress. At the meeting of Thursday, M. Dupont traced the connection of the various populations in Belgium among each other at the different ages of stone; after which a lively debate arose on the question of the descent of the present race of men from the troglodytes, and on the causes of the difference of types. In the afternoon the problems of the Tertiary age and the age of Bronze occupied the Congress. On Friday morning the question of determining the relative remoteness of the ages of bronze and of iron led to many valuable disquisitions; and Mr. Hyde Clarke gave a summary of the recent anthropological discussions at Brighton.

M. de Quatrefages summarised the results of the present Congress, and stated as the principal ones that the elements of the prehistoric populations—even of the age of stone—are discernible in the present population, and that even in the most remote ages the migrations of races took place on a much more extensive scale, and with more frequency than was believed by any one till recently. M. Vervoort, one of the Belgian vice-presidents, next presented to the Congress, in the name of M. Geefs, the well-known sculptor, a bust of M. d'Omalius d'Halloy, who presided in person at this the last meeting of the Congress. This bust is a most striking likeness of the venerable *savant*, who was congratulated by M. de Quatrefages, speaking for the Congress, on the homage rendered to him by his colleagues. M. d'Halloy's services to ethnography have been long and valuable, and his vigour of mind and youngness of heart are astonishing in a man on the verge of ninety.

The proceedings terminated with the distribution to the members of a commemorative bronze medal on the part of the Belgian Government. This medal, having a diameter of nearly seven centimetres, bears on one side, within a laurel wreath, the inscription, "Congrès International d'Anthropologie et d'Archéologie Préhistoriques à Bruxelles. 6e Session, sous la Présidence de M. T. T. d'Omalius d'Halloy, 1872." The obverse represents the Genius of Science as a female figure, seated, and pointing with her left hand to the entrance of a cavern, bearing the inscription "Furfooz," and a mammoth's skull; while on the other side of the figure the geologist's shovel and pickaxe are displayed. The medal is by M. J. Geerts, of Brussels, and is very finely executed. M. d'Omalius then formally declared the Congress terminated, congratulating the members on the scientific progress achieved, and the harmony which had characterised the meetings.

In accordance with the invitation of the Swedish Government, the next assembly of the Congress will take place at Stockholm in 1874; the proposition to confer the presidency on that occasion on Prince Oscar of Sweden was carried by acclamation. On Saturday the members of the Committee, Belgian and foreign, dined with the King.

THE FRENCH SCIENTIFIC ASSOCIATION

AMONG the subjects expected to be discussed at the general meetings of the French Association at Bordeaux are one on Fermentation, by M. Pasteur, and another on Aërial Navigation, by M. Dupuy de Lôme. In the Mathematical Section, M. d'Abbadie is expected to read a paper entitled "Expériences pour constater les variations de la verticale." In the Physics Section, M. Cornu reads a paper on the "Velocity of Light;" M. Mercadier, one on "Musical Intervals;" M. Poter, on the "Theory of Light." In the Chemical Section, M. Berthelot is to speak on "Questions of Chemical Philosophy," and M. Wurtz on "The Densities of certain Vapours, and particularly on the Density of the Vapour of Perchloride of Phosphorus." In the Meteorological Section, M. Marié Davy is expected to read a paper on "The Organisation of Meteorological Observatories."

Other expected papers are—In Geology, M. Daubrée, "Beds of Phosphates in the South of France;" M. des Cloiseaux, "Amblygonite and Martebrasite." In Botany, M. Baillon, on "*Rheum* and on the Botanic Origin of Officinal Rhubarb;" M. Chatin, "Study of the Development of the Ovule and the Grain in the Scrophularias." In Zoology, MM. de Follin, Fischer, and Périer, contribute a paper on "Recent Submarine Explorations; M. Chatin, "Researches on the Odorous Glands of certain Mammifers;" Dr. Pouchet, on "Animal Pigments;" M. de Quatrefages, on "Some Species of Inferior Animals of the Basin of Arcachon." Anthropology, M. Broca, on "The Occipital Angles." Geography, M. Gustave Lambert, on "An Expedition to the North Pole."

The Excursions are:—1. To the embouchure of the Gironde, to inspect the encroachment on the coast. 2. To Arcachon, to visit the oyster-beds, dredge the sea for molluscs, &c. 3. To Les Eyzies, to inspect pre-historic remains and bone-caves. 4. To Roueyre, to inspect the iron of the Landes, &c. 5. To Bidassoa, on the Spanish frontier, to inspect a rich bed of iron ore. 6. To Medoc, on a visit to the celebrated vineyards of Château-Margaux and Château-Montrose. Besides these excursions, visits will be made in Bordeaux itself, to M. Gintrao's establishment for rearing silkworms in the open air; to the docks, dockyards, &c., and the artesian wells of Vigan In our last number we gave a list of the public lectures.

TEMPERATURE OF THE SEA BETWEEN GREENLAND, NORTHERN EUROPE, AND SPITZBERGEN

PROF. H. MOHN, Director of the Norwegian Meteorological Institute at Christiania, publishes in *Petermann's Mittheilungen* some important facts regarding the variations of temperature in the North Atlantic. The yearly variation of temperature of the surface stratum amounts to 9° Fah. and more; it becomes less as we go down, the decline, however, being not everywhere the same. Deep-sea strata reach their lowest and highest temperatures a little later than the surface stratum, the changes offering two very distinct aspects for summer and winter. Deep-sea observations in several of the deep fjords along the Norwegian coast, which are protected against the great depth of the Atlantic by submarine ridges lying before them, show that the water in them is derived from the Gulf Stream, and that they are filled with it from top to bottom, even if the latter lies deeper than the icy bed of the Gulf Stream outside the coast region; were this not so, the temperature of the water in the fjords would be a much lower one, and Norway would not enjoy such a happy union of land and sea climate. In summer, near the coast of Norway, and in its fjords, at a depth of from 100 to 300 fathoms, we find a uniform temperature of about 44° Fah.; farther out to sea, however, at the same depth, only about 39° Fah. The deep-sea temperatures in winter are less known, but it is almost certain that at great depths the same temperature reigns all the year round, although a continual cooling from the surface downwards necessarily takes place in winter. In the north-western part of the Greenland Sea, and below the depth of the Gulf Stream, exclusively icy water is found, which somewhat compresses the latter on that side, at any rate on the surface, where the water cooled during the winter nights remains over the warmer waters beneath. Along the coast of Norway the cold from the land acts on the surface and the upper strata of the sea, increasing

with the nearness of the land, so that here the temperature of the sea rises with its depth, and the axis of warmth of the Gulf Stream is moved away from the coast towards the open sea. Taking the form of the Gulf Stream as that of its surfaces having the same temperature—isothermal surfaces—we can compare it with the shape of one of the small boats called prams, which are broadest at the stern, deeper in the centre than behind, and possessing a somewhat rounded stem. The stern of this Gulf Stream pram is formed by a vertical section from Iceland to Scotland; the longitudinal section forms the axis of warmth, running along the coast of Norway. The side nearest the Polar Ocean (the larboard side) is much more considerable than the starboard side, which leans against the Norwegian coast. In summer the starboard side is pushed quite close to the Norwegian coast, and hangs strongly over, while the larboard side is perpendicular, or only slightly inclined outward; the keel near Spitzbergen sitting deep in the water. In winter the starboard side is thirty (geog.) miles broad, and has in the parts lying nearest to the coast sides strongly inclining inward, while the strata in the centre and those bordering on the Polar Ocean rise nearly perpendicularly, the keel in the fore part raising itself almost into the position of the stem, which ends in the same point as that formed by the isotherms of the surface at this season. Generally this aspect is only presented by the part of the sea which lies westward from Norway and partly from Spitzbergen.

The warm waters of the Novaja Semlja Sea are like a wedge placed horizontally, with its base between Spitzbergen and Norway, and its horizontal sharp edge turned towards the north and east.

THE ROYAL SOCIETY OF VICTORIA

WE are glad to notice the progress of Science in Victoria as exhibited by the address of the President, Mr. Ellery, on the occasion of the annual *conversazione* held on July 8. We reprint the following extracts from the *Argus* of the following day:—

"We have now entered upon our fifteenth session, and as you have done me the great honour to again choose me as your President, it devolves on me, in accordance with our rules, to address you on the past year's history and progress of the Society; and also to call your attention to some of the more noteworthy facts which mark the last year's history of general scientific progress. First, then, in reference to our own business, I regret to have once more to inform you that, since the last publication of the *Transactions* of the Society, the funds have not been in a sufficiently flourishing condition to enable the council to resume the printing. For many years past the only revenue of the Society has been that derived from entrance fees and subscriptions of members. From this not only the current expenses but the interest on money borrowed for carrying out the alterations and additions to our buildings has to be paid; and although our income will amply meet these demands if the annual subscriptions of members are regularly paid, there has hitherto been an insufficient sum left to print our *Transactions* without other aid. The Government have been solicited for help every year since 1867, when the last aid was granted to us by Parliament. The council hope, however, that this year their request will be acceded to. I am happy to state, moreover, that (many arrears of subscriptions having been received of late) the financial condition of the Society is just now better than it has been for years. It is intended, therefore, at all events to at once print the *Transactions*, and the council trust that they may be able henceforward to publish promptly and regularly the proceedings of our meetings, which they will be quite able to do if the Parliament resumes its small annual grant-in-aid. Our last anniversary meeting was held on August 14, 1871. Since that time the Society has held eight ordinary meetings. On September 11 a valuable paper 'On Ocean Waves and their Action on Floating Bodies,' was contributed by Mr. Deverill. Mr. Macgeorge also read a paper, contributed by Mr. Horne, of Adelaide, 'On a Linear Method of Finding the Stability of Ships;' and Mr. Pain, on 'Aboriginal Art and its Decadence in Australasia, Polynesia, and Oceanica.' The meeting of October 9 was occupied with Mr. Macgeorge's account of 'Changes in η Argus,' and Mr. G. Foord's 'Aërometer for Measuring Specific Gravities.' On November 13, our next meeting, the Rev. W. Kelly and Mr. Bosisto contributed papers, the former on 'On a Method of Combining Marsh's Test for Arsenic with Reinche's, so as to secure very reliable results;' the latter 'On the Cultivation of *Mentha piperita* in Victoria.' On November 22 it will be remembered the Australian Eclipse Expedition started from Melbourne. Our next meeting was a special one held on January 22, and was devoted to matters connected with the Eclipse Expedition, and to the approaching elections of council and office-bearers, which took place on our next meeting, on March 11. In April Mr. Harrison read a paper 'On Patents and their Utilisation.' Mr. Caldwell contributed one on 'Meat-preserving,' and Mr. P. F. Foord 'On Bi-angular Co-ordinates.' On May 13, Mr. F. Poolman read a description of his 'Self-Acting Safety Regulator and Coal Economiser for Steam Engines,' and Mr. A. K. Smith exhibited and described 'An Improved Valve for the Fire Plugs in Water Pipes,' the object being to prevent the entry of sewage water into the pipes when the pressure was off—a thing that might occur with the ordinary fire-plug valves. At our last meeting, on June 10, Mr. Macgeorge contributed the 'Results of Observations on Sirius and its Companions' with the great Melbourne telescope. Mr. White exhibited some new five-figure card logarithms which he had arranged, and Mr. Gibbons read a few 'Notes on M. Berthelot's Analysis of the Cranbourne Meteorite.'"

After alluding to the reports received from the Austra- Expedition for observing the total eclipse of Dec. 12, with which our readers are already acquainted, the President continued:—

"I have but little of more than ordinary interest to record of the past year's history of our several science or art institutions. The Technological Museum attached to the Public Library has made considerable progress; not only have the Commissioners established classes of chemistry, mineralogy, and practical mining, but have organised evening courses of lectures on popularised science and art. These have always been so well attended that it is to be regretted that a larger lecture-room than the one which was built for class teaching has not been erected. The earlier courses of these lectures have been printed and circulated by the Commissioners. They appear to have attracted considerable attention in England and on the Continent, especially those by Baron von Mueller on Forest Culture, and the purely technological series of Mr. George Foord. Prof. Negri, president of the Royal Geographical Society of Italy, in referring to Baron von Mueller's lecture, said he wished the Italian Government would have it translated into Italian and circulated throughout the country. A telegraph class for ladies has also been established in connection with the museum, at which pupils are instructed in the manipulation and ordinary use of the Morse telegraph instruments. It is intended, I believe, to hold periodic examinations of the pupils, and to grant certificates to such as prove themselves to be competent. The most recent step in the right direction the Commissioners have taken is the appointment of a gentleman of undoubted ability to conduct classes in geometry and mathematics. The additions that have been made from time to time to our national gallery of pictures now form a most valuable and beautiful collection, and it seems well adapted to fulfil one of its

principal objects—the foundation of a school of painting. Already we have seen in Melbourne copies after pictures in our national collection of no small merit, and giving good promises of future excellence. For so young a colony as ours the number of students is even now large, and is, I hear, increasing. The National Museum at the University, under the care of Prof. M'Coy, is becoming more complete and perfect every year; the space that has become available, through the removal of many of the mining and machinery models to the Technological Museum will be most advantageously bestowed upon numerous beautiful specimens and collections which hitherto have appeared somewhat too crowded. Botanical science in the colony, represented by our fellow member, Baron von Mueller, has made considerable progress during the past year. I have already referred to his lectures on forest culture, in which he clearly set forth the more important and lasting objects of a botanical department in a new country, and, to quote his own words, 'A botanic garden has not merely to gratify the passing hour, but has to fulfil great objects of the whole community, as well for this as for the coming generation.' Baron von Mueller, I am glad to say, intends shortly to issue some popular works on Australian botany; the first, I believe, is to be devoted to the ferns, and it is intended to illustrate it by photo-lithography. I have been also informed that Count Castelneau, the well-known zoologist, has prepared a descriptive essay on the fishes of Victoria, which is to be issued with the report of the Acclimatisation Society. I refer to these points, although they do not belong to our past year's history, because they indicate scientific vitality and progress; and although the fruition may belong to another year of this Society, the work evidently belongs to this. In our Observatory one of the most interesting results of the past year's work is the establishment of the fact that the nebula in η Argus has not only undergone marked change since the time it was observed and drawn by the late Sir John Herschel at the Cape of Good Hope, but has also exhibited notable change since the erection of the great telescope in Melbourne. Drawings of it made at intervals of only a few months, as was pointed out by Mr. Macgeorge in the paper he read before you at our October meeting, present such differences that we can now hardly escape from the impression that observable changes in this nebula take place very rapidly. Several observers in the southern hemisphere have devoted a good deal of attention and observation to this celestial object—notably, Mr. F. Abbott, of Hobart Town; Mr. H. C. Russell, director of the Sydney Observatory; Mr. Tebbutt, of Windsor, New South Wales; and Lieut. Herschel, in India. Mr. Abbott, I believe, was the first to draw attention to the fact that it no longer appeared as drawn by Sir John Herschel. Mr. Russell made a very careful drawing of the nebula as seen with the Sydney $7\frac{1}{4}$-in. refractor. Mr. Abbott also made some drawings from observations from a $4\frac{1}{2}$-in. refractor, and Lieut. Herschel by the aid of a 12-in. reflector. They have all indicated that the general appearance of the nebulæ differed considerably from that represented by Sir John Herschel's drawings, although none of the apertures used could in any way pretend to reach the more minute details grasped by Herschel's 2-ft. reflector. Several of the drawings which reached home had evidently not been executed with that precision which is so necessary to establish a fact of this kind in the minds of astronomers who are unable to see for themselves. There has arisen, therefore, in the minds of many of our most renowned observers in England and elsewhere, doubts as to the real existence of these changes. For it must be remembered that the immense distance of the nebulæ from us—probably far beyond the most distant stars—makes it necessary that changes such as these described, to be visible to us even with the aid of such light-gathering apertures and optical power as is possessed by our large telescope, must be stupendous in the highest degree, and almost beyond comparison with the most ordinary cosmical changes with which we are familiar. Now, since the great telescope has been erected, special attention has been given to this object. Mr. Le Sueur devoted a great deal of time, extending over long periods, to examination and drawings, repeating his observations again after the lapse of many months. He constantly referred to me to establish or throw doubt on his observations, so that I often observed with an unbiassed eye for this purpose. The stars down to the 16th magnitude were carefully plotted (those to the 12th magnitude with the micrometer), to form an unchanging groundwork for the mapping. He announced on several occasions in this society and elsewhere that there were unmistakable changes since Sir John Herschel's drawings. Mr. Macgeorge, who succeeded Mr. Le Sueur, and who has also observed and drawn the nebulæ constantly, pointed out to you in his paper in October last the progressive changes that had been noted. The diagram he then exhibited I had photographed and sent home to Dr. Robinson (one of the Great Telescope Committee), with a copy of Mr. Macgeorge's paper. The paper got home first, and Dr. Robinson says, in a letter I received last mail: 'I lose no time in forwarding the paper to Sir E. Sabine, Mr. Lassell, and Mr. Warren De La Rue. . . . . . Mr. Lassell seems to cling to the idea which he published some time ago, that there was no change whatever in η Argus. He justifies this suspense of opinion by not being able to refer to the drawings, a difficulty which I hope you will soon be able to remove. I think his real difficulty is an opinion that nebulæ must be at a distance much greater than that even of small stars, and hence an incapability of conceiving the possibility of such changes as could be visible to us.' The photographs reached him by next mail, and he then writes:—'The photographs are very remarkable, and I think it is impossible to look at them and doubt the reality of the immense changes that have taken place. Are these changes periodical? I send one of the photographs by this post to Sir Edward Sabine, with request to forward it to Messrs. Lassell and De La Rue.' It is to be regretted that the minute and careful drawings made by Messrs. Le Sueur and Macgeorge have not yet been engraved, as they establish the facts beyond all doubt, as the photographs sent home were from a somewhat rough diagram intended only to show the principal features of the observed changes. No one accustomed to observing could fail to be convinced of change going on, if he only saw the nebulæ with a power of six or seven hundred on the great telescope on good nights at at intervals of three or four months. Mr. Macgeorge reports from observations made only two months since that still further changes were evident. The full significance of these changes can hardly yet be estimated; but they overthrow many of our hitherto-received notions of the condition of these tenants of space. It is a subject of the highest interest in physical astronomy, and one that will demand unremitting observation and drawing for its further elucidation. I am glad to inform you that the Government has given me authority to publish every month the results of our observations in meteorology, terrestrial magnetism, and of other phenomena; the numbers from the commencement of the year till the end of May are already before the public. By this means all the useful information derivable from the Observatory work in these branches of investigation is made quickly and generally available. Photography of celestial objects has been commenced with the great telescope, and some exceedingly fine and promising negatives of the moon were taken, enlargements from which have already been exhibited at one of our meetings. Since April the weather has been too unfavourable to proceed with this work. Attempts to obtain photographs of planets and nebulæ

have since been made; but while those of the planets promise well, no impression whatever of the brightest nebulæ could be secured. Among the many subjects which have occupied a large share of the attention of scientific circles in the older world, and which mark indelibly the progress of scientific research during the past year, there is one which appears to me of surpassing imporance. The Royal Astronomical Society awarded its gold medal this year to Prof. Schiaparelli, director of the Observatory at Milan, principally on account of his researches on the relations that exist between comets and shooting stars. You will remember in a former address I had the honour of delivering to you, I spoke of the 'meteor shower' which fell in Europe in November 186—, and that it had been established beyond a doubt that these bodies travelled in orbits intersecting that of the earth at different points; that one coterie intersected it in November, another in August, and so forth. Since then, however, it has been found from observation that the number of these meteor rings is very large, and that they intersect the earth's orbit at numerous points. And it may be stated generally, that all falling or shooting stars, at the time we see them, are, or have been very recently, members of groups travelling in true orbits, and not merely stray wanderers in space. Prof. Schiaparelli has concluded from his researches that 'celestial matter may be divided into the following classes:—1. Fixed stars. 2. Agglomeration of small stars (resolvable nebulæ). 3. Similar bodies, invisible except when approaching the sun (comets). 4. Small particles, composing a cosmical cloud.' He thinks the last occupy a large portion of space, and have motions similar to fixed stars. The latter are the sources of falling stars. Brought by the motion of our system in space within the sphere of our sun's attraction, they become in a measure part of his family and subject to him. If, while making their sun journey, they approach a planet—the earth for instance—they get disturbed in their orbits, and, becoming subject to the earth's mass, liable to enter the upper regions of our atmosphere, under which condition they appear to us as 'shooting stars.' 'Thus meteors and other celestial phenomena of like nature, which a century ago were regarded as atmospheric phenomena—which La Place and Olbers ventured to think came from the moon, and which were afterwards raised to the dignity of being members of the planetary system —are now proved to belong to the stellar regions, and to be in truth falling stars. They have the same relation to comets as the asteroids have to the planets; in both cases their small size is made up by their greater number. Lastly, we may presume that it is certain that falling stars, meteors, and aerolites differ in size only and not in composition; therefore we may presume that they are an example of what the universe is composed of. As in them we find no elements foreign to those of the earth, we may infer the similarity of composition of all the universe—a fact already suggested by the revelations of the spectroscope.' Professor Schiaparelli had noticed a remarkable likeness between the elements of the orbits of some of these meteor groups to those of some well-known comets, the perihelion passage occurring approximately at near dates, the direction of their motion alike, the point they intersect the ecliptic, and their inclination to it very similar, while the distances of their nearest approach to the sun, and their period of revolution, have also a marked likeness. The relations are very remarkable, and Prof. Schiaparelli concludes one of his last memoirs on this subject in these words:—'These approximations need no comment. Must we regard these falling stars as swarms of small comets, or rather as the product of the dissolution of so many great comets? I dare make no reply to such a question.' The conclusions of Prof. Schiaparelli are of the highest interest, and suggest some new and interesting questions on the constitution of the universe. Are the irresolvable nebulæ systems of these cosmical particles? If so it will add a fresh interest to our observations of the changes going on in that of η Argus.

"In a new country, such as ours, in which all are so fully engaged in business pursuits, it would be unreasonable to expect so large an annual crop of scientific facts as are realised in the older countries; but as the fields for original observations in a new country are really wider in many respects than in the older, it is of course, of the first importance that what we do obtain should be properly recorded and disseminated. I have mentioned that the Society's *Transactions*, the printing of which has been too long suspended, will be immediately resumed, and I believe I may confidently state that the present prospects of the Society are such as to warrant the belief that they will henceforth appear with regularity. It should be remembered that although this Society has how existed for so many years, its ranks are still thin, wanting both workers and supporters. It has been recently proposed in your council, as a means of strengthening and increasing the utility of the Society, that a rule should be adopted to admit of residents at a distance joining us as country life-members, on the same scale as ordinary members are now admitted, by payment of half the usual subscription. This will entitle such members to the Society's publications, and to all the privileges of membership when in Melbourne. I have chosen the earliest occasion for announcing this proposition, which will no doubt be presently adopted by the generality of the members. I also wish to remove an impression which, I believe, holds some ground, that advanced scientific attainments are indispensable qualifications for membership. The object for which our Society is founded was the promotion of literature, science, and art in the colony. Whoever can assist in this is, so far, eligible for membership."

NOTES

MR. STANLEY has forwarded to the daily papers a letter from Zanzibar, dated July 22nd, stating that communications have been received from the interior, which render it probable that Dr. Livingstone would receive his stores and letters about August 1st. In that case he would leave Unyamyembe about August 10th, and be now near Mrera, in Central Ukonongo.

THE following letter has been sent by Lord Granville to Mr. H. M. Stanley, the special correspondent of the *New York Herald*, accompanied by a magnificent gold snuff-box richly set in brilliants:—"Foreign Office, Aug. 27, 1872.—Sir,—I have great satisfaction in conveying to you, by command of the Queen, Her Majesty's high appreciation of the prudence and zeal which you have displayed in opening a communication with Dr. Livingstone, and so relieving Her Majesty from the anxiety which, in common with her subjects, she had felt in regard to the fate of that distinguished traveller. The Queen desires me to express her thanks for the service you have thus rendered, together with Her Majesty's congratulations on your having so successfully carried out the mission which you so fearlessly undertook. Her Majesty also desires me to request your acceptance of the memorial which accompanies this letter."

ON Monday evening the "Livingstone Search and Relief Committee of the Royal Geographical Society" met to consider its final judgment upon the conduct of the expedition under Lieutenant Dawson, which left England on the 9th of last February, and arrived at Zanzibar on the 17th of March, some months after Dr. Livingstone had been found and relieved by Mr. Stanley. The Society, however, adjourned the inquiry, and have agreed to put their questions in writing, so that Lieutenant Dawson may give them a categorical answer. The blue book

containing Dr. Livingstone's despatches of 1870, has been placed before Parliament.

THE *Times of India* of Aug. 9 contains the order of the local Government on the report of the Madras Cyclone Committee. In this order Mr. Pogson, the Government Astronomer, is severely blamed for his negligence in not giving due warning of the coming storm, as it was his duty and in his power to do. "Mr. Pogson," the order says, "endeavours to explain this omission as having been caused partly by an accident which happened to his carriage at noon on May 1, but partly also by disinclination to suggest anything to the Marine Department, his advice not having of late years been sought by that department. It does not appear to have occurred to Mr. Pogson that an occasion on which a most serious loss of life was imminent was not one for the indulgence of such susceptibilities. The Governor in Council considers that Mr. Pogson has failed to justify his negligence on this occasion. It is hardly necessary that the Government should, after the disastrous consequences of Mr. Pogson's neglect, inform him that they expect from him in future the strictest observance of that portion of his instructions which require him 'to furnish notices of approaching stormy weather,' and that the most essential part of his duty is constant, and, when necessary, personal communication with the head of the Marine Department." The Marine Department and all the officials connected therewith are severely blamed; and Mr. Dalrymple, the Master-Attendant, comes in for special censure on account of his negligence, and especially "for omitting to remain at his office during the night of May 1." The Government have ordered the appliances for saving life and property to be considerably increased, and accept in their entirety the recommendations of the Committee, which they resolve to adopt and embody in a code of rules, which will be communicated for the strictest observance by all the departments concerned.

NEXT year's London International Exhibition will consist of three divisions:—1. Fine Arts; 2. Manufactures; 3. Recent Scientific Inventions and Discoveries of all kinds. We notice that of the future Exhibitions that of 1874 will embrace Artificial Illuminations by all Methods; Gas and its Manufacture. 1875.—Hydraulics and Experiments; Supply of Water. 1876.—Photographic Apparatus and Photography, and Philosophical Instruments and Processes depending upon their use. 1877.—Health; Manufactures, &c., promoting Health, with Experiments. 1880.—Chemical Substances and Products, and Experiments; Pharmaceutical Processes.

WE have received some official details concerning the Universal Exhibition to be held at Vienna from May 1 to October 31, 1873. Her Majesty has appointed a large British Commission, headed by the Prince of Wales, to look after British interests in connection with this exhibition, which is expected to be of unusual interest, on account of Vienna being in a measure half way between East and West. The exhibition is to be held in the Prater—"the Windsor Park of Vienna"—in buildings erected specially for the purpose, and in the surrounding park and gardens. At no previous International, to judge by the official programme, have so many facilities been afforded to exhibitors. Especially is every encouragement given to the bringing forward of machinery of all kinds, the cost of exhibition to the owners being reduced to a minimum. If the Exhibition does not turn out a success, the blame can hardly be attributed to the Austrians. All information will be given to those who desire it by Mr. Philip Cunliffe Owen, Secretary to the Commission, 41, Parliament Street. British exhibitors can communicate with the Austrian Commission solely through the British Commission.

A BEQUEST of 10,000 fr. has been made to the Academy of Medicine in Paris by M. Fabret, for the purpose of founding a prize in mental and nervous diseases.

THERE has recently been formed at Amiens a Society calling itself "Société Linnéenne du Nord de la France," having for its object the study of all the branches of Natural History in its wide sense, and is divided into three sections—Zoology, Botany, and Geology. The society will hold general meetings, as well as meetings of sections, and during the favourable season will make excursions for the purpose of exploring the surrounding region. It intends to publish annually a volume of memoirs, and a monthly *Bulletin des Sciences Naturelles.*

WE are glad to be able to record the addition to the Brighton Aquarium, of a specimen of Muller's Topknot (*Rhombus hirtus.*) It was netted off the Brighton coast last week. But one capture of this rare fish off the Sussex coast is recorded by Yarrell, but it is more frequently taken off the Cornish coast. The interesting event is also announced of the birth of a young cuttle-fish, which signalised its entrance into the world by an immediate discharge of the sepia fluid.

SOME little time ago we referred to the proposed aquarium for Manchester (NATURE, vol. v. p. 487). A recent report of a meeting of shareholders, shows that it is hoped the building will be completed and opened next spring, and that temporary buildings with the necessary tanks have been provided for the reception of such marine animals and plants as can only be obtained in the summer season. They will then become acclimatised, and the tanks can be afterwards removed to their permanent places in the aquarium.

THE Committee for the Recording of Earthquakes in Scotland reported at the British Association Meeting that none had occurred within the past year. However, about the very time the report was being drawn up, and a few days before it was read, Scotland was visited by quite a sharp shock, which is thus described in the Scotch papers:—On Thursday, the 8th of August, an earthquake shock was felt at ten minutes past four o'clock at the Bridge of Allan, and was also felt over a considerable extent of country. At Braco and Kinmuck panes of glass were broken; at Dunblane and Bridge of Allan a number of houses were severely shaken, and glass was broken on sideboards. At about the same time the shock was felt in Stirling, and was attended by a loud rumbling noise like thunder. It is stated that no such sharp shock has been felt since 1839. In the evening a fine display of aurora borealis was observed in South Wales for nearly two hours.

A SLIGHT shock of earthquake was felt at Chopea, in Khandeish, on the evening of Friday, July 12, at about seven o'clock. The shock lasted for about a minute, and appears to have been felt at the same time at Amalner, Dhurrangaon, Dhulia, and Julgaon. Its course was from west to east.

A SLIGHT shock of earthquake is also reported to have been felt at Tripatore, in the Salem district in India, on the morning of the 15th of July.

AN earthquake shock was felt along the Long Island coast on July 11, and also in the northern part of Missouri, but it did no damage. A good deal of fright was caused in various Long Island villages.

A VERY violent tornado passed over Philadelphia on August 6. It was accompanied by vivid lightning and loud peals of thunder, and a tremendous downpour of rain. Trees were blown down, houses and churches unroofed, and much damage done by falling bricks and tiles, &c. No loss of life is reported, but the damage to property throughout the city is immense.

MANY of our readers will be glad to hear that Mr. Robert Swinhoe, H.B.M. Consul at Ningpo, China, is recovering from the serious illness which laid him prostrate about a year ago. Letters which were received from him by the last mail announce

his gradual convalescence, and that he was already resuming the zoological investigations which have rendered his name so well known to naturalists. Mr. Swinhoe has now succeeded in obtaining living specimens of the singular hornless deer which he lately drescibed, and figured in the "Proceedings" of the Zoological Society as *Hydropotes inermis*, and will forward them to that Society's gardens by the first opportunity. He has also obtained specimens of several mammals and birds new to the Chinese fauna.

THE *Madras Athenæum* of July 19 records the death of Capt. Mitchell, the Superintendent of the Central Museum, Madras, well-known as an accomplished naturalist and a gentleman of most engaging personal character.

DR. SCHWEINFURTH, the renowned German explorer in Central Africa, is about to return with the object of continuing his explorations, chiefly in the interests of botany. His brother, a merchant at Riga, has come forward with a handsome sum of money, the interest of which will be given to aid Dr. Schweinfurth in his undertaking, and will afterwards be handed to the Polytechnic School of Riga, to found a prize to defray the travelling expenses of future explorers who may have studied there with success.

WE learn from the *Madras Times* of July 18 that the pioneering party which was sent to Cummum some five or six months ago to bore for coal have been very successful in their operations, notwithstanding the difficulties and hardships they had to contend against. Three distinct and promising seams of coal have been struck, and the quality of the coal is spoken of as being superior to that of Sasti. The party will return to renew operations at the fall of the year. The attention of Government is also being drawn to the discovery of copper in certain districts where hitherto its presence was unknown. In the Nagur Kurnool the existence of this ore has recently been discovered, and samples of it are, with a piece of copper wire manufactured in the district, transmitted to Government, who have forwarded them to scientific men for examination and report. It is also said that copper ore has been discovered near Yedlabad, in the Indoor district; but doubts are entertained as to whether the ore is indigenous to the locality where it was found, or whether it has been washed down from the hills to the west of Yedlabad. This doubt is to be cleared up as soon as opportunity offers. The Government have also been recently directing their attention to the iron ore of the Cummum district. This is no late discovery, but the Government were not before aware of the abundance and excellence of the iron to be obtained in that part of their territories. This, it will be remembered, is also a promising coal district. So here we have side by side those two mighty engines of civilisation to which the "old country" is greatly indebted. It is much to be regretted that the resources of the territories are so imperfectly known. But the vigorous and earnest measures the Minister is taking to develop them will do much to bring them to light.

WE would recommend to those Interested in scientific education and the establishment of colleges of science in this country the report of the Massachusetts Institute of Technology for 1871-72. The subjects embraced in the course necessary to qualify as a graduate of the Institute are varied, and the curriculum in each department is comprehensive and thorough. For example, the course in the department of Geology and Mining Engineering extends over four years, and is so arranged as to secure to the student a liberal mental development and general culture as well as the more strictly technical education which is his chief object. The space devoted to laboratories, and the prominence given to laboratory work, in Physics, Chemistry, Assaying, Blowpipe Analysis, Metallurgy, and Ore-dressing, is a marked feature of the scheme of instruction of the Institute. The Institute seems to flourish as it deserves.

WE have received a reprint from the "Proceedings of the Liverpool Geological Society" of the address of the President, Dr. Ricketts, on valleys, deltas, bays, and estuaries. In a thoroughly praiseworthy and fair spirit he considers the opinions that have been held from time to time by different geologists on the subject of denudation, and especially the formation of valleys. His own interpretation of the facts deserve consideration, and the address as a whole is worthy of perusal.

THE *Journal de Physique* for August contains the third part of M. Cornu's paper, "Sur les Mesures Electrostatiques," and a paper on the Electric Chromoscope of MM. F. Lucas and A. Cazin.

WE take the following from the *Chemical News*:— There are no handbooks on chemistry in the Italian language; but a work has been in course of publication since 1867 somewhat similar to the first edition of the celebrated German "Handwörterbuch der reinen und angewandten Chemie," viz., "Enciclopedia Chemica," edited by F. Selmi, of Bologna, with the co-operation of Arnaudon, of Turin, for technical chemistry, and of Sestini, Paterno, and others, for pure chemistry. There are 2,000 subscribers to this work, which is highly valued in Italy. The Italian Government has appointed Dr. Cannizzaro, Professor of Chemistry at Rome; and 20,000*l.* has been voted by the Italian Parliament for the establishment of a chemical laboratory in Rome. The Florentine Institute (*Istituto Superiore*) receives, in addition to its present subsidies, an annual subsidy of 25,000*l.*, and will be converted into a kind of Polytechnic University.

THE following is from the *British Medical Journal*:— M. Lindeman continues his investigation of the parasitic bodies (Gregarinidæ) found on the false tresses and chignons commonly worn by ladies. They are to be found at the extremity of the hairs, and form there little nodosities, visible, on careful examination, to the naked eye. Each of these nodosities represents a colony of about fifty psorosperms. Each psorosperm is spherical; but, by the reciprocal pressure of its neighbours, it is flattened, and becomes discoid. Under the influence of heat and moisture, it swells; its granular contents are transformed into little spheres, and then into pseudo-navicellæ—little fusiform corpuscles, with a persistent external membrane, and enclosing one or two nuclei. These pseudo-navicellæ become free, float in the air, penetrate into the interior of the human organism, reach the circulatory apparatus, and produce, according to this author, various maladies—"cardiac affections, especially valvular affections, Bright's disease, pulmonary affections." M. Lindeman calculates that, in a ballroom containing fifty ladies, forty-five millions of navicellæ are set free; and he concludes that it is necessary to abolish false hair, which often proceeds from unclean persons.

WE have two small blue-books issued by the Government Meteorological Committee. They are both translations, specially intended for the use of seamen. The one, a paper issued by the Royal Meteorological Institute of the Netherlands, is Lieutenant Cornelissen's "Notes for the Navigation of the Indian Ocean between Aden and the Straits of Sunda," which gives details concerning the winds that affect that ocean, and contains four charts, having the outward and homeward routes for the four quarters of the year clearly indicated. The other is translated from No. III. of the *Mittheilungen aus der Norddeutschen Seewarte*; being a paper on "The Winds, &c., of the North Atlantic along the tracks of steamers to New York," and contains some carefully-constructed tables, showing the distribution, force, &c., of winds and storms in the North Atlantic throughout the year.

THE BRITISH ASSOCIATION

SECTION A—MATHEMATICAL AND PHYSICAL SCIENCE

On the Duty of the British Association with respect to the Distribution of its Funds, by Lieut.-Col. A. Strange, F.R.S.

IT is probably well known to most men of science in England that the British Association succeeded, in 1870, in inducing Her Majesty's Government to appoint a Royal Commission to inquire into the whole question of scientific instruction and the advancement of science. The Commission is composed of the Duke of Devonshire (chairman), the Marquis of Lansdowne, Profs. Stokes, Sharpey, Huxley, H. Smith (of Oxford), Sir John Lubbock, Sir J. Kay Shuttleworth, Mr. Samuelson (members), and Mr. J. Norman Lockyer (secretary). This powerful body has, since its constitution, been sedulously engaged in taking evidence. That which relates to "Scientific Instruction" has been already published, and it is now engaged in the second branch of its inquiry, namely, the "Advancement of Science." It is to this latter branch that the present communication refers.

Since the movement was begun at the Norwich Meeting of the Association in 1868, great progress has been made towards the formation of definite views as to the duty of the State with respect to Science. As having been myself examined by the Commission, and as having been in communication with many of the witnesses who have appeared before it, I am able, without intending to anticipate the publication of the proceedings, to say that the following specific points have been forcibly and extensively brought under their consideration:—(1) That the objects of scientific teaching and of scientific investigation are distinct, and require for their respective attainment distinct machinery; (2) That the State is bound, in the interests of the community, to maintain institutions—such as laboratories and observatories—for scientific research, apart from teaching; (3) That all State scientific institutions and action of every kind should be subject to the direction of a single Minister of State; and (4) That such Minister of State should have the assistance of a permanent, paid, Consultative Council composed of eminent men of science.

Of these measures, unquestionably the most important are the two last—a Minister and a Council. I believe I am justified in saying that the Commission are giving their most earnest attention to those fundamental steps on which the whole fabric of a consistent administrative system for science must be based.

The question having reached this point, it appears to me that the British Association may well now consider how they may still further advance it; and I beg to tender a suggestion to that end.

Of all difficulties in the way of science reform which, in the course of my study of the question, has appeared to me the most obstructive, I should pick out the confusion of thought which prevails as to what scientific objects should properly be undertaken, as a duty, by the State, and what objects may be safely left to be worked out by private enterprise. The confusion of thought exists even amongst scientific men; and it is characteristic in a much more marked degree of the occasional references to science made by the Government and by politicians generally. It appears to me that the British Association has it in its power to clear up this most prejudicial obscurity, and to contribute powerfully to the much-needed scientific education of the Government.

I will here briefly allude to a few recent examples of the confusion of thought to which I allude.

Mr. Gladstone, on two late occasions—namely, at the anniversary dinners respectively of the Civil Engineers' Institute and of the Royal Society—expressed the opinion that the more science was left to itself the better for it. He termed the intervention of the State as "interference" with science, calculated to discourage individual exertion, and so obstruct discovery and progress. If this opinion be sound, let us see what its consistent application must lead to. It must logically mean that the Royal Observatory, the British Museum, the Ordnance and Geological Survey, and our various botanical gardens and other scientific institutions, should forthwith be abolished as "interferences." No one has yet ventured to recommend this.

Such a recommendation would no doubt at once be met, even by Mr. Gladstone, by a clear exposition of the great importance to the nation of such institutions, and of the reasons why they cannot be maintained in efficiency but by the State. At once his general and sweeping proposition would thus be shown to be liable to so many and such extensive exceptions as utterly to destroy it as the basis of the argument. He would have, therefore, to deal with each example of proposed State intervention on its merits, and, before resisting it, to show that either it was not needed by the community, or that, being within the fair scope of private action, Government aid could be dispensed with. And this, in fact, is the only way in which we can possibly test the claims of science on the State. It seems to me that to substitute the term "interfering with science" for the more correct one of "aiding science" is as fair and rational as it would be to term our Post Office an interference with freedom of correspondence, our Railways an interference with freedom of communication, or our Police an interference with the good order of community. Yet many persons, who will not give themselves the trouble to think, will accept a word falling from an eminent man like Mr. Gladstone, even when so grievously misapplied as this, and will found upon it the most mischievous conclusions. I do not doubt for a moment that Mr. Gladstone used the word in all good faith, but I am also forced to believe that he cannot have applied his powerful and logical mind to this subject with the same energy and earnestness which have given him the mastery of so many others of equal or greater difficulty. When he has given it his full consideration, as he will shortly no doubt have to do, I am confident he will withdraw from the indefensible position he lately assumed.

Another recent example of confusion of thought as to the duties of the State is afforded by the refusal of the Government to aid in tidal researches. A committee of the British Association—of which its late president, Sir William Thomson, is chairman—has been for several years engaged on this subject. The funds provided by the Association being exhausted, application was made to Government for 150*l.* in aid. Her Majesty's Lords of the Treasury replied in these words:—"That they are fully sensible of the interesting nature of such investigations, but that they feel that if they acceded to this request it would be impossible to refuse to contribute towards the numerous other objects which men of eminence may desire to treat scientifically. Their Lordships must, therefore, though with regret, decline to make a promise of assistance towards the present object out of public funds."

If we contrast this refusal of aid to tidal researches with the aid afforded to the two last expeditions to observe solar eclipses, we shall be forced to conclude that mere parsimony and indifference to science cannot have dictated it, but that our statesmen have as yet arrived at no principle whatever on which such questions should be dealt with. The importance of eclipse observations is very great, but such researches partake, in the present state of our knowledge, more or less of a speculative character, whilst tidal researches, though bearing on various high cosmical problems, contribute in the most direct and practical manner—obvious to the least scientific person—to the welfare of our commerce and navy, and to many other branches of national activity. Yet several thousands of pounds, with the use of ships, were freely accorded by Government in the one case, and 150*l.* refused in the other. Such extraordinary inconsistency can only arise from the absence of due knowledge on the part of Government as to what are duties of the State in science and what are objects fairly devolving on private exertion.

The question I would now ask is—How can the Association help to impart this indispensable knowledge to Government?

In my opinion this can be done by the adoption on the part of the Association of some more settled rule for aiding science than those which at present prevail. So far as I know, the Association is guided, in making grants, by two main considerations only—first, the total sum at their disposal; second, the number and relative importance of the objects proposed. Acting principally on these considerations the Association has, in my opinion, whilst prompted by the most sincere desire to advance science to the utmost, contributed somewhat to the confusion of thought to which I wish to draw attention. By aiding numerous objects which, under a systematic administration of science, would unquestionably devolve on the State, they have, I fear, helped to justify that undue reliance on the all-sufficiency of private enterprise which Mr. Gladstone expressed, and on which the Government, in the case of the tides and in many others, have acted.

The remedy for this evil—which is every day becoming greater—that I would now propose is that the Association, in making their grants, shall discriminate more than they have hitherto done between objects which are national and those which are not national; and that they should give the preference to the latter. I would further recommend that a list of national scientific researches requiring immediate attention should be forwarded yearly

by the Association to the Government, with such advice as to the best mode of conducting them as may seem necessary; and that previous to each annual meeting the Association should request the Government to state what had been done with respect to such researches, the result being published in their annual volume of Proceedings.

It is not by any means my object nor my wish to bring the Association into collision with the Government. Such a result is strongly to be deprecated. But I do not believe it would follow from the course I suggest, whilst I see no other mode of putting in a practical form before the administration those urgent requirements of science on which so much of the material economy of the State rests.

The Association has undoubtedly the right to distribute funds entrusted to it by private individuals as may seem best for science. And being the most powerful scientific body in the kingdom, both intellectually and numerically, the duty properly devolves on it of endeavouring to remedy evils arising from imperfect knowledge of science wherever discernible. These two considerations afford an ample justification for the course I suggest, should it seem otherwise judicious.

It may be objected that no definite test exists by which we may discriminate between the two classes of scientific objects which for brevity I will call Public and Private. I therefore propose the following:—

Public science should be characterised by three principal features—(1) Continuity; (2) Probability of Expansion; (3) Unremunerativeness to the individual cultivating it, combined with profit or advantage to the community generally; (4) Costliness. Each individual research, properly Public, may not present all these three features in equal prominence, but with the great mass of questions which come before the Association there will be no difficulty, in most cases, in arranging each under the proper category. Cases of doubtful character must be classified according to the discretion of the Association, than whom no one can be more competent for the task.

I would here, in order to illustrate my meaning, mention a few typical cases of Public Science which the Association and other private bodies and persons have attempted to deal with. The Kew Observatory was one such case. An institution of that kind satisfies exactly all the three conditions constituting it, according to my definition, Public Science. It was discontinued chiefly on the ground that the cost of its maintenance, 600*l.* per annum, absorbed an undue proportion of the income of the Association. I was one of those who assented to its discontinuance, but on other grounds besides the one I have named. I considered that the annual sum spent upon it, though a large one relatively, was quite insufficient for such a purpose, that it needed great expansion, and finally that as long as such an institution existed, even on so contracted a scale, Government would not found a really sufficient one, as I considered they ought to do. After its relinquishment by the Association, Mr. Gassiot came forward and undertook the cost of its continuance. While offering my humble meed of admiration of such rare liberality, I must still say, what I urged when the arrangement was first proposed, that, though supplying to a certain extent a temporary want, it could not do so on the requisite scale, and that its effect would be to postpone the period at which Government would be able to see that such institutions must be maintained on the most liberal and comprehensive scale at the public expense. I also instance the subjects of Sewage, of Rainfall, of the Map of the Moon, and of the Tides, as bearing all the three characteristics of Public Science—and many others could be added. As to the Sewage question, the committee which undertook it no sooner began their labours than they perceived the utter inefficiency of the funds allowed by the Association. They sought to supplement these by appeals for help to the large towns, and questions of a delicate nature respecting the personal expenses of the members of the committee led to unpleasant consequences—the whole showing clearly that the subject was far too extensive, costly, and arduous for the powers and resources of private enterprise, and that it was, in fact, a national question which could be grappled with by national agency only.

As to the Rainfall question, it is well known that for several years Mr. Symons has devoted the greatest energy and skill to it, and that he has established a considerable number of rain-gauges all over the kingdom. He has received annual grants of money from the Association, but, unless I am misinformed, he considers the system which he has created still incomplete, and I believe he has incurred very considerable sacrifices in bringing it to its present condition. Now this case strongly illustrates the evil on which I have dwelt.

When, on the death of Admiral FitzRoy, the present Meteorological Office was established, no provision whatever was made for ascertaining the general rainfall of the kingdom. This, it was found, was being done by private enterprise, and the excuse for excluding one of the most important of meteorological elements from the programme of the State Meteorological Department was eagerly seized, although a little reflection would have shown that the very existence of the private system depended on the zeal and life of a single individual; indeed, it was threatened with total collapse that winter, in consequence of Mr. Symons' health failing from overwork.

The Map of the Moon was another large subject to which many eminent astronomers—of whom the late Sir John Herschel was one—attached much importance. The funds which the Association was able to furnish for the purpose being utterly inadequate, the project was abandoned. It is still kept alive by the zeal of Mr. Birt, assisted by a few friends; but its complete realisation by such means may be considered as indefinitely postponed. I am justified in assuming that the fact that the Association did make the attempt will be used, when the subject is pressed on the Government, as a proof that it is one properly devolving on private enterprise. I have already described the position of the Tidal question, which constitutes the most conclusive demonstration of the effect on the Government of such undiscriminating application of private funds and private enterprise.

I trust I shall not be considered, in consequence of what I have said on the subject, to depreciate or undervalue private enterprise. It is one of the just boasts of Englishmen that in no nation are there to be found such wonderful examples of individual zeal for high and unremunerative objects as here. Our colonisation, libraries, museums, hospitals and charities, the missionary agencies—all supported by voluntary means—surpass those of all the world put together. In some instances—as in that of our charities—private beneficence, for want of due direction, has actually gone too far and done harm. In science, also, England is pre-eminent for the number of observatories, laboratories, and other forms of activity maintained by individuals; whilst no civilised nation is so backward in its State organisation for science. The question I wish to raise is whether our private science, exuberant as it is, suffices for the national wants in the present age; and if not, whether the indiscriminateness of private scientific enterprise in England has not tended to induce the feeling that science is already sufficiently provided for, and does not need what Mr. Gladstone calls "the interference of the State."

I would strongly urge that no State organisation of science can possibly chill the zeal of private enterprise. The love of individual exertion, the pride of persona prowess, and the liberality of private wealth, are sentiments too deeply imbedded in the genius of Englishmen to be capable of such easy eradication. Nor will the Association find, that by the classification of scientific objects which I have recommended, there will remain of those which may properly devolve on individuals a number insufficient to absorb the moderate income which it has at its disposal.

The only other effect of such classification that appears to me open to possible objection is that some of the scientific objects which would otherwise be, however imperfectly, advanced by the help of the Association, may, by being referred to the Government, suffer total neglect. I at once admit that this effect will at first very probably take place in some instances. But for my own part I should be prepared to incur the risk of that sacrifice, in order to expedite a full consideration of the great question of the duty of Government towards science. The measure I propose is avowedly not intended to meet at once pressing temporary want, but to contribute to the creation of a great permanent system. It is my wish, not to ease, by small local applications, the sufferings of the patient, but to effect a radical cure. The treatment has as yet consisted of small expedients which, though they have given occasional relief, have not touched the seat of the disorder. I do not shrink from recommending, instead, a bold, if painful, operation that shall strike at the very root of the malady.

Report of the Committee for Discussing Observations of Lunar Objects Suspected of Change, by W. R. Birt.

The Committee have pleasure in presenting their Second Report on the above subject. It will be remembered that the Report of last year was confined principally to the discussion of

the possible variations of visibility of the numerous spots and craterlets upon the floor of Plato under the same conditions of illumination. That now presented is directed chiefly to the discussion of the various streaks and bright patches which interlace the spots and craterlets. One interesting and important change has been fairly shown; the floor of Plato becomes darker with the increase of the sun's altitude, Mr. Birt has offered an explanation of the phenomenon; whatever be the true cause of this change, it is very difficult to account for it by the ordinary laws of reflection; when we consider the varying aspect of the streaks at the same time of the luni-solar day, we cannot but think that, with careful observations made with powerful instruments such as the Newall refractor and many others, we may be able to confirm or otherwise a physical explanation of these curious changes involving the existence of certain gases and vapours upon the surface of the moon. The Committee can only look upon the study of Lunar physics as in its infancy, and they trust that in future years the Association will not overlook this important branch of astronomical inquiry.

After reading this Report of the Committee, Mr. Birt read extracts from his report of the discussion of the streaks on the floor of the lunar crater Plato which had been entrusted to him, the opening portion was to the following effect:—

"In completing the task assigned to me of discussing the observations of the streaks on the floor of Plato, I have been desirous of including every, even the most minute circumstance bearing on the exhibition of phenomena that may possibly illustrate the condition of a small portion of the moon's surface from April 1869, to April 1871. Drawing my conclusions from the experience of twelve years, I feel that I may confidently say that it may be some years before another series of observations of a particular region will be undertaken with the view of so closely examining the spots and streaks characterising it, unless a staff of efficient observers be organised, with the provision of a fund sufficiently ample to defray all the necessary expenses. The work is a difficult one, the staff should consist of not less than six devoted observers who would independently and most probably, as in the present case, work with instruments of varying aperture, and carefully record all their observations. The principal qualification is a keen eye for the appreciation of delicate variations of tint and the detection of minute spots of light, with a readiness of referring them by estimation and alignment to the respective localities of the region on which they are seen. The observations should not be allowed to accumulate, but should be forwarded at once to an experienced selenographer charged with the work of arranging and discussing them. Taking into consideration the results of the discussions of the present and previous years embodied in the two reports, it appears that in order to confirm these results and to open up new investigations the requisite time cannot well be fixed at less than three years—five would most probably afford the best results.

"The results of the present work may be briefly characterised as confirming by a direct reference to the sun's altitude above the horizon of Plato the supposition that variations of tint in some measure depend on increasing and decreasing altitudes. The ascending and descending branches of the curve obtained from independent estimations of tint by the several observers, are sufficiently near those of the sun's altitude to enable me to delineate a normal curve representative of the sun's influence in darkening the floor of Plato, or else in overspreading it with something of the nature of a dark covering as his rays strike the surface at the increased angle of about forty degrees. While this darkening influence comes out most unmistakeably, there are variations in the lighter and darker portions of the floor which are quite irreconcileable with solar influence of a gradual character. The treatment of the observations under intervals of the luni-solar day fails to bring out any regularity in these variations, and it is only by treating the observations *chronologically* that the true sequence of the changes can be detected."

Mr. Birt proceeded to notice that in order to assist in showing more distinctly the changes observed on the floor of Plato and their connection with certain supposed agencies, he had introduced the *hypothesis* of a dark obscuring medium overlying the surfaces of the lower parts of the moon; he did not insist upon this hypothesis further than its utility in connecting the observations. The Report, which was rather voluminous, referred especially to the influence of the sun on the floor of Plato; an examination of the changes recorded in August 1869, formed a separate portion of the Report as well as the history of a single streak from its first detection in September 1869, to the close of the observations. A considerable portion of the Report consisted of "Notes" furnished by the several observers.

SECTION B—Chemical Science

On Filiform Native Silver, by J. H. Gladstone, F.R.S.

The object of this communication was to show that metallic silver might be obtained artificially in the same filiform condition in which it frequently occurs in a mineral, and thus to throw light on the origin of this native variety. Specimens of the metal were exhibited, from Kongsberg in Norway, associated with calc-spar, and from Chili, associated with greenstone, and in each case the silver resembled twisted threads or wires non-crystalline, but often bending at sharp angles. Under the microscope were exhibited precisely similar threads of silver produced by the decomposition of nitrate of silver by sub oxide of copper. The latter substance is partly dissolved and partly converted into the black oxide, while filaments of the white metal shoot forth and bend in every direction. Most of these are extremely fine, perhaps $\frac{1}{25000}$ of an inch in thickness, so that, as was said, a gramme of such wire would stretch from London to Brighton. Since sub-oxide of copper is no rare metal, it seems probable that filiform native silver may often, if not always, originate from it.

SECTION C.—Geology

On the Occurrence of a remarkable Group of Graptolites in the Arenig Rocks of St. David's, South Wales, by John Hopkinson, F.G.S., F.R.M.S.

In a series of black, iron-stained shales, about 1,000 feet in thickness, which form the lowest beds of the Silurian rocks in the immediate vicinity of St. David's, the author noticed the occurrence of about twenty species of graptolite, which, he considered, furnished conclusive evidence of the equivalency of these beds with the Quebec group of Canada, the Skiddaw slates of Cumberland, and the Arenig rocks of Shelve.

The Graptolites, of which there are more than twenty species, were collected in the lower beds of the series at Ramsay Island and Whitesand Bay. Of the true Graptolites, or *Rhabdophora*, the only genera of undoubted occurrence are *Didymograptus*, *Tetragraptus*, and *Phyllograptus*. *Didymograptus* is represented by five species, three of which—*D. extensus* Hall, *D. patulus*, Hall, and *D. pennatulus* Hall—are characteristic of the Quebec group and the Skiddaw slates, *D. patulus* also occurring in the Arenig rocks at Shelve; the other species are new. Of *Tetragraptus* but one species, *T. serrus* Brong., also a Quebec and Skiddaw form, has been found. *Phyllograptus* also is only represented by a single species, which is new. There is also another new species—a very peculiar branching form referred provisionally to *Loganograptus*. The absence of any specimens undoubtedly referable to *Dictyograptus* is remarkable, as this is a common Quebec genus. *Diplograptus* and *Climacograptus*, genera of very rare occurrence in the Quebec group, have not as yet been found here.

Of the allied forms, all the genera of the so-called "Dendroid" Graptolites, so characteristic of the Quebec group, are present in the St. David's beds. *Phyllograptus* is represented by two new species, and *Dendrograptus* by five species, three of which—*D. divergens* Hall, *D. flexuosus* Hall, and *D. striatus* Hall—are at present only known to occur elsewhere in the Quebec group, the other not being new. *Callograptus* is also represented by five species, three—*C. elegans* Hall, *C. diffusus* Hall, and *C. Salteri* Hall—being Quebec forms, and two being new; and, lastly, of *Dictyonema* but one species, which is new, has been found. Many obscure impressions referred to the genus *Retiolites* also occur, one species seeming to agree perfectly, as far as its state of preservation allows of comparison with Prof. Hall's figures, with his *R. ensiformis* of the Quebec group. Another appears to be distinct from any species yet figured.

The Graptolites and their allies are now thus known to be represented in the Arenig rocks of St. David's by nine genera and about twenty-two species. Of the true Graptolites three genera—namely, *Tetragraptus*, *Loganograptus*, and *Phyllograptus*, are exclusively confined to the horizon of the Quebec and Skiddaw groups. The remaining genus, *Didymograptus*, is represented in higher rocks but by one species, *D. Murchisoni*. With this exception, *Didymograptus* is exclusively an Arenig genus occurring in rocks of this age in Canada, Cumberland and Shrop-

shire. The four genera of dendroid Graptolites have a more extensive range, but until now they were only known to occur together and in any abundance in the Quebec group of Canada.

The author then stated that he could now give another locality for these genera. During a recent visit of the Geologists' Association to Ludlow and the Longmynds he had found, at Shelve, in the lower part of the Arenig rocks, underlying the great mass of the Llandeilo, a Graptolite zone in which these four genera are represented by species, some of which are identical with, and others nearly allied to, those in the St. David's beds and in the Quebec group of Canada; these beds, and also the Skiddaw slates of Cumberland, being therefore of Lower Arenig age.

Prof. Harkness, after referring to the labours of Mr. Hicks, remarked upon the occurrence at so early a period, of so many new forms of life, alluding especially to the discovery of a star-fish. He thought the name Skiddaw would be more appropriate for the beds immediately underlying the Llandeilo flags, than Arenig, although he acknowledged that the latter name was one which had been a long time in use.—Prof. James Hall, of Canada, on being called upon, said that he had examined the specimens on the table and was much pleased to find the Graptolites from St. David's so intimately allied to those he had described from the Quebec group; indeed had he not known where these specimens had been obtained he should have thought that they had really come from some of the beds in Canada. Allowing for differences caused by pressure and cleavage, the resemblance between these and the Canadian forms was truly remarkable.—Dr. Nicholson said that *Didymograptus* had a wider range than Mr. Hopkinson had given, several species of this genus being found in the Llandeilo flags in the south of Scotland and elsewhere.—Mr. Hicks, in his reply, said that he was pleased to find that Prof. Hall so thoroughly agreed with his ideas of these beds in regard to their equivalents in Canada. In reference to the remarks of Prof. Harkness as to the name of Skiddaw being preferable to that of Arenig, he said that as some of the rocks in the Shelve district which had for some time gone under the name Arenig, were now proved to be the equivalent of these beds, he thought it best to adopt this name.—Mr. Hopkinson, in reply to Dr. Nicholson's observation on the genus *Didymograptus*, stated that the species referred to by Dr. Nicholson, in his opinion belonged to a distinct genus to which he had given the name *Dicellograptus*, and which differed entirely in structure from *Didymograptus*. He was very glad to find his views of the equivalence of the St. David's beds, as shown by their Graptolites, with the Quebec group of Canada so decisively confirmed by Prof. Hall.

Saturday, August 17.—*Sur les divisions de la Craie en France, leurs limites et leur faune, l'identité de ces divisions des cotés du détroit*, by Prof. E. Hébert.

The author objected to the divisions of the chalk commonly adopted in England, into chalk with flints and chalk without flints. He proposed to subdivide the chalk according to the characteristic fossils of certain horizons, affirming that the divisions thus adopted were constant, and could be applied as well to the English chalk as to that of France. Taking the Gault as the natural base of the chalk, he classed the overlying beds, in ascending order, as follows:—1. *Craie glauconieuse* (Upper Greensand and Grey Chalk); 2. *Craie à Inoceramus labiatus* (Chalk marl, chalk without flint, and part of the chalk with flint); 3. *Craie à Micraster cor-testudinarium* (part of the chalk with flints); 4. *Craie à Micraster cor-anguinum* (chalk with flints); 5. *Craie à Belemnitella mucronata* (Norwich chalk).

Between the first and second divisions comes the great series of Sandstones of the Maine; and between the second and third division comes the Hippurite limestone. These beds are not represented on the coasts of the English Channel, but at the points where the "breaks" occur there are hardened beds of chalk, often pierced with holes.

The author showed that the chalk area of the North West of France is traversed by five well-marked anticlinal folds, which run in a general south-westerly direction, but converging somewhat towards the coast. These folds the author identified with some on the English coast.

Mr. Davidson then made some remarks upon Prof. Hébert's paper, pointing out that the Upper Greensand in parts of England assumes a much more important character than that given to it by Prof. Hébert. Prof. Phillips, Mr. Godwin-Austen, and Mr. Seeley also took part in the discussion, Prof. Phillips remarking upon the great good that results from meetings of this kind, at which geologists of different countries could meet and personally discuss their views.

Monday, August 19.—Three Reports were read at the commencement of the meeting. That by J. Thomson, *On the Continued Investigation of Mountain Limestone Corals*, dwelt upon the great difficulty which had been experienced in determining the species and genera of corals. The author showed that all systems of classification founded upon the arrangement of special parts of the coral were artificial and misleading. He had prepared careful drawings tracing the coral through the whole of its stages of growth, and he believed that only in this way could we arrive at satisfactory results.

Prof. Duncan and Prof. Jas. Hall both insisted upon the great difficulties that were encountered in classifying corals. It was clear from this discussion that in the corals at least there is no lack of the "intermediate forms" which Mr. Darwin assumes to have existed in all groups of animal and vegetable life.

Dr. Bryce, in his *Report on Earthquakes in Scotland*, said, that nothing of importance had occurred during the past year, no disturbance of the earth's crust or oscillation of the lakes had been observed. The attention of the committee had been turned to the remedying of those defects which from time to time are apt to occur with instruments long in use. It was stated that the Seismometer belonging to the Association, which now occupies the lower part of the parish church of Comrie, is of too complex construction for general use. Simpler and cheaper instruments have been constructed by Mr. Geo. Forbes, which will be distributed amongst the stations of the Scottish Meteorological Society, and the results obtained will be detailed in a future report.

Mr. W. Jolly's *Report on the Discovery of Fossils in certain remote parts of the North West Highlands*, was likewise richer in promise than performance. Certain work had been done in investigating the limestones occurring with the Laurentian Quartzites and Sandstones, but the best part of the report was the announcement that the clergy and schoolmasters of the district had entered warmly into the projects, it was therefore hoped that before the next meeting of the Association a good deal of valuable information as to fossiliferous localities would be obtained.

On the Geology of the Thunder Bay and Shabendowan Mining Districts on the North Shore of Lake Superior, by H. Alleyne Nicholson, M.D., D.Sc.

Having recently had an opportunity of accompanying an exploring party to the north of Lake Superior, the author had been able to examine geologically the silver-mining district of Thunder Bay, and the gold-bearing district of Shabendowan (sixty miles to the north-west of Thunder Bay). Having described the chief geographical features of Thunder Bay, the author gave an account of the series of rocks known as the "Lower and Upper copper-bearing series." The chief argentiferous lodes were also described, and the more important mines were shortly noticed. The leading geological features of the country between Thunder Bay and Lake Shabendowan were next glanced at, and a detailed account was given of the geology of Lake Shabendowan itself The most interesting rocks described are the so-called "talcose" slates, in which the auriferous lodes are situated. These slates are of Huronian age, and they occupy, along with interstratified and intrusive igneous rocks, a vast area, which extends to an unknown distance north of Lake Shabendowan. Having described their mineral characters, the author expressed his opinion that these "talcose slates" are truly of the nature of bedded felspathic ashes, and that the talc which they often contain is a secondary product developed in them as the result of the metamorphic action to which the whole series has evidently been subjected. It was shown also that these Huronian slates, with their interstratified traps, presented the most striking resemblance to the Borrowdale series of green slates and porphyries of Cumberland and Westmoreland. The paper concluded with a description of the chief auriferous veins which have hitherto been found traversing these rocks.

On Ortonia, a new genus of Fossil Tubicolar Annelides, with Notes on the Genus Tentaculites, by H. Alleyne Nicholson, M.D.

Having recently had the opportunity of carefully investigating the genus *Tentaculites*, the author was led to the conclusion that fossils of diverse zoological affinities had been included under this head (Amer. Jour. Science and Arts, vol. iii. 1872). The author showed that some fossils formerly referred to *Tentaculites* were truly Pteropods, whilst others were genuine tubicolar an-

nelides. For some of the latter he had proposed the genus *Conchicolites*; and he restricted *Tentaculites* to straight unattached conical tubes. With this restriction the genus may safely be regarded as Pteropodous, since no Pteropod has an irregularly bent or twisted shell, and none can possibly have a shell attached parasitically to foreign bodies. In the present communication the author founded a new genus for the reception of a fossli which had been kindly sent him by Mr. Edward Orton, of the Geological Survey of Ohio, after whom he proposed to name the genus *Ortonia*. This fossil had formerly been referred to *Tentaculites*, and is of common occurrence in the Lower Silurian (Hudson River group) of south-western Ohio. No doubt can possibly be entertained as the proper reference of this fossil to the tubicolar annelides. Only a single species is known, which the author named *O. conica*, and this occurs in the form of conical tubes attached by the whole of one surface to the shells of Brachiopods and other molluscs, *Strophonema alternata* being the form which is most commonly infested in this way. The sides of the tubes are furnished with strong annular ridges, which die away upon the dor al surface, leaving a narrow vacant space or belt of a peculiar cellular character, exhibiting numerous small alveoli, strongly reminding one of the peculiar cellular structure of the tube of *Cornulites*. From this latter *Ortonia* is separated by the complete attachment of the tube along one side, and by its much smaller size. From *Conchicolites* it is distinguished by its mode of attachment, and by never growing socially in clustered masses.

The Rev. Canon Tristram's paper *On the Geology of Moab* was then read. After referring to the researches of M. Lartet and others, the author described the general structure of the southern end of the Jordan valley, which, he said, coincided with a great synclinal depression. The lowest rocks exposed are New Red sandstone; these occur only on the east side of the Jordan, and are there capped by tertiary limestone, resembling that of the "back-bone" of Palestine. Abundance of springs break out at the junction of the limestone and the New Red, rendering the eastern shores of the Dead Sea very fertile. On the west side only three springs occur, and, excepting near these spots, the country is barren. Great deposits of marl are heaped against the western banks, but only a little of this occurs on the eastern side. Many streams of basalt occur on the eastern side of the Dead Sea. These overlie the tertiary limestone, and are, therefore, of later age than that. The origin of the lava flows is not yet known—no craters were observed in this district.

To the north-east of the Dead Sea, on the east of the New Red plain, there is a range of hills formed of tertiary limestone. Beyond, to the east of this, the Arabs tell of a vast volcanic tract, covered wlth ruined cities, which is as yet wholly unexplored.

In the course of the discussion, Prof. Hull remarked that the statements of the author gave a good example of the formation of a valley by disturbance, and he thought that comparatively little was due to denudation. Mr. Topley thought that even if a fault or synclinal ran along the valley, yet the valley itself was still due to denudation. Even if this were not the case, there was the line of hill, or an escarpment of tertiary limestone, on the north-east of the Dead Sea. The westerly continuation of this had been removed by denudation. He saw no reason why the whole of this denudation should not have been subaërial, the material having been carried southwards down the continuation of the Jordan valley before the great depression was proved. All the evidence compels us to believe that the great depression is of extremely recent geological age.

Canon Tristram, without giving an opinion as to the denuding agents, thought that the valley of the Jordan was marked out, and in great part formed by disturbance. In reply to Mr. Sharp, he said that the Moabite stone was a block of basalt of the country. Many such blocks of basalt are preserved at the houses there. In reply to Mr. Scott, he observed that the great deposits of salt at the southern end of the Dead Sea were of New Red sandstone age. The great saltness of the Dead Sea is mainly due to this salt being washed down by streams. Salt occurs all along the line wherever the New Red sandstone has been brought up, as in the Sahara and elsewhere.

On the Trachyte Porphyries of Antrim and Down in the North of Ireland, by Prof. Edward Hull, F.R.S., Director of the Geological Survey of Ireland.

Trachyte is one of the rarest of the British rocks, and it is as yet uncertain whether it is to be found amongst these islands except in the North of Ireland. In this district it was discovered and identified by the late Prof. Jukes and Mr. Du Noyer during the progress of the Geological survey in the year 1867. No description has as yet been published of this remarkable species of volcanic rock, and I propose to give a short account of its characters and relations to the surrounding formations as it occurs both in Antrim and Down.

Trachyte Porphyry of Antrim.—The principal mass forms a group of eminences about four miles to the north of the town of Antrim, called Tardree mountain, Carnearny Hill (1,043 ft.,) Brown Dod Hill and Scolboa Hill. The tops of three of these hills are formed of basalt in beds capping the trachyte rocks, and it is supposed that basaltic sheets enclose the whole of the trachytic district; though the survey of the district being incomplete the actual limits have not been determined in every direction.

The mineral constitution of the trachyte is generally uniform, although the relative proportions of the individual minerals occasionally vary. In general, the rock consists of a nearly white or grey felspathic base, with individual crystals of Sanidine, a triclinic felspar, blebs or grains of smoke quartz, and rarely a little mica. In some places the grains of silica are exceedingly abundant, giving the rock the appearance of Rhyolite or Perlyte as described by Cotta, minute crystalline grains of magnetite appear in a sliced section under the microscope. It is in this state that the iron mentioned in the analysis below probably occurs.

The rock is quarried as a building stone at Tardree mountain, where it sometimes assumes a columnar structure. A specimen from one of the quarries was subjected to an elaborate analysis by Mr. E. T. Hardman, of the Geological Survey of Ireland, who gives the following as the constituents:—*

Analysis of Trachyte Porphyry, Tardree quarry.

Silica	76·960	per cent.
Alumina	5·101	,,
Peroxide of Iron	2·344	,,
Lime	7·064	,,
Magnesia	0·294	,,
Potash	4·262	,,
Soda	1·818	,,
Loss by ignition	2·102	,,
Phosphoric acid	trace	
	99·943	

Specific gravity 2·433

Relations of the trachytic and basaltic rocks. — During a recent visit I was enabled to ascertain with the greatest certainty the relative position of the trachytic to the basaltic rocks of the district. In the first place, there does not appear to be any passage or graduation of the two classes of volcanic rock into each other, and each having been erupted and spread out in sheets, exhibits a laminated, or bedded structure, which enables the observer to determine their relative positions without much difficulty. Both at Carnearny and Tardree Hills the trachytic porphyry may be observed to dip beneath the basaltic rocks of the surrounding country; and the observations made here and elsewhere tended to show that, of the two kinds of rock, the trachyte is the older.

On the other hand, both at Carnearny Hill and Scolboa the trachyte seems to have been penetrated by "necks" of later date filled with basalt, from which some portions of the overlying basaltic sheets may have been erupted. We are not, however, as yet in a position to say whether or not the trachyte is the oldest and lowest of all the Tertiary Volcanic rocks of County Antrim, as its base is nowhere exposed.†

The events which have taken place in the volcanic history of this locality appear to have been as follows:—

At some early stage of the miocene period large masses of trachytic rocks were poured forth from one or more vents, doubtless accompanied by craters as in Auvergne. After, probably, a long interval of repose new interruptions of basalt and dolerite took place through fissures and small volcanic vents breaking in some places through the trachyte. These later eruptions of basalt may have enveloped the whole of the trachytic masses which have been subsequently laid bare by denudation. The denudation of this region has been very great during postpliocene and later times; and to it is due the obliteration of the

* Jour. Roy. Geological Soc. Ireland. Vol. iii. part i. p. 27. (New Ser.)
† Messrs. Hull and J. L. Warren. Explanatory memoir to sheet 36 of the Geological Survey of Ireland (1871).

actual craters of eruption over the whole volcanic region of Antrim.

Trachyte Porphyry of Co. Down. This rock is very similar in appearance and constitution to that of Antrim, consisting of a greyish felsitic base with crystals of sanidine and blebs of quartz. It is only visible at Ballyknock, about four miles west of Hillsborough, surrounded on all sides by Lower Silurian rocks, but not very far distant from the margin of the basaltic plateau of Antrim. There can be little doubt that it is of the same age as the trachyte porphyry of Antrim; both being referable in all probability to the great volcanic outbursts of the miocene period.

Considerable uncertainty exists regarding the relations of the Downshire trachyte to the volcanic rocks of the adjoining country. It only appears in two or three spots within a small area: but the probabilities are, that it is portion of an old neck from which trachytic lava was erupted contemporaneously with that of Antrim, the higher portion of the mass as well as the original vent having been removed by denudation. The district has since been deeply buried beneath boulder clay.* The author then proceeded to show the similarity of the Antrim volcanic rocks with those of Auvergne, the Siebengebirge and Eifel districts.

SECTION D—Biology

Sub-section Zoology and Botany

On the Occurrence of the Supra-Condyloid Process in Man, by Prof. Struthers, of Aberdeen.

The author showed dissections of this part in several animals. An arch of bone is thrown, like a bridge, over the great nerve, and generally also the great artery of the limb, a little above the elbow, protecting them from pressure and injury. No such structure exists normally in the human arm, but it occurs occasionally as a variation. When it exists, the process grows from exactly the same spot as in animals which possess it, and the arch is completed by a ligament, the nerve and generally also the artery passing through the arch. This variety had attracted some notice lately, and is supposed to be very rare, but the author has found it often, and he exhibited a large number of specimens of it from the human arm, in its various degrees of development. He had also met with it occasionally in the living body, and had lately been able to prove the correctness of his previous supposition that it may be hereditary, having met with it in the members of a family, in the father and in two sons. The author remarked on the great interest attaching to this variation. In animals which possess it, it is what, in olden phraseology, would be called a contrivance specially designed for the protection of the nerve in them, and it looks as much a piece of contrivance as London Bridge or Temple Bar. But why should the same contrivance occur as a variety in man? The old argument from final cause, and no less its successor the theory of "type," besides being metaphysical, becomes untenable in the face of the existence of these rudimentary structures. The theory of so-called type has a great deal to answer for in obscuring the natural interpretation. If species are of independent origin, how comes it that animals have in their bodies parts of other animals, parts which are of no use to them, sometimes even dangerous to them? To those who are able to overcome the prejudices of their early education, the evidence comes with irresistible force in support of the hypothesis of the origin of species by evolution.

On the Sternum and Pelvic Bone in the Right-Whale and in Great Fin-Whales, by Prof. Struthers.

The sternum exhibited showed a very different form from that of the same species of Fin-Whale which Prof. Struthers had brought under the notice of the Association last year. Instead of a singled median cervical process, it has a deep median notch with a broad crest on each side; and the posterior process is very narrow. Two sterna of the Greenland Right-Whale exhibited were large. The author divides the sternum into three parts. The middle between the first ribs is thick, completing the thoracic girdle, and essential. The part in front of this, and the part behind it vary greatly, being more or less rudimentary. The sternum of the Finner has two joints with the first rib, that of the Right-Whale only one joint, and this difference in the thoracic adaptation, together with the great breadth of the first rib in the Right-Whale, might explain the very different forms presented by this bone in these two kinds of whales.

One of these breast-bones exhibited marks of former inflammation of the bones. The author mentioned that he had often met with this condition in whales, in some cases ankylosis of vertebræ had resulted, and in some there must have been considerable suffering to the animal. This fact might be commended to the notice of those, if there be yet any such, who have the notion that disease occurs in animals only when they come under the influence of man.

On the Occurrence of Finger Muscles in the Bottle-Nose Whale (Hyperoodon bidens), by Prof. Struthers.

This bottle-nose stranded on the Aberdeenshire coast just after the meeting of the Association last year at Edinburgh, at which the author read an account of the finger-muscles in the great Fin-whale, first noticed by Prof. Flower. It had been believed that these muscles do not exist in the toothed whales, but in this bottle-nose they were even better developed than in the Finner. The extensor muscles especially were better marked, the external extensor, corresponding to the so-called extensor of the little finger of man, being also present. An extensor *carpus radialis* was also present. Besides the muscles which were known to exist at the shoulder and arm in the Cetacea, he found a representative of the biceps present here. These muscles were mainly to be regarded as rudimentary, but they had a certain low amount of function by which their presence as muscles is maintained. In some other cetaceans they are represented entirely by fibrous tissue. Prof. Struthers exhibited also a dissection of the rudimentary teeth concealed in the gum of this bottle-nose. They are alive but useless, and their presence could be reasonably interpreted only by the hypothesis of evolution.

Sub-section Anthropology

Exploration of some Tumuli on Dartmoor, by C. Spence Bate, F.R.S.

The author had examined several cairns of the usual kind common on Dartmoor with but little success; they apparently had been previously rummaged by unknown hands. In one, a broken urn and an implement of white slate was found; the latter was supposed to have been that with which the potter formed the rude urn.

On Hamel Down, near the centre of Dartmoor, the author explored a barrow composed of earth surrounded with small stones; in this he found, beneath five large stones which were placed horizontally one beside the other, some burnt bones on the ground, a bronze dagger blade, and an amber ornament inlaid with gold, which is supposed to have been the extremity of the handle of the dagger.

The author contends that from the character of this interment, the burnt bones not being enclosed within an urn, and the amber ornament taken together with the names associated with the locality, are evidence of an early incursion of the old Scandinavian Vikinger in search of that tin which was necessary for them to manufacture their bronze.

On the Ethnological and Philological Relations of the Caucasus, by Hyde Clarke.

This paper communicates the further researches of Mr. Hyde Clarke on the classification of the languages of the Caucasus. It identifies (1) the Ude with the ancient Egyptian and Coptic; (2) the Abkhass with the Agau, Falasha, &c., of the Upper Nile; (3) the Circassian with the Dravidian; (4) the Georgian, Lazian and Sivan with the Caucass—Tibetan. The Ude and Abkhass are connected with the statements of Herodotus (Book II.) as to the Egyptian colony established in Colchus by Sesostris. Mr. Hyde Clarke observed that the Caucasus was not a centre of population for the world, but a place of passage, and showed the relations of the Abkhass (Agau) and Circassian with the Ougeners in Europe, Africa, Asia, Australasia, and America, illustrating the common population of the new and old world, and the knowledge of America by ancient nations, dimly preserved, though not understood by the Greek and Roman geographers.

The Origin of Serpent-worship, by C. Staniland Wake.

After referring to various facts showing the existence of serpent-worship in many different parts of the world, the author proceeded to consider the several ideas associated with the serpent among ancient and modern peoples. One of its chief characteristics was its power over the wind and rain; and a

* Mr. Hardman considers that the amount of lime shown by the analysis, proves that the trachyte has undergone some amount of metamorphosis or alteration, and considers it probable that it is consequently older than the basalt of Antrim, a view which subsequent examination in the field has enabled me to verify.

second, its connection with health and good fortune, in which character it was the agathodæmon. It was also the symbol of life or immortality, as well as of wisdom. This reptile was viewed by many uncultured peoples as the re-embodiment of a deceased ancestor, and descent was actually traced by the Mexicans and various other peoples from a serpent. The superstition thus became a phase of ancestor worship, the superior wisdom and power ascribed to denizens of the invisible world being assigned also to their animal representatives. When the simple idea of a spirit ancestor was transformed into that of the Great Spirit, the father of the race, the attributes of the serpent would be enlarged, and it would be thought to have power over the rain and hurricane. Being thus transferred to the atmosphere, the serpent would come to be associated with nature or solar worship. Hence, the sun was not only a serpent-god, but also the divine ancestor or benefactor of mankind. Seth, the traditional divine ancestor of the Semites, was the serpent sun-god, the agathodæmon, and various facts were cited to establish that the legendary ancestor of the peoples classed together as Adamites was thought to possess the same character. It appeared that serpent-worship, as a developed religious system, originated in Central Asia, the home of the great Scythic stock from which the civilised races of the historical period sprung, and that the descendants of the legendary founder of that stock, the Adamites, were in a special sense serpent-worshippers.

Sir Walter Elliot read a paper *On Some of the earliest Weapons in Use among the older Inhabitants of India*. These he traced to a curved "throw-stick" resembling, but differing from, the Australian bomerang, in as much as it does not return to the hand when thrown. The Indian "throw-stick" is found among the rude races inhabiting the mountain and forest tracks of Central and Western India, as the Dhangars, Kolis, and Gonds, and more to the South, the Kallars, Marawars, and other low castes. In waste and jungle tracts the people turn out in great numbers during the hot season, commencing with the first day of Hindu new year in March, and continued on every succeeding Sunday till the Monsoon begins. Hares, deer, hog, pea-fowls, partridges, &c., raised by this lowly race of beaters, each carrying a "throw-stick," are knocked over by showers of these weapons, thrown with great force and precision.

From the form of such sticks, which are from $1\frac{1}{2}$ to 2 feet long and 3 to 6 inches broad, thrown with the concave side foremost, the author deduced the form assumed by the iron weapons subsequently formed by the same races. Specimens of these were exhibited, such as the Gurkha knives of Nipal, those of the Nairs, Moplas, and of the Malabar coast, and the common woodman's knife used everywhere, and which the late Capt. Forsyth states the Gonds, Bygas, and other tribes of the central Highlands throw at game with wonderful precision. These remarks apply more particularly to the Druoidian races, although not exclusively so. The earliest or aboriginal people now represented by the servile classes, seem to have used stone implements like people of the same condition in Europe and elsewhere, while the early Aryans passed through a bronze or copper period—specimens of the weapons of which era were exhibited.

Sir Walter observed that Prof. Huxley in classifying the varieties of the human race, exclusively for physical characters, had included under one head the people of New South Wales, of the Highlands of Central India, and of Ancient Egypt, all of whom he includes under the term Australoid. Now it is a remarkable coincidence that among these three far distant peoples the "throw-stick" was the weapon of the chase, and that examples do not occur in the intermediate countries. The pictures in the tombs of the kings at Thebes represent hunting scenes in which the curved sticks found at this day in India are extensively represented. The bomerang of Australia is precisely of the same form, but, being thinner and lighter, is so fitted to have a recoiling property.

SECTION E.—GEOGRAPHY

On the Orography of the Chain of the Great Atlas, by John Ball, F.R.S.

The representations of the chain of the Great Atlas given on the most modern maps show how very vague and incomplete our knowledge still is. They agree in very little beyond the fact that high mountains extend in a nearly direct line from the west coast, where they approach the Atlantic, near Agadir, in about 30° 30′ N. lat. for about 500 miles inland, where they subside at no great distance from the frontier of Algeria about the parallel of 33° 30′.

All but the most recent maps indicate a single range similar in general character to that of the Pyrenees, while in these we find represented two nearly parallel ranges at an average distance of sixty or seventy miles, of which the northernmost alone terminates near the Algerian frontier, its axis lying exactly in the line of the great shallow lakes, or chotts, that occupy a great part of the high plateau of southern Algeria, while the southern range, with some slight interruption, is continuous with the elevated zone that forms the northern limit of the Algerian Sahara. The details, however, as given in these recent maps, are strangely discordant, especially in regard to the region lying E. and N.E. from the city of Morocco, and connecting the main range with the mountains of North Morocco.

It is not surprising that such discrepancies should exist, when it is known that the best maps have been compiled with no better materials than the reports of natives, and that none but a very small portion of the entire region has ever been traversed by civilised men. In regard to Gerhard Rohlfs, one of the most remarkable of recent African travellers, it must be remembered that he was forced to maintain a rigid disguise, to associate constantly with natives, and to suit his movements to theirs. He was unable to make more than scanty and occasional notes, and was altogether debarred from the use of instruments. It is not surprising that, under such conditions, his contributions to the topography of a region never before visited by European traveller tend more to excite than to satisfy curiosity.

During the spring of last year the Sultan of Morocco, at the request of the British Minister, Sir John Drummond Hay, granted permission to Dr. Hooker, the eminent Director of the Royal Gardens at Kew, to explore the portion of the Great Atlas subject to the Imperial authority; and although the main object of the party, consisting of Dr. Hooker, Mr. Maw, and myself, was to investigate the Flora of the mountains, it might not unreasonably be expected that we should be able to make some considerable addition to existing geographical knowledge in regard to a region so little known.

Those who are best acquainted with Morocco will be least surprised to learn that in this respect the expedition has not borne abundant fruit. The obstacles which stood in the way were partly anticipated by us, but were in great measure insuperable.

The authority of the Sultan extends over but a small portion of the region included under the denomination Great Atlas. It is in fact limited to the northern declivity of the main chain, and only throughout the western part of this, for it extends to a distance at the utmost not more than 120 miles E. of the city of Morocco. The time at our disposal was too limited to enable us to explore even the limited field that was thrown open to use The cares and responsibilities attaching to his official duties prevented Dr. Hooker from prolonging his stay in and near the mountains beyond about three weeks, and the private engagements of Mr. Maw compelled him to separate from us and to return to England at a still earlier date. But by far the most serious obstacle which we encountered arose from the persistent though covert opposition of all the persons holding local authority, aggravated and not seldom stimulated by the chief of our escort, whose charge, as we had been assured, was to remove all impediments from our path.

But for the difficulties incessantly placed in our way, we should undoubtedly have attained several of the higher peaks, and could not fail to have learnt a good deal respecting the disposition of the greater masses and the direction of the main valleys in the territory which we could not actually traverse.

In point of fact we were able to make but two considerable ascents. On the first occasion, when we ascended the Tagherot Pass in a storm of snow and hail that completely intercepted all distant view, the cold was so severe that we willingly turned our faces from the storm when only Mr. Maw, the foremost of the party, had actually set his foot upon the summit, about 12,000 feet above the sea level. On the second occasion, after Mr. Maw had departed from us, we attained a conspicuous peak, called Djebel Tezah, about 11,500 feet in height, in a much lower part of the range than that previously visited. In addition to the very limited results of personal observation, we naturally availed ourselves of every promising opportunity for obtaining topographical information from natives. Much of the information obtained in this way appears to me utterly unreliable, especially when derived from persons holding local authority, but the particulars supplied

by a very intelligent Jew residing in Morocco, so far as they rest on personal knowledge, deserve more confidence.

The following are the chief points as to which I think myself entitled to express an opinion, premising that as to some of them I may place undue confidence in my own personal conclusions:—

1. The portion of the Atlas chain that is seen from the city of Morocco is considerably higher than has generally been supposed. The higher summits approach nearly to the same elevation, and the majority of these approach very nearly, if they do not occasionally surpass, the level of 14,000 feet. Westward of the district of Glaoni, S.W. of the city of Morocco, the range subsides gradually as it approaches the coast.

2. There is a certain amount of tolerably good evidence tending to show that the interior part of the range extending from the upper valley of the Wed Tessaout to Eastern Morocco contains peaks of higher elevation than any seen by us.

3. The existence of an anti-Atlas or range parallel to the main chain, and enclosing on the south side the great valley of the Sous, was established by Rohlfs, if not by previous travellers; but we are probably the first who have looked across the wide intervening space and scanned the outline of the anti-Atlas. The portion seen by us at a distance of from 50 to 60 miles is far less bold in form than the main range. The utmost height of that portion can scarcely exceed 10,000 feet.

4. The map, compiled by Capt. Beaudouin, and published in Paris at the Depôt Général de la Guerre in 1848, which is decidedly the best that has hitherto appeared, is defective in representing the main chain as arising abruptly from the low country, scarcely indicating considerable lateral valleys. At the same time it should be remarked that the projecting ridges which divide these lateral valleys appear to be lower in comparison with the peaks of the main chain than is usual in other great mountain ranges.

5. There is a marked tendency to the formation of considerable valleys parallel to the main chain, and in such cases the remark made in the last paragraph does not apply. Some of the higher peaks, and amongst them those named Miltsin by the late Captain Washington, lie in ridges nearly parallel to the main chain.

6. It appears at least possible that the Anti-Atlas, if we may so denominate the range forming the southern boundary of the Sous Valley, is merely an example on a large scale of one of the parallel ridges just referred to, many examples of which are to be found in better known mountain regions.

7. The existence of two parallel chains so continuous as those represented in Gerhard Rohlfs' map appears to be open to reasonable doubt. In the absence of direct evidence, it appears at least equally probable that the conformation of the main chain may be best represented by a series of ridges slightly inclined to the axis of elevation of the entire mass.

8. The remarkable valley of the Beni mquald, laid down on Beaudouin's map as extending more than one hundred miles from S.E. to N.W. in a nearly direct line must be pronounced imaginary or based on false information. The details given in Rohlfs' "Reise durch Marokko," however incomplete, are manifestly inconsistent with the general plan of the mountain system laid down in that map.

SECTION G—Mechanical Science

Experiments on Surface Friction in Water, by W. Froude, F.R.S.

The object of investigation was to determine the laws which govern this force, in those especial relations under which it forms a portion of the resistance experienced by a ship when moving through the water at various speeds.

These are, (1) the relation of the force to the speed, (2) its relation to the quality of the surface, (3) its relation to the length of the surface along the line of motion. The necessity of investigating it under the latter of these relations, may not be at once obvious, it having been generally held that surface friction varies directly as the area surface, and will be the same for a given area whether it be long and narrow or short and broad. But a little reflection shews that this cannot be so, because the portion of surface that goes first in the line of motion, in experiencing resistance from the water, must reciprocally communicate to the water motion in the line in which itself is moving, and, consequently, the portion of surface which succeeds the first, must be rubbing, not against stationary water, but against water partially moving with it, and cannot experience as much resistance from it.

The experiments were performed with carefully-made apparatus, which automatically recorded the resistance and the speed, and the errors and uncertainties of the results probably did not in any case exceed on the whole $\frac{1}{2}$ per cent.

The surfaces used in the experiments were of yellow pine board, about $\frac{3}{16}$ of an inch thick, loaded at the edge with lead keels of the same thickness, fastened fair and flush with the board, the weights being such as to just neutralise the flotation, and hold the boards stably in a vertical plane. The head end (so to call it) of each board in turn was fastened into a tin sheath, or fine-edged cutwater, which formed a portion of the dynamometric apparatus, and which held the board resolutely in a vertical plane, with its length horizontal, and in the line of motion. The width of each board, including the lead keel, was 19 in., their lengths, including the cutwater, varied from 1 ft. to 50 ft. Great pains were taken, and successfully, to eliminate, and, indeed in effect to obliterate the resistance due to thickness.

It turned out that the effects of the three conditions under which the variations of the force were to be determined, could not be regarded as absolutely independent of each other, because certain variations in the quality of the surfaces were found to affect in some degree the relations of the force to the speed and to the length. The results may be approximately stated in brief, as follows:—

1. As regards the relation of resistance to speed. With the surface coated with shellac varnish, Hay's composition, or Peacock's composition, or tallow, the resistance varied very nearly as the power 1·83 of the speed; with the surface coated with tinfoil, very nearly as the power 2·05 of the speed; but the experiments with the tinfoil are not yet complete.

2. As regards the relation of resistance to quality of surface. With the surface coated with shellac varnish, Hay's composition, Peacock's composition, or tallow, the resistance differed extremely little; such variations as occurred scarcely exceeding 1 per cent., and being probably not greater than belonged to the small differences of smoothness in the laying on the composition.

With the surface coated with glue, and thus simulating the sliminess of a living fish, three successive experiments were tried at the same speed, so as to test the effect of the gradual growth of the slimy character. The first experiment showed an increase in resistance of 2 per cent., the last of 4 per cent., as compared with the shellac surface which the glue resembled before immersion, a proof that the attempted imitation of the fish's surface was not advantageous.

Comparing a tinfoiled surface with one coated with shellac, when the length is 1 ft. the resistance of the former is on the average only $\frac{2}{3}$ that of the latter, making the comparison with planes of 1·6 in length, the ratio is $\frac{3}{4}$, and with planes of 16 ft., more than $\frac{9}{10}$, instead of $\frac{2}{3}$; indeed, the total difference becomes progressively less as the planes compared are longer. At higher speeds also the difference tends to become less, in consequence of the higher power of the speed to which it is proportioned with the tinfoiled surface.

3. As regards the relation of resistance to length of surface. There plainly is a very considerable diminution of average resistance per square foot as the length of surface is increased, and this probably from the cause already indicated, though the *rate* of diminution becomes gradually less as the surface becomes longer; there is, in fact, as great a diminution between 3 ft. and 4 ft. of length as between 30 and 50.

The following tabular statement gives the mean resistance per square foot on surfaces of from 1 foot to 50 feet in length, with speeds of from 200 to 800 feet per minute.

Length of plane. Feet.	Speed in feet per minute.				
	200	400	600	800	
1	0·048	·200	·460	·830	Resistance in pounds.
2	·045	·188	·413	·725	
3	·043	·183	·390	·673	
5	·042	·166	·358	·608	
7	·041	·154	·333	·563	
10	·040	·145	·312	·529	
20	·036	·131	·278	·473	
30	·035	·123	·264	·446	
50	·035	·117	·250	·417	

The table is applicable to a clean planed surface coated either with shellac varnish, Hay's or Peacock's composition, or tallow.

SCIENTIFIC SERIALS

Proceedings of the Newcastle-on-Tyne Chemical Society, 1871-72.—The number of meetings held by the society during the past year has been 6, the session only lasting from October to March with one meeting in each month. The October number opens with the address of the president, Mr. John Glover, which contains a short review of the papers read before the society during the previous year. The first communication is one which does not seem to have attracted the attention which it deserves; it is by Messrs Pattinson and Marreco "on the residual sulphur in purified coal gas," that is to say, the sulphur contained in coal gas after the removal of the sulphuretted hydrogen by means of oxide of iron or by lime. At various times violent fluctuations have taken place in the amount of the residual sulphur in the gas supplied to Newcastle, the quantity varying from 25 grains in the 100 cubic feet down to 4 grains. The authors believe that the explanation of this lies in the fact that the lime purifiers then in use were sometimes allowed to become "foul" or acted on to a great extent by the sulphuretted hydrogen, &c., contained in the crude gas. Contrary to what might have been expected, when some of the purifiers had become foul, the quantity of sulphur decreased rapidly, but that when the foul lime was replaced by clean lime, the quantity of sulphur immediately rose to some 25 grains per 100 cubic feet. An example is given of an occasion when clean lime was placed in the boxes, the amount of residual sulphur in gas was found to be 17·58 grains, and that as this lime became foul, the succeeding weekly tests gave 12·10 and 6·69 grains respectively. The method employed for the estimation of the sulphur is not stated; it is to be hoped, however, that one of the more recent methods has been adopted, and not the "Letheby sulphur test," which, as is well known, gives at the best, most inaccurate results. According to the authors it would seem a simple matter for our large gas companies to considerably reduce the quantity of sulphur present in gas, at comparatively no expense to themselves. The probable chemical action which appears to take place is the formation of a sulphocarbonate from the combined action of the carbon disulphide in the gas and the foul lime. Most of the remaining papers possess principally a technical interest. Amongst these we notice one "on the action in the black salt-pan and calcining furnace in alkali manufacture," by Mr. Moorhouse, and "on a new mechanical calcining-furnace" by Mr. Gibb, who also contributes a paper "on the formation of sodic carbonate by the action of carbonic anhydride on solutions of sodic sulphide." Dr. Lunge also contributes the abstracts of two papers by Fresenius, the first "on the quantitative estimation of sulphuretted hydrogen in presence of carbonic anhydride," and the second "on the best method of analysing artificial manures." This latter paper should be read by all interested in artificial manures, and will well repay a careful study. One feature to be noticed at the meetings of this society is that there is almost always a spirited discussion on the papers read, which shows very well the interest taken by the members in promoting the advance of chemistry, and also the welfare of their society.

Annali di Chimica applicita alla Medicina compilati del Dottor Giovanni Polli, No. 4, 1872. The contents of this number is of varied interest, the papers being grouped together under various heads, such as pharmacy, toxicology, therapeutics, &c., are very easy of reference. Under the head of pharmacy there are several papers given, which are abstracts of papers already published in other countries, such as "On the determination of the value of chloral hydrate," "On a new reaction of alcohol," by Berthelot, and others. Amongst them there is a note on the adulteration of essence of peppermint, which is now adulterated with the essential oil of copaiba; there is a second note on the adulteration of argentic nitrate with zincic nitrate, the amount of which, in some specimens, leaves no doubt of its having been introduced with fraudulent intention.

SOCIETIES AND ACADEMIES

PHILADELPHIA

Academy of Natural Sciences.—October 3, 1871.—Dr. Ruschenberger, president, in the chair.—Mr. Thomas Meehan referred to some observations made by him last spring before the Academy in regard to the office of bud scales and involucral bracts. The general impression was that they were formed for the purpose of protecting the tender parts beneath. At that time he exhibited branches of *Fraxinus excelsior* on which some of the buds were entirely naked, and others clothed with scales in the usual manner. They could scarcely be for protection in this instance, as both were equally hardy. He now had to exhibit an ear of corn which had been produced without the usual involucral bracts or husks, and yet was as perfect as if clothed in the usual way, showing that the husk was of not much importance as a protecting agent. An interesting point was that this ear had been formed on the end of a male panicle or tassel. It was not uncommon to find scattered grains of corn amongst male flowers, but a perfect ear like this he had never before seen. The ear was eight-rowed, and contained two hundred perfect grains. It was the variety known as "popcorn."

November 7.—Dr. Ruschenberger, president, in the chair.—Prof. Cope exhibited a specimen of a *Galeodes*, probably *G. pallipes* of Say, taken in the town of Denver, Colorado, by Dr. Gehrung. According to that gentleman, it was common in that place in houses, and was an enemy and destroyer of the *Cimex lectularius* (bedbug). In captivity, it showed a preference for them as food, and crushed them in its short cheles, preliminary to sucking their juices.—Mr. Thomas Meehan said that while travelling through a wood recently he was struck in the face by some seeds of *Hamamelis virginica*, the common Witch Hazel, with as much force as if they were spent shot from a gun. Not aware before that these capsules possessed any projecting power, he gathered a quantity in order to ascertain the cause of the projecting force, and the measure of its power. Laying the capsules on the floor, he found the seeds were thrown generally four or six feet, and in one instance as much as twelve feet away. The cause of this immense projecting power he found to be simply in the contraction of the horny albumen which surrounded the seed. The seeds were oval, and in a smooth bony envelope, and when the albumen had burst and expanded enough to get just beyond the middle where the seed narrowed again, the contraction of the albumen caused the seed to slip out with force, just as we would squeeze out a smooth tapering stone between the finger and thumb.

THURSDAY, SEPTEMBER 12, 1872

THE POTATO DISEASE

THERE seems little doubt that the present season will prove one of the most unfavourable within this generation as regards the yield of the fruits of the earth. The steady rise in the price of corn indicates a widely-spread fear that the harvest will turn out to be considerably below the average, both in quantity and quality. The crop of fruits of nearly every kind may be described as all but a complete failure. The potatoes are estimated as irredeemably bad, to the extent of three-fourths of the yield. Hops are in many parts scarcely worth the pulling. The grass and root-crops have alone benefited by the wet and ungenial summer. The cattle are, moreover, suffering from the foot-and-mouth disease on almost every farm in some counties, and we hear of the outbreak of rinderpest in Yorkshire.

In this dismal list the palm of failure must be given to the potato, with the exception, perhaps, of the apple crop, which has been destroyed by causes not affecting the health of the tree. It is generally admitted that the potato crop is, taken as a whole, the worst since 1845 or 1846. The cause of failure is the same—one, in fact, that has been more or less in existence ever since—the attack of a parasitic fungus, *Botrytis* or *Peronospora infestans*, peculiar to plants belonging to the same natural order as the potato, and unknown before 1845, or some say 1842. The mycelium of this fungus eats into and completely destroys the tissue of the leaf and stem, and when once its ravages have commenced it is almost impossible to arrest them. When the disease made its first great onslaught in 1845, innumerable remedies were suggested, some of which have again cropped up during the present season. Unfortunately, no sooner does one experimenter announce in the *Times* a mode which he has found effective of preventing or arresting the disease, than another grower replies that he has tried the same plan, and with him it has utterly failed. The exact mode of action of the parasite, and the operation of the proposed remedies, we intend glancing at on another occasion. It is satisfactory, at all events, that Dr. Hooker has given in public the weight of his authority in favour of the statement that the starch of the potato is not affected by the complaint, if only some economical mode can be found of separating it from the diseased ingredients. This is some alleviation of a calamity which, according to a statement in the *Times*, threatens the country with a loss of between twenty and thirty millions sterling.

The point to which we specially desire to call attention at the present time, is the enormous material loss which the country is now suffering, and has suffered year after year, from causes which are unquestionably within the range of scientific means to prevent, or at all events materially to alleviate. We are satisfied that we are within the mark when we say that the increased expenditure in most middle-class families within the past eight years, caused by the enhanced price of butchers' meat, milk, and potatoes, represents an income-tax of from a shilling to eighteen-pence in the pound. A portion of this rise is no doubt due to increased consumption, caused by the general prosperity of the country; but the greater part is owing to the prevalence of epidemic diseases in our crops and our herds. Surely Science can find no worthier object than in an earnest attempt to find a remedy for this. And yet what is English Science doing? It was cogently asked a few days since in the *Times*:—"What are we doing, or what have we done, to obviate the recurrence of a disease which is always impending? Probably all we can remember is that there is always a talk of the potato rot, and that some years it has been worse than others. We can only say that this is a disgraceful confession. There is no matter in which Science could interfere with more advantage; and we seem to have all the conditions of the subject under control." We fear that the rebuke here given to English Science is not wholly undeserved.

This brings us to the question which has so often been debated in these columns:—Where are we to find the proper individual or body to start and to carry on scientific investigations of this nature—in private individuals, in societies like the Agricultural or the Horticultural Society, or in the Government? Few will probably contend in favour of the first alternative. Individuals, no doubt, have been found, and will be found, to spend their lives and lavish their fortunes in investigations in which they have no or only a remote pecuniary interest. But it is surely unwise in the extreme to subject our national prosperity to the hazard of private generosity. The societies we have named, and others of a more local character, such as the Highland Society, have done eminent service in promoting sounder views and practices in agriculture and horticulture; but it is questionable whether inquiries of this nature are not beyond their scope, or whether any conclusions at which they might arrive would obtain the universal acceptance which would be desirable. We are, therefore, driven once more to the third alternative; and compelled to inquire whether we have not a right to look to the Government of the country to "interfere" in the matter, as Mr. Gladstone would term it, that is to institute and to promote an investigation into the Origin, Cause, and Remedies for the Potato Disease.

Little objection can be anticipated to the course we advocate on the ground of the money value at stake in the question. We are at the present time spending a large sum of money and employing the highest talent in the country in the settlement of a claim for a few millions; to save the country several times as much per annum cannot be objected to as a matter unworthy the attention of our rulers. And yet, because the one infliction will fall upon us in the form of an additional twopence to our Income-tax for a single year, the other in the form of a much heavier addition to our butchers' and greengrocers' bills for many years in succession, we are content in the latter case to grumble and bear it, without making any serious efforts to relieve ourselves from it. Science is often charged with being "unpractical;" indeed, in the minds of perhaps the majority of people there is a kind of hazy feeling of a necessary antagonism between what is scientific and what is practical. It is time for Science to redeem herself from this imputation, and no better opportunity could be found

than in discovering a remedy for the Potato Disease. The questions which would present themselves for solution in such an inquiry are numerous. It would not be difficult to collect the facts; but they have never yet been tabulated or presented to the public in such a form that any conclusions can be drawn unquestionably from them. A competent authority on these subjects, the *Gardener's Chronicle*, recently remarked:—"Though for nearly a quarter of a century, more or less, cultivators have had to wince under the losses inflicted by the enemy, they have not yet learnt either the mode of invasion or the method of destruction." The Commission would have to inquire whether the disease is most prevalent on any particular soil; whether, as some assert, seed left in the ground through the winter enjoys comparative immunity as contrasted with that sown in the spring; whether seed introduced from a distance is safer than that grown in the neighbourhood; whether old varieties are dying out and new ones comparatively healthy; whether, if the disease can by any means be warded off till August 10, the crop is then comparatively safe, and very many others, on which every diversity of opinion exists at present? On one point almost all authorities are agreed, viz., that the disease generally makes its first decided appearance during thundery weather. The exceptional amount of electrical disturbance which extended over almost the whole country during July of the present year appears to have been most unfavourable to the potato crop; while a clergyman, writing from a district where thunderstorms are remarkably rare, in the portion of the county of Devon to the south of Dartmoor, averaging about six in twelve years, states that it is there almost free from disease.

It is worthy of note that an unusual development of the potato blight has been hitherto accompanied by murrain or epidemic diseases in animals and in other crops, and that a certain periodicity appears to be manifested. The present year has witnessed the most virulent outbreak since 1846; the worst of the intermediate years were nearly midway, from 1859 to 1861, showing an approximate recurring interval of about twelve years. A writer in the *Gardener's Chronicle* thus describes the crops in the latter year:—"My potatoes are in as bad a state as I ever remember to have seen them; my turnips are rapidly rotting, and many are filled with a semi-fluid offensive matter; the lettuces in various parts of the kitchen-garden are nearly all rotten; the roots are found generally diseased; the cabbages, savoys, and others of the *Brassica* are what gardeners term blind; the beans are spoiled by the black fly; the peas are all more or less blighted or mildewed; many of the plum and cherry trees are destroyed; I never witnessed anything more lamentable and disheartening." Other accounts agree in the main with this, at least as regards the potatoes in that year. Now, it is very remarkable that an interval of from eleven to twelve years coincides with the period of maximum sun-spots. The present time is near the maximum of sun-spots, so was 1860, so was 1848, the curve showing but little decline for one or two years on each side of the actual maximum. Now, if it can be shown that epidemics like the potato blight are connected with great cosmical cycles, an important step is gained. Physicists are now nearly of accord that a connection exists between the sun-spot period and the recurrence of electrical and other disturbances in the earth's atmosphere. It may be urged that such a conclusion as this would make cure hopeless, and paralyse, instead of stimulating, energy, by inducing a kind of hopeless fatalism. Not at all. An evil which cannot be avoided may, nevertheless, be greatly mitigated by scientific knowledge and skill. To be forewarned is to be forearmed, and a knowledge of the cause of a disease is already halfway towards its cure. If we were certain that in another twelve years we should be liable to a recurrence of the blight with unusual severity, the farmers might be persuaded to plant only so much as would be likely to yield seed for the next year, and that only under the most favourable circumstances, where comparative immunity might be predicted; and large breadths might be devoted to turnips, beet, or other root-crops which experience showed to be likely to yield good results, and which would furnish some substitute for the lost potato.

We have endeavoured to sketch out only a few of the questions which would present themselves for solution were we in earnest to institute a thorough scientific investigation of the cause and cure of the potato blight, and to point out that few subjects are more worthy the attention of a commercial and practical nation.

SHARPE & DRESSER'S BIRDS OF EUROPE

The Birds of Europe. By R. B. Sharpe and H. E. Dresser. Parts xi. and xii. (Published privately.)

THE completion of the first volume of this important work by the issue of Parts xi. and xii., affords the authors an opportunity of expressing their determination to continue the monthly issue with as much punctuality as is compatible with the fulness and accuracy at which they aim. This volume has occupied eighteen months in its publication; but as it contains 101 coloured plates and about 800 or 900 pages of letterpress of large quarto size, the wonder is rather that so near an approach to regularity has been attained in a work which is taking so much larger dimensions than was at first anticipated.

The present parts show no lack of the energy and care hitherto exhibited. In addition to the seventeen species figured and copiously described, we have three additional plates with eight figures of the Sparrow Hawk in various states of plumage, and two others with additional figures of the Ring Ouzel and the Rock Thrush. As an example of the great care bestowed by the authors in the accumulation and critical comparison of specimens from all parts of Europe, and from other quarters of the world where necessary, we may state that the present part discriminates between several birds that have hitherto been confounded, and thus adds two species to the list of European birds, and one to that of Britain. A fine Woodpecker (*Picus lilfordi*), found in Greece and Turkey, has been separated from *Picus leuconotus* which inhabits the more northern parts of Europe; while the British form of the Cole Tit (*Parus ater*) is found to be so constantly different from that which inhabits the Continent as to require a distinct specific name, and it has accordingly been called *Parus brittanicus*. To illustrate these minute specific differences the excellent plan is adopted of giving figures of the allied species on the same plate.

We cannot, however, equally praise the system of including American and other stragglers as European birds. It needlessly encumbers an already very bulky work, and leads to misconception, and it will also have the effect of making the book apparently imperfect whenever fresh stragglers reach our shores. Is it not absurd in a book of European birds to have seven pages devoted to the American Stint, with full details of its distribution over North America, and the statement that it has occurred "twice in Britain" as the sole justification for including it? Another seven pages is devoted to the American Hawk Owl on the strength of its occurrence four times in Britain. Such birds should be rigidly excluded from the body of the work, and only described in notes or an appendix when it is necessary to do so in order to avoid confusion with the allied European species.

It is a pity that the temporary paging of the letterpress to each species had not been altogether omitted, as it is of no use whatever, and occupies the prominent position which should have been left for the permanent paging. As the only means of remedying the evil, we would suggest that when the work is completed a series of numbers be printed in squares reaching to the highest number of pages in a volume, and be issued with the last part on gummed paper, so as to be cut out and fastened in the proper position over the temporary numbers.

The figures by Mr. Keulemans continue to be as spirited and lifelike as ever, and the authors devote the same attention as heretofore to giving the fullest and most reliable information obtainable. The work will thus satisfy the requirements both of the scientific naturalist and of the general reader and amateur. The former requires accurate descriptions and figures, careful measurements, and precise indications of distribution and habits. The latter wants to determine readily any bird he may meet with at home or on the Continent, with an intelligible and interesting account of its habits and distribution, and other topics of general interest. To both these classes of readers we can cordially recommend this book, and we believe that it is calculated at once to take a high position as a scientific work, and at the same time to popularise the delightful branch of natural history of which it treats. A. R. W.

GEOMETRICAL CONIC SECTIONS

Geometrical Conic Sections: an Elementary Treatise, in which the Conic Sections are defined as the Plane Sections of a Cone, and treated by the Method of Projections. By J. Stewart Jackson, M.A. (Macmillan and Co, 1872.)

The Geometry of Conics. Part I. By C. Taylor, M.A. (Deighton, Bell, and Co, 1872.)

MR. TAYLOR'S present work is by no means a second edition of his "Geometrical Conics" (1863). His object in this volume is a highly laudable one; from more than one quarter has recently come the complaint that the subject of geometrical conic sections is in an unsatisfactory state. The work under consideration is stated to be "the result of an attempt to reduce the chaos of geometrical conics to order, the subject having suffered not a little from desultory treatment." As in the earlier treatise, our author does not define the conics in question to be sections of a cone; and here he is at direct issue with Mr. Jackson:—"I am unable, despite his skilful advocacy, to acquiesce in the primary definition of conics from the solid."

This feud among writers on the conic sections is of old date. Simson, in his preface, stated that Wallis (1655) treated of these curves not as being sections of a solid (*nullâ coni habitâ ratione*), and that he was followed by De Witt and De la Hire. T. Newton, in his "Treatise" (1794), remarks that in the University of Cambridge the preference seems to have been given to that method which begins with a description of the curves *in plano;* whereas in the sister University, the Savilian professor, Abram Robertson, in a nearly contemporary work (1802), adopts the more ancient definition, and bases on it a very interesting exposition of the principal properties of conics. This latter method is the one we are inclined to prefer in a school book, though it is not that adopted by our standard writers, as Drew, Besant, and Taylor. Mr. Wilson, we were glad to see, has adopted it in his very handy though concise introduction to the study of these curves.

Putting on one side the numerous typographical errors in Mr. Jackson's work, and some few inelegancies, as we think, in the proofs—the results, doubtless, of too great haste in bringing it out—we have much pleasure in commending this volume, and hope that he will soon have an opportunity of removing these slight blemishes. If he has this opportunity, we are sure it will not be the result of luck ("in case this work should be so fortunate as to reach a second edition"), but the reward of genuine merit.

It is hardly needful to enter into any details respecting Mr. Taylor's mode of treatment of his subject. He is too well known and approved a writer upon it to need our commendation. Suffice it to say that many waifs and strays which he has previously communicated to the mathematical journals here find a fitting place. His leading principle, and that which tends so much to the clearness of his exposition, is that "Chord properties should take precedence of the Tangent properties, the latter being deduced from the former and not the former from the latter." A noteworthy feature is the prominence assigned to the treatment of a curve usually hurriedly passed over—the rectangular hyperbola. To this curve he devotes pp. 61—77. He very fully acknowledges his indebtedness to Prof. Wolstenholme's investigations of the properties of the curve. He has himself elsewhere (*Messenger of Mathematics*, vol. i. pp. 121—127) treated of the curve in question.

The book is a valuable contribution to the literature of this branch of pure geometry; and though it may not take the place of Besant's fuller treatise, as it does not go over the same extent of ground, yet it is worthy of being ranked side by side with it. We shall hail with pleasure the remaining part or parts of the work.

OUR BOOK SHELF

An Introduction to the Practical and Theoretical Study of Nautical Surveying. By J. K. Laughton, M.A. (London: Longmans and Co., 1872.)

THIS work is intended to supply a want that has long been felt by young officers of the navy who have not had an opportunity of gaining a knowledge of the methods of conducting a coast survey used on board vessels regu-

larly employed on such work. We are accustomed to quote with pride the old saying, that wherever wood would float an English pendant was to be seen, and it is true at the present time, that every sea, well known or slightly known, is visited more or less frequently by our men-of-war. But unfortunately many of these places are roughly surveyed, the coast lines inaccurately laid down, and the positions of the principal dangers doubtful. Here much valuable work can be done by those not surveyors, who have time and are willing to take the opportunities often given them, to improve our knowledge by making a correct survey or verifying the charts of the coasts they may visit. To these Mr. Laughton's book will be exceedingly valuable, and though in his introductory chapter the author modestly says that he writes "not for the guidance of surveyors, but for those who know little or nothing at all about it," we are sure that many old surveyors will find their work easier from having the principles so clearly brought before them. The work is the more valuable in showing what can be done with the means at hand on board every vessel, though not especially equipped for the work. The second chapter describes the choice and measurement of the base line, and the methods for determining the exact latitude and longitude of the first position. The rules given are exceedingly clear and simple, and can be readily followed by anyone in the habit of using the sextant and artificial horizon. The hints on the choice and adjustment of the sextant will be found very useful to every navigator. Mr. Laughton's practical way of dealing with the subject is shown in his suggestion to get an old sextant and let it fall on the deck in order to acquire a thorough acquaintance with its mechanism in putting it to rights again. But it is a pity that the description of the instruments should be placed between the rules for the choice and measurement of the base line, indeed it would be better if this chapter were re-arranged. A great deal more might be said on the selection of objects for triangulation, this is a point on which the beginner encounters his greatest difficulty; some hints also as to the best way of noting angles would be useful, this want is supplied when levelling is treated of. Chapter III. is devoted to the construction of charts and various projections of the sphere, it is very clear and concise, and will prove valuable not only to the chart-maker, but also to the navigator, who will here gain a clearer knowledge of the plan on which the chart he uses is laid down, than is to be found in most books on navigation. We recommend, especially to young surveyors, the method advocated for graduation of charts according to the gnomonic projection, it is more comprehensive and certainly more mathematically correct than the methods usually employed, and we do not remember to have met it described in any other work. The part of Chapter IV. relating to the determination of positions is perplexing, and would with difficulty be understood by an inexperienced surveyor, without examples. The author might have well supplemented this part by showing graphically the way of protracting the angles, and finding the points of intersection. It is not clear why he has omitted from the description of instruments all mention of the protractor, an instrument as essential to the surveyor and navigator as his pair of compasses. The remarks in the last few pages on the "danger angle," or as it was called by old surveyors the "approximative angle," will be found very useful by all navigators, especially those who since the introduction of iron ships have experienced the difficulty and uncertainty of determining positions quickly by the compass when the course is changing rapidly. The running survey is ably treated, but we regret there is no illustration of the mode of surveying a harbour; this is a serious omission, but notwithstanding this, and the want of illustration of the choice of stations and selection of objects, we can recommend the book as the best out on the subject.

The Lepidopterist's Guide, intended for the Use of the Young Collector. By H. Guard Knaggs, M.D., F.L.S. Second Edition, illustrated. (London: Van Voorst.)

THE want of such a "Guide" as the present was long felt by "young collectors" before the appearance of this book; but now this want is so well supplied that a second edition has not only been issued, but nearly exhausted, and we call attention to it with confidence, because, although eminently popular in its style and treatment, it is the work of a practical hand, and is as reliable as it is full and complete. In these days of cheap books it is marvellously cheap, and we are led to wonder how a scientific manual of upwards of 120 pages, closely printed, and copiously illustrated, can be produced for one shilling. Everything that the young collector is likely to require information upon will be found by a little searching, which a copious index would greatly facilitate, and which we hope to see appended to a future edition. We have no doubt this Guide will continue to receive the support it so well deserves. C.

LETTERS TO THE EDITOR

The Variation in Outline of American "Flint" Arrow-heads

I FIND, after a careful perusal of the sixteenth chapter of Mr. Evans's magnificent work on British Stone Implements—on javelin and arrow-heads—that he has considered the American forms far more uniform, less varied in outline than they really are. I am familiar with many collections made at distant parts of the Union, and have an immense assortment of my own collecting now in the Museum of the Peabody Academy, at Salem, Mass. In these several collections is every form that Mr. Evans has figured, and several that he has not mentioned.

On page 362 of Mr. Evans's work, I find the author asserting as a prevailing type, "that with a notch at the base on either side." While this form unquestionably is very common, it cannot be considered as the "prevailing" one, inasmuch as several distinct patterns equal it in numbers found, and some exceed it, as those that "have merely a central tang, with little or no attempt at barbs." A second statement of Mr. Evans strikes me as very remarkable. He says, "the leaf-shaped form is very rare." This is a very great error. In any locality where arrow-points are to be found at all, they are always to be met with; and I have gathered scores of them that for symmetry far excel any of the figures given by Mr. Evans.

Nor can I admit the correctness of Mr. Evans's assertion concerning arrow-points, that "for the most part the chipping is but rough, as the material, which is usually chert, hornstone, or even quartz, does not readily lend itself to fine work." I believe no arrow-points have ever been discovered that can exceed, in beauty of finish, those I have myself gathered from the fields and meadows of central New Jersey. And I am the more surprised at Mr. Evans's remarks, inasmuch as the specimens I have found, that have been wrought from white or rose quartz, are remarkable for the smooth surfaces and sharp edges they present. So, too, of our jasper and hornstone specimens. Remarkably diversified in form, uniformly well finished, they strike the beholder with astonishment, when the "intractability" of the material is recognised. I have seen but few specimens of arrow-points not found in the United States; but judging from them and the illustrations of Mr. Evans's work, I unhesitatingly assert, that although we have no convenient flint in New Jersey or near it—Prof. T. A. Conrad has discovered true flint and chalk in Colorado—we have, in the jasper, chert, hornstone, quartz, and slate arrow-heads, examples of such weapons, as are in no wise inferior to those of Europe in beauty of finish, or less diversified in the various so-called "types."

Mr. Evans seems to have based most of his impressions concerning our antiquities upon Schoolcraft's ponderous tomes, which present little or nothing of value, of our "antiquities," whatever may be their reliability as concerning the "Indians," at the time when the volumes were compiled.

In conclusion, I will give a list of the arrow-points gathered on Wednesday, July 31, during the course of a three hours' search, and over fields that have yielded hundreds during the past and present summers.

Nos. 1—5, genuine leaf-shaped arrow-heads; four of black jasper or hornstone; all symmetrical, perfect. The largest specimen measures five-eighths of an inch in width at widest part, which is near the base, which is a beautifully wrought half-circle. The length is one inch and eleven-sixteenths. The other four specimens are somewhat smaller; one a little broader; and none can be considered as rough or badly-made examples.

Nos. 6—8 are what may be called triangular arrow-points, but are different from the ordinary examples of that pattern, in that they have very concave sides and base, and a rounded rather than pointed tip. Nothing in any way similar is figured by Mr. Evans, nor was I acquainted with this pattern when I wrote of our arrow-heads in the April No. of the *American Naturalist*. These arrow-points vary little in length and width; being about an inch and a quarter to an inch in length, by about one in width. The main portion of the specimen and the projecting barbs are nearly the same length, and have all the same degree of finish. One specimen is of brown jasper, one of hornstone, and the third, we suppose, is what Mr. Evans means by "chert."

Nos. 9—14 are triangular arrow-points, with straight or very slightly convex sides, and well-marked concave bases. None measure over an inch in length, by three quarters of an inch in width. One specimen is of "chert," three of hornstone, one of green, and one of chocolate jasper. The finish of all is good, and of two in particular very fine. The chocolate-coloured jasper example has a row of uniformly shaped notches or serrations, throughout the greater part of one side.

Nos. 15 and 16 are triangular arrows, both of which have straight bases, and one with straight sides, the other with very convex sides. Both are well finished, and the smaller quartz specimen with the convex sides is as smooth, well-edged and pointed, as though it had been "rubbed" down.

No. 17 is a yellowish "flint-like" stone, chipped into an arrow-point of the triangular pattern, but with a notch in the base, and also at each side. This form I have figured in the *American Naturalist*. It is but sparingly met with, and is there called a stemmed arrow-head, or one with a projecting base, which I think now is scarcely correct; the notches at the sides and base give it a "stemmed" appearance only.

Nos. 18—20 are three fine specimens, having projecting stems, which are narrower than the body of the specimens, and are not notched, but taper to a blunt point. Mr. Evans's figures 300 and 301 and the base of 302 well represent the specimens now lying before me.

Nos. 21—25 are stemmed arrow-points, with notches, that is, the "base" projects beyond the base of the body of the specimen, which gives "barbs" to the weapon—a style not given by Mr. Evans; or the base or "tang" is narrower than the body of the specimen, and flaring at its termination, produces the notches, by which the shaft was attached. A poor example of this pattern is Mr. Evans's figure 303. One of these "tanged" arrow-points has a projecting "tip," like that figured by Mr. Evans, as a peculiar feature of his leaf-shaped arrow-head, figure 283.

Nos. 26—33 are plain "tanged" arrow-heads, very similar to Mr. Evans's figure 304, which he refers to as "a magnificent specimen." The only marked difference in the little series before me and the illustration mentioned is that the tangs are all broader and a little shorter. The specimens themselves are not much smaller. They are of slate, jasper, hornstone, and "chert."

No. 34 is a lozenge-shaped arrow-head, very similar to Mr. Evans's figure 277, but is somewhat smaller. It varies from everything I have found as yet, and is a reproduction of those lozenge-shaped specimens, only of handsomer outline, that Mr. Evans has found on the Yorkshire wolds. The finding of this specimen lessens the number of forms found in Europe, that have not occurred here.

Besides these thirty-four specimens, which are all perfect, I gathered innumerable "chips" and broken specimens, some of them being of patterns not enumerated in my list. I have here briefly referred to nine distinct patterns, numbers of which, save two, were found during one day's hunting; and the result in numbers and varieties was nothing more than "a good average." I cannot therefore admit any one form to be a "prevailing" type, and the idea of inferior finish and of general elegance of appearance, is, we respectfully assert, a very great mistake. CHAS. C. ABBOTT

Trenton, New Jersey, Aug. 5

Millions of Millions

THE fact that I have myself slipped into an error by writing eleven noughts instead of ten in setting out a number expressed by a row of sixteen integers, only serves to confirm my former remark that millions of millions are awkward numbers to deal with, and that it will be well to avoid them by making use of the very simple rule-of-three sum indicated at the end of my list of errata to Professor Mayer's paper.

A. COWPER RANYARD

Fertilisation by Moths

IT has recently been suggested to me that the following note on the readiness with which moths wander, and their efficiency in fertilising orchids, is worth publication; I therefore forward it to you.

In the summer of 1869 I caught here on an island of less than six acres, in the middle of Derwentwater, twenty specimens of the common 'shark' moth (*Cucullia umbratica*); of these, seven had the pollinia of the butterfly orchis (*Habenaria chlorantha*) sticking to their eyes. I know for certain that there were no plants of *H. chlorantha* growing on the island, and all the moths must have come from places separated from the island by half a mile of water. W. C. MARSHALL

Derwent Island, Sep. 9

Origin of Insects

MR. J. J. MURPHY, in writing "that it is true that the water-beetles are wingless" (NATURE, No. 140, p. 373), has surely made a *lapsus calami*, since many waterbeetles are not only winged but use their wings. Other orders furnish examples of an aquatic winged insect fauna. The hemipterous genera *Notonecta*, *Corixa*, &c., are well-winged, and use their wings (especially *Notonecta*). *Corixa* affords an example of the elytra (*i.e.* the front wings) assisting in respiration, but probably not in the way that Mr. Murphy means. At the base of the anterior margin of the elytron there is a channel which retains a supply of air. Of course everybody knows the use of the elytra in *Dytiscus* to catch and retain air.

The Lepidopterous genus *Acentropus* affords another instance. The perfect winged insects frequently descend into the water. The females are sometimes winged and sometimes apterous, and the winged male has been seen entering the water in pursuit of—it is supposed—the apterous virgin female.

I think that it is possible that these apterous females exhibit the same kind of "parthenogenesis" as occurs in the *Psychidæ*. It would be well if those observers who have an opportunity would try to ascertain if parthenogenesis ever occurs in *Acentropus*. F. BUCHANAN WHITE

Solar Spots

BY an observation of the sun this morning at 11h. 25m., I find that several parts of his surface are in a disturbed condition, and that several largish spots (*maculæ*), surrounded with penumbræ, are visible. In the north-west quadrant of the disc, near the west limb, there was a group seen, in which two rather conspicuous spots were situated, and below these, in the southern hemisphere, there were three others of somewhat considerable dimensions. In the same hemisphere there was an irregular train of spots of various forms and sizes, extending almost to the margin of the south-eastern part of the disc. In the north-east quadrant I could discern no spots at all. Light clouds were continually passing over the sun during the time of observation. I used a 4-inch metallic mirror reflector, with the aperture contracted to three inches. WILLIAM F. DENNING

Bristol, Sept. 8

Correlation of Colour and Music

A VERY brilliant rainbow, which occurred on the evening of September 6th, recalled to my mind the note on the correlation of colour and music by Mr. W. F. Barrett, which appeared in

NATURE of January 13, 1870, and the subsequent correspondence. The violet of the primary bow passed into red at its concave edge, and within this violet-red arc there was a faint appearance of prismatic colours, blue or green (and I think yellow), and then a distinct red arc, and within this again yet another very faint red arc. Between these last two the other colours of the spectrum, if they existed, were too faint to be seen; but the impression given by a *coup d'œil* was that of three complete series of colours. There was nothing beyond the red on the outside of the primary bow, except, of course, the secondary bow, at some distance.

This is the phenomenon alluded to by Mr. Justice Grove, in his letter to NATURE of January 20, 1870, in which he queries whether these colours are repetitions of the spectrum, such as are suggested by Sir John Herschel. Your correspondent, Mr. C. J. Munro (NATURE, February 3, 1870), appears to regard them as analogous to "Newton's Rings." I should much like to see the point more fully elucidated. Is it established that under no circumstances can the spectroscope show visible rays beyond the violet?

GEORGE C. THOMPSON

Cardiff, Sept. 8

Cat's Teeth

I HAVE in my collection the skull of a cat, which has the peculiarity of possessing an extra molar tooth on the left maxilla; this tooth is tricuspid, and is situated between the last premolar and the carnassial tooth, on their interior side, so that it does not disturb their normal position. Will some of your readers inform me whether this is not very unusual? and whether from its position it does not overthrow Professor Owen's theory, that the two premolars are respectively third and fourth?

Harpenden, Sept. 2

DANISH EXPEDITION TO THE FAROES

THE United Steamers Company (*forenede Dampskibselskab*) in Copenhagen, having got a grant from the Government for the exploration of the Faroe coal-fields, is about to send an expedition to these islands, for the purpose of scientifically examining into the extent of the coal-fields in the north of Süderoe, and discovering in what manner coals may be best transported from that island to Copenhagen.

Besides having in view commercial purposes, the expedition will be accompanied by men of science, who will investigate the natural history of these little-known islands. The Government has asked Prof. Johnstrup to visit the different coal-fields on the southern island, and to investigate the geological features. The managers of the steam company, represented by Consul Koch, have also kindly allowed the writer of these lines to accompany the expedition for zoological purposes.

The geological features of the islands are best known from Forchhammer's researches, published in the "Transactions of the Danish Society of Sciences" (1828). The rocks of the Faroes are for the greatest part of volcanic origin, dolerite-porphyry being found in large masses in all the islands. Coal sediments are only to be seen in the south (Süderoe), and in the little islands of Myggenäs and Tindholm. To what formation these beds belong has not been cleared up, as fossils have hitherto not been discovered. But as the coal-fields of Iceland and Greenland, in which fossil plants have been found, belong to the miocene-tertiary period, it is very probable that those of the Faroes belong to the same formation. The researches which now are to be made by Prof. Johnstrup and his assistant, Cand. Geisler, will, we hope, throw further light upon the nature of these deposits.

The fauna of the islands, as far as the vertebrates are considered, was already tolerably well known at the beginning of this century, as may be seen from Landt's "Beskrivelse over Faeröerne," published in 1800. The only wild mammals inhabiting the interior of the islands are a few species of the genus *Mus*, which follow man's steps wherever he goes. But the shores of the Faroes are visited by a large number of *Pinnipedia* and *Cetacea*, from the capture of which the inhabitants have every year a good profit. The birds—those inhabiting the rocks of Store and Lille Dimon, as well as those of some of the other islands—have been made known by Graba, and, so far as they also occur in Iceland, by Faber. Later publications, especially by Swedish authors, are well known to have thrown much light on the natural history of these inhabitants of the north. Reptilia and Amphibia do not occur at all in the Faroes; but fishes of various species come to the shores and ascend the rivers in considerable numbers. They have been collected with great zeal by Sysselman Müller, of Torshavn, who has sent a list and specimens of all the species known to him to the zoological museums of Copenhagen. The lower animals are less known; we have lists of echinoderms and molluscs by Lütken and Mörch, and we know something about the worms from the investigations made there by Prof. Oscar Schmidt, who for a short time visited the Faroes. The writer of these lines hopes to gather further information about the lower animals by dredging on the shores of the islands; and, while collecting the fishes for the Munich Museum, he will continue his researches into the natural history of their parasites.

The expedition will leave Copenhagen early in September, and, when returning from the Faroes, may perhaps pay a visit to a Scottish port.

RUD. V. WILLEMOES-SUHM

Copenhagen, Sept. 4

NATURAL HISTORY EDUCATION AT HARVARD UNIVERSITY

WE reprint the following interesting article on the scientific instruction given in Harvard University from the pages of the *American Naturalist*:—

The changes which have been made in the departments of Natural History at Cambridge within the last two years have been very great, greater perhaps than in any other school within the same time. As there are many persons of both sexes who are seeking opportunities for study such as the University now offers, we give a sketch of the plans of education in the different schools as far as they concern the student of natural history. There are five schools in the University where natural history is taught: the College, the Museum of Comparative Zoology, the Botanic Garden, the Scientific School, and the Bussey Institution. Let us trace in a general way the course of a student in these departments.

The student who enters the college to-day is no longer compelled to follow the one uniform road over which the boy of twenty years past had to go; after his first or freshman year, he may begin to turn himself into the paths of natural science. At the commencement of his second year he may begin his studies by courses which lay the foundations of a knowledge of chemistry, taught in the laboratory; of physical geography, geology, and meteorology, taught by text-books, lectures, and excursions in the field. The time allowed for these studies during the year is estimated at twelve hours per week. It is expected that the student will in this year lay the foundations for the work he may wish to do during the following years, by getting that general idea of the physics of the globe which forms the necessary basis for the work of the naturalist in any department of labour.

With the junior year the studies of a strictly biological character begin. One course includes the elements of comparative zoology, with elementary teaching in

microscopy, another the elements of botany, a third the elements of comparative anatomy. The principle on which the teaching of zoology is based is that the student should at the very beginning be put into the position of an investigator. With this object in view the student is at first required to do all his work upon natural objects. Beginning with the solid part of a Fungia, or some other object of equal simplicity, the student is then required to draw and describe the specimen, aided only by such questions and suggestions as may be necessary to get him over the worst obstacles. As soon as he has done the little he can do in the way of close observation, he is given a Manacena or Agaricea, which he proceeds to compare with the Fungia, and so making at least diagrammatic drawings with a dozen other specimens of Polyps, Halcynoid and Actinoid. Thus the student gets some idea of the general relations which exist among the members of that group. When, say, in thirty hours of labour he has got through this work, a few lectures serve to supplement and connect the knowledge he has obtained from the personal study of the dry parts, illustrated by a sufficient series of alcoholic preparations, and helped out by such individual teaching as can be given without weakening the habit of self-reliance. In this way he goes through group after group, until, from a study of about one hundred species, he has gotten a general idea of the organic forms above the Protozoa. In this stage of the student's work care is taken to avoid the use of diagrams; this avoidance being dictated by the conviction that the student remembers the diagram and not the object. During this year botany is also taught, with the same object and by much the same method. In connection with the zoological instruction the students are taught the elements of microscopy, the development of the subject being left to the next year.

The second-year courses are advanced zoology, palæontology, historical geology, geography, and advanced botany. The first two have one common feature; three lectures or readings are given each week to the discussion of the history of zoology and palæontology, with special reference to modern opinions concerning the relations of animals. An effort is made to acquaint the students with the character of the greater works in the science, by giving them constant opportunities for consulting them in their studies, and by showing them the methods of the masters in the several departments. Besides this, each student is required to pursue some special line of work. In the choice of subject the largest liberty is allowed, but the student is, however, recommended during a half-year to study advanced microscopy; in this work the aid of an instructor is given for four hours a week. In this four months he should acquire a sufficient knowledge of the practical management of the instrument in all ordinary investigations. The laboratory is well supplied with instruments of instruction in this branch of work.

Besides the course in the history of the science, the student who takes the elective in palæontology is required to traverse the ground covered in that part of "Dana's Manual" which is entitled historical geology, acquainting himself in a practical way with the most important characteristic fossils of the several periods.

The greatest value in this work is set upon the keeping of full and accurate note-books in both the last described courses. The rank of the student turns upon the condition of his note-books as much as upon the quarterly examinations which he is required to pass.

Those students who desire to contend for honours at the graduation in zoology or in palæontology are required to have taken, besides their junior election in natural history, one election in physical science, and at least three natural history elections in the senior year, in all of which they must have attained excellence. They are moreover required to write an acceptable thesis, which must contain an original discussion of some question in biological science. Hereafter the junior electives will consist of a course in anatomy and physiology, one in zoology, and one in botany; and the students in this as well as in the last year will be allowed to substitute for the themes required in other branches theses upon scientific subjects prepared under the direction of their instructor.

The natural history education of the scientific school has undergone a great change within a year; hitherto the students have worked with the professors of the several departments, giving their whole time to any speciality which they might select. This plan, admirably suited as it was to the needs of the trained student who had fitted himself in other schools for the work of a special department, was not adapted to the needs of those to whom this teaching was to fill the whole office of higher education. With the introduction of the doctor's degree into the plan of the school, it became necessary to make a change which has long been desirable, by fixing a definite scheme of general scientific instruction in place of the imperfect system which had hitherto prevailed. A three years' course has been arranged which secures to the student a broad view over the whole field of science, and the advantage which comes from a knowledge of the methods of research in use in its several branches. It gives to those persons who may not have the desire or the means to go through a regular college course a systematic training which will occupy their full time for three years, and give the best results of culture which can be attained in any scientific course. Students who can pass the required examinations are admitted to the degree of bachelor of science. Graduates of colleges where science is taught in an effective way should be able to enter this course in advanced standing. Students of the college, graduating with honours in the departments of natural history, should be able to obtain the degree in this course in a year of study. The student is trained in the important art of expressing himself clearly on the matters which he is studying, by requiring him to keep carefully planned note-books; and he is urged to the preparation of theses which may embody the results of some research. Ample opportunities are given for the prosecution of studies in the field, by excursions during term time and vacation, led by the instructors in zoology, botany, and geology.

After two years' further study, one of which must be spent in Cambridge, the student may apply for the degree of doctor of science, which is given after an examination conducted by a committee appointed by the Academic Council of the University.

The study done, the preparation for the degree must be in some special department, when the student will generally become the private pupil of some one professor. The degree will be a certificate of capacity as an investigator or teacher in the science which the student has made his specialty.

The resources of the University for teaching science are, it is believed, not only unrivalled in this country, but unsurpassed in Europe. The scientific departments have a list of twenty-four instructors, and the material resources which they afford have cost in the aggregate over a million and a half of dollars. There are six museums in the University—the Museum of Comparative Zoology, the Botanical Museum, the Museum of Comparative Anatomy, the Museum of Morbid Anatomy, the Museum of Mineralogy, and that of Ethnology. These collections are unsurpassed by those of any educational institution in this country; and, taken together, they furnish an efficient basis for the acquisition of the wide ranging knowledge on which a scientific career must be based. The opportunities for contact and intercourse in scientific societies are excellent. There is a working society of natural history in the University, and the Boston Society of Natural History, one of the largest and most efficient of the American institutions of this nature, is also open to all students of the science.

MELTING AND REGELATION OF ICE

IN NATURE of January 4th of this year, there is a most interesting account of some experiments on melting and regelation of ice by Mr. James T. Bottomley. These experiments of Mr. Bottomley's suggested the possibility of passing large bodies through ice in the same way as he caused the wires to pass. I accordingly placed a sixpence on a block of ice, and applied pressure to it by means of a fine steel wire about one-sixteenth of an inch in diameter. On examining the block of ice sometime afterwards, I found the sixpence had passed into the centre of the block, and that the space through which it had passed, except the small part occupied by the steel wire, was again solid ice. I tried the same experiment with a shilling, and found that it also easily passed through the ice, the experiment was then repeated with a half-crown with the same result. I did not attempt anything larger, but have no doubt much larger discs of metal might be made to pass through ice if sufficient pressure were applied. The ice in the parts of the blocks through which the coins had passed did not look very solid, but was rather full of air-bubbles; on breaking the block, however, it did not seem much weaker than the rest of the ice. Another form of the experiment was then made, a block of ice was supported on two boards placed near each other. A loop of fine wire was passed over the ice, and hung down between the two boards and a weight attached to it, as in Mr. Bottomley's experiments, pieces of wood were placed so as to stop the wire when it had passed half way though the ice. After the wire had passed into the centre of the block, the weight was removed, the wire cut, and a disc of metal half an inch in diameter was attached to one end of the wire, and a weight to the other end. In this manner the disc was drawn through the ice, leaving apparently perfect solid ice behind. The path of the disc could only be traced by its slightly cloudy appearance, it looked as if the few air-bubbles passed through by the disc had been broken up into a great number of small ones. On breaking the ice afterwards it seemed quite as strong where the disc had passed as elsewhere.

The explanation of these experiments is of course the same as for the experiments with the wires; Professor James Thomson showed that the freezing point of water is lowered by pressure, and also that ice has a tendency to melt, when forces are applied which tend to change its form. So that the ice under the coins has a tendency to melt, and has its freezing point lowered by the pressure. The under side of the coin will thus have a lower temperature than the upper; there will therefore be a transference of heat from the upper to the under side of the coin, this heat melts the ice under the coin, the water so formed passes round the edges of the coin to the upper side. This water being at a slightly lower temperature than the freezing point at ordinary pressure, a very small proportion of it will freeze and raise the temperature of the rest to the freezing point. The water arrived at the upper side of the coin, the coin being at a temperature a little below the freezing point, the water will be frozen, giving out its latent heat, which will pass through the coin and melt an equal quantity of ice on the under side, this having absorbed its latent heat of liquefaction will in turn pass to the upper side, and will there be converted into ice, giving out its latent heat to melt another quantity, and so on.

A slightly different form of the experiment was then made, a small metal cup was filled with water and laid on a piece of ice, and a heavy weight placed on the cup. After some time the water in the cup was frozen. The freezing point of the ice under the cup being, owing to the pressure, lower than that of the water in the cup, the water in the cup parted with its heat to the ice outside. A quantity of ice outside the cup was thus melted equal to the quantity of ice formed in the cup.

At first sight these experiments might seem to have an important bearing on the motion of glaciers. It might be thought, that if large bodies flowed thus easily through ice, why should not ice flow easily in its channel? But when we consider the circumstances, we find they are not so similar as might at first appear. When a body flows in this way through ice, there is not only a displacement of matter but also a displacement of heat, and the displacement of the matter cannot take place till there has been a displacement of the heat. In the preceding experiments, circumstances were most favourable for both displacements taking place quickly. The heat easily flowed through the very small thickness of the good conducting silver discs, and the water had only to flow from the one face to the other round the edges of the coins, whereas in glaciers, the ice and the rocks over which it moves are bad conductors of heat, and the distance to which the heat has to be conducted is so much greater than in the above experiments, that the exchange of heat can take place but very slowly; and when we further remember the very small difference of temperature between the freezing point of ice under pressure and not under pressure—if the lowering of the freezing point is the result of hydrostatic pressure alone, a pressure of one hundred atmospheres not lowering the temperature one degree centigrade—we can easily see that there will not be sufficient difference in temperature between the different parts of the glacier to cause the heat to flow quickly from one part to another, through such bad conductors.

In the explanation given of the passage of the coins through the ice, it has been assumed that the passage depends on the exchange of heat from the freezing ice on the one side of the coin to the melting ice on the other side. If this explanation is correct, then, if the coins had been non-conductors of heat, they would not have passed through the ice. The test was put. A shilling was placed on a block of ice, and over it a disc of a non-conductor (india-rubber), the same size as the shilling and over that another shilling; a weight of 90lbs. was applied by means of a small steel rod. After four hours it was found that the shillings had only sunk about an eighth of an inch into the ice, most of the heat to sink it this short distance being, in all probability, got by radiation from surrounding objects; as other two shillings and non-conducting disc placed on a block of ice and similarly situated, but not under pressure, had sunk to nearly the same depth.

There is another point in these experiments in their relation to glacier motion, which requires to be noticed. In all the experiments referred to, ice at the melting point was used. Sir William Thomson showed that the freezing-point of water was lowered $0^{\circ}\cdot13$ C. by a pressure of 16·8 atmospheres. We should therefore expect that, if we lowered the temperature of the ice by half a degree or a degree below the freezing-point, a much greater pressure would be required to cause the coins to pass through the ice. In order to test this, a block of ice was surrounded with ice, salt, and water. After it was cooled about a degree below the freezing-point, a shilling was placed on the block of ice, and a pressure of 90 lbs. applied. On examining it three and a half hours afterwards, the shilling was found not to have entered in the slightest degree into the ice. The freezing mixture was then removed, and within an hour the shilling had passed some distance into the ice. It would therefore appear, considering the enormous resistance offered by ice at a temperature of even one degree below the freezing-point to change of state, that the motion of glaciers at the higher parts, where their temperature is below the freezing-point, is, in all probability, not caused by the melting and regelation of the ice in the same manner as in the experiments.

Darroch, Falkirk JOHN AITKEN

A GIGANTIC "PLEASURING GROUND": THE YELLOWSTONE NATIONAL PARK OF THE UNITED STATES

THE Americans do their pleasuring as gigantically as they do everything else. This is the first and strongest impression made upon one by an Act of Congress of March 1872, to which we alluded in a recent number of NATURE, enacting that a district about half the size of Wales, and 1,000 square miles larger than the largest Swiss Canton, be "dedicated and set apart as a public park or pleasuring ground for the benefit and enjoyment of the people." It is forbidden that anyone shall hereafter settle upon or enclose any part of the immense area thus set apart, and only such buildings can be erected upon it as the Secretary of the Interior, who has the exclusive control of this "park" (what an inadequate name!), may deem conducive to the accommodation and comfort of the visitors.

The estimated extent of the district thus set apart is 3,575 square miles, and coincides to a large extent with the area contained between the 110th and 111th degree of W. long., and the 44th and 45th parallels of N. lat. The southern boundary, however, is about eight miles farther north than and parallel with the 44th degree, and about seven miles westward of and parallel with the 111th degree, the whole district forming very nearly a square, and looking on the map like a huge slice out of one of the most mountainous parts of Switzerland; one of the heights, Mount Washburne, is 10,575 feet above sea level. Even the lowest part toward the south, containing the basin of Yellowstone Lake (330 square miles), "one of the most beautiful lakes of the world," is about 7,000 feet above the sea. Besides the huge mountains that form the most prominent features of this pleasure ground, the

FIG. 1.—Natural Walls in Yellowstone Park.

beautiful lake just mentioned, and a large part of the upper courses of the picturesque Yellowstone and other rivers, the district embraces some of the most remarkable natural phenomena that are to be seen in any part of the world—wonderful falls, multitudes of hot springs, steam springs, mud geysers, mud puffs, water geysers, some of them rising to a height of 200 feet, and other objects of interest. This whole region was in comparatively modern geological times the scene of wonderful volcanic activity. The hot springs, geysers, &c., represent the last stages, the vents or escape pipes, of these remarkable volcanic manifestations. All these hot springs are adorned with decorations more beautiful than human art ever conceived, and which have required thousands of years for the cunning hand of Nature to form. The geysers of Iceland sink into insignificance in comparison with the hot springs of the Yellowstone and Fire-hole basin. No portion of this tract could ever be made available for mining or agricultural purposes. The mountains that wall it in on every side form one of the most remarkable watersheds on the continent. From whatever point of view we survey this remarkable region, it is unsurpassed in interest, and the Act is one that should cause universal satisfaction throughout the States. "This noble deed," Mr. F. V. Hayden truly says, "may be regarded as a tribute from our legislators to science, and the gratitude of the nation, and of men of science in all parts of the world, is due to them for this munificent donation."

Several exploring parties have lately visited the district, and from an account of one of these, under Mr. F. V. Hayden, U.S. Geologist, to whose courtesy we are indebted for the accompanying woodcuts, we condense the following description of some of the most remarkable phenomena to be witnessed.

Nine-tenths of the area is covered with volcanic material in some form. The base rocks are the usual metamorphic granitoid series of the country, with basalts and basaltic conglomerates in every variety. The sedimentary rocks belong to the Carboniferous, Jurassic, Cretaceous, and Tertiary ages. The Triassic is probably wanting. The sedimentary rocks occur in patches, covering very restricted areas, yet presenting evidence that, up to the period of the Eocene Tertiary inclusive, they were extended uninterruptedly over the whole country. In the Yellowstone valley, as in the valleys of all the streams of the West, there is a chain of lake basins that must have existed during the Pliocene period. There was a continuous chain of these lakes of greater or less size to the source of the river; thence it expanded into an immense double lake, of which only a remnant, Yellowstone Lake, now remains. This lake was once much larger than at present, and it was partially connected with another lake about 30 miles long and 20 wide, which terminated at the Grand Cañon, at the upper falls of the Yellowstone.

FIG. 2.—Sulphur and Mud Springs, Eight Miles below Yellowstone Lake.

The term Yellowstone Basin is sometimes applied to the entire valley; but the basin proper comprises only that portion enclosed within the remarkable ranges of mountains which give origin to the waters of the Yellowstone, south of Mount Washburne and the Grand Cañon. This basin is about 40 miles in length from north to south, and on an average 30 miles in width from east to west. It might be called the vast crater of an ancient volcano made up of thousands of smaller rents and fissures, out of which the fluid interior of the earth, fragments of rocks, and volcanic dust have been erupted in unlimited quantities. Hundreds of the nuclei or cones of these volcanic rents are now remaining, some of them rising to a height of nearly 11,000 feet above the sea. Indeed, as has been said, the hot springs and geysers of this region are only the closing stages of that wonderful period of volcanic action which began in Tertiary times. Even at the present time there are connected with these manifestations of internal heat earthquake phenomena which are well worthy of attention. Earthquake shocks are not

uncommon, and are at some seasons of the year very severe.

Yellowstone Lake itself has at all seasons the temperature nearly of cold spring water, and its area is gradually but very slowly diminishing. Mr. Hayden estimates that since the period of volcanic activity the depth of the lake has been about 500 feet greater than at present, the shore line having then been high up on the sides of the surrounding mountains.

Warm springs are not uncommon in the valley of the lower Yellowstone, but the temperature is seldom higher than 60° or 80°. It is not until we reach Gardiner's River, a small branch flowing into the Yellowstone on the left side, opposite the third cañon, that the true hot springs commence in their full force. About three miles above its junction with the Yellowstone, the valley bottom is covered with a thick calcareous crust, the deposits of hot springs which are now extinct; but flowing swiftly from beneath this crust is a stream of hot water six feet wide and two feet deep, with a temperature of 132°. A little distance farther up is a high hill, on the slope of which has been formed a system of terraces, each from 200 ft. to 300 ft. in height, and covered with a thick deposit of lime. On the ascent of the hill, about three-fourths of a mile from the river bottom, there is to be met with one of the most remarkable exhibitions of hot spring deposits that is to be seen in this land of wonders. In the distance it looks like a vast glacier of snow and ice, on which account it has been named the White Mountain. Indeed, the different terraces can be compared, for their wonderful beauty, only to a frozen cascade. The remains of once active springs are plainly visible;

Fig. 3.—Sulphur and Mud Springs, Six Miles below the Lake.

old chimneys, irregular openings, like entrances to caverns, which extend beneath the crust, are numerous. This crust is probably from 20 ft. to 50 ft. in thickness, and underneath it is supposed that the surplus water from the active springs above flows down to the river. A little farther up is a series of basin-like pools, from 4 ft. to 8 ft. in diameter, and on a terrace about 200 ft. farther still are numbers of active springs, with basins 20 ft. to 50 ft. in diameter, some of them with several centres of violent ebullition in the same basin. The temperature at the outflow varies from 150° to 162°.

Upon the terrace, down about midway on the side of the mountain covered with this deposit, the principal active springs are now located, and here is presented another picture to the eye which transcends any description in words. The water is perfectly transparent, and down in the clear depths can be seen distinctly the minutest ornament upon the inner sides of the basin; and the exquisite beauty of the colouring and the variety of forms baffle any attempt to portray them, either with pen or pencil; various shades of red, from the most brilliant scarlet to light purple; yellow, from deep-bright sulphur through all the shades to light cream colour; and green of various shades. These springs also are full of a kind of vegetation, which under the microscope proves to be composed of diatoms, among which Dr. Billings discovers *Palmella* and *Oscillaria*. There are also in the quiet springs, and in the little springs that flow

from the boiling springs, great quantities of a fibrous, silky substance, apparently vegetable, which vibrates at the slightest movement of the water, and has the appearance of the finest quality of cashmere wool. A qualitative analysis made at the springs shows that the water contains sulphuretted hydrogen, lime, soda, alumina, and a slight amount of magnesia. Carbonate of lime predominates over all other elements in the deposits, and they may therefore be called calcareous springs.

There are two classes of springs in the Yellowstone valley, one in which lime predominates, in the other silica. With the exception of the White Mountain Spring in Gardiner's River, and one or two of not much importance, the other springs of the Yellowstone and Firehole basins are siliceous. They may be divided again into intermittent, boiling and spouting, and quiet springs. Those of the first class are always above boiling point during the period of action, but during the interval the temperature lowers to 150°. Those of the second are always at the boiling point, and some of them throw the water up two to six feet by regular pulsations. The springs of the third class may have once been geysers, but are now quiet, and have a wide range of temperature, from 188° to 80°. Where the temperature is reduced below 150° great quantities of the sesquioxide of iron are deposited by the water, lining the inside of the funnel, and covering the surface where the water flows. Taken in the aggregate, these springs have been in constant operation during our present period, and

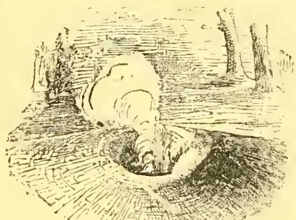

FIG. 4.—Hot Spring.

Mr. Hayden estimates that under favourable circumstances, at least six feet of this deposit have been precipitated within the space of one century.

We must omit an account of the basaltic columns in the cañons of the Yellowstone and Gardiner's river, and of the great cañons, falls, cascades, and other wonders of this unique region, and pass to the hot springs of the upper basin. A few springs are seen at the mouth of Tower Creek, at the lower end of the Grand Cañon; but it is not until we pass the range of mountains which forms the north wall of the upper basin, about twenty miles above the lake, that the great hot spring district of the Yellowstone commences. There is here an area, within the drainage of the Yellowstone, forty miles in length, and on an average fifteen miles in width, that either is at the present time, or has been in the past, occupied by hot springs. The old deposits cover the region, and here and there are groups of active springs—mere remnants of what formerly existed. The Grand Cañon is a deep channel 1,000 to 1,500 ft. in depth, carved out of the basaltic rocks, and hot spring deposits, and on the sides of the walls may be seen the irregular fissures which communicate from the surface with the heated interior. Resting upon an irregular surface of basalt are immense deposits of silica of all colours, every shade of red, yellow, and white. Much of the deposit is as white as snow.

On the west flank of Mount Washburne, in the north of the area, there is a remarkable group of springs, in a constant state of action at the present time. Alum, sulphur, soda, and common salt, are found upon the surface in considerable quantities. Sulphuretted hydrogen is emitted from the spring in such quantities as to fill the air, rendering it oppressive with sulphurous odour. This group extends across the Yellowstone to the eastward for several miles. The springs, which are now in active operation, are only a few out of hundreds which once covered the entire area, but which are now dead or dying out.

Two remarkable groups deserve particular mention, the sulphur and mud springs, shown in Figs. 2 and 3. The largest group (see Fig. 2) is found on the east side of the Yellowstone, at Crater Hills, eight miles below the lake. This district covers an area of about half a mile square, and is sometimes called the "Seven Hills," from the fact that there are here several mounds of siliceous deposits from extinct springs, varying in height from 50 ft. to 150 ft. The old craters of dead and dying springs, and the immense quantity of the siliceous deposits, show that the present active springs represent only the last stages of what must have been at some period in the past a magnificent group. There are still numerous steam-jets, one of which, on the west side, produces a sound like that of a locomotive, which can be heard for a long distance. The surface is fairly riddled with little steam vents, and the crust sends forth a hollow sound beneath the tread; and on removing this shelly covering at any point, hot vapours come forth, while its under surface is encrusted with the most beautiful crystals of sulphur.

The springs at this point are either boiling, mud, or quiet springs. The principal boiling spring, which is in a constant state of ebullition, sends up a column of water 2 ft. to 4 ft.; has a basin about 15 ft. in diameter; and gives forth such a column of steam that it cannot be approached except on the windward side. But perhaps the most interesting objects here are the mud springs, which are of every size, from an inch in diameter to 20 ft. One of the largest is filled with fine light brown mud, which is in a constant state of agitation, the surface covered all over with puffs like hasty pudding. Others send forth a thud-like noise every second, with an impulse at long intervals that throws the mud up several feet. The water in the vicinity, as well as the mud, seems to be thoroughly impregnated with alum. In an adjoining valley are little mud or turbid water vents, which keep up a simmering noise, showing the nature of the earth beneath the crust.

Two miles above, on the same side of the Yellowstone, is the other group of springs, similar to those just noticed. Besides these are the geysers, to be alluded to presently. One of these is a true intermittent spring, and throws up a column of water 10 ft. in diameter, from 15 to 30 ft. high. The crater becomes filled with boiling water; suddenly immense columns of steam shoot up with a rumbling noise, the water overflows the basin, another column of water is thrown up for the space of 10 or 15 minutes, when it quiets down, and the basin is nearly empty. This operation seems to be performed about eight times in 26 hours. Upon the side of the hill bordering the river is one of the most terrific mud-cauldrons seen by Mr. Hayden during his visit. A large column of steam is constantly ascending, 500 ft. or more, from a deep funnel-shaped basin, 25 ft. in diameter; when the wind carries away the steam for a moment, the thin, black mud may be seen 25 ft. below the rim in the most violent state of agitation, with a noise like distant thunder.

On the shore of the south-west arm of the lake is an interesting group of hot springs, which extend along the margin, covering a belt about three miles long and nearly a mile in width. Many of these, which might be called pulsatory springs, are in a constant state of quite violent ebullition, but rise and fall every second or two, and with each pulsation throw out a quantity of water. Quite a

pretty, symmetrical, funnel-shaped crater is formed with a circular rim, varying from a few inches to several feet in diameter. Some of these funnel-shaped chimneys (see Fig. 4) extend out into the lake several feet, and the hot spring deposits may be seen through the clear depths for fifty yards. The same variety of colours, quiet springs, mud springs, old ruins, &c., that have before been described, occur here. No geysers have been observed, but the group of mud springs keep up a constant thud-like noise, which can be heard with great distinctness for half a mile. At Steamboat Point are two vents, which keep up a constant pulsatory noise like a high-pressure engine on a river steamboat; columns of steam are thrown out at each pulsation to the height of 100 feet or more.

(*To be continued.*)

NOTES

We may hope that we and the public have now heard the last of the unfortunate Hooker and Ayrton dispute. We learn that Mr. Ayrton has expressed himself satisfied with Dr. Hooker's explanation of the "offensive" matter in his letter to Mr. West, and here the matter will probably rest. It would be more satisfactory to know that all probability of similar unpleasantness for the future had been removed, and that the Government recognises the principle that a servant selected to control a great scientific establishment must necessarily be entrusted with all the details of its management.

The rejection, by the Committee of Recommendations of the British Association, of the resolution of Section D respecting the treatment of Dr. Hooker as Director of Kew Gardens, resulted in the sending up to a subsequent meeting of the committee of a more strongly worded resolution to the same effect, which was then passed, not only by the Committee of Recommendations, but by the General Committee.

At the meeting of the French Academy on the 2nd instant, the President presented to M. Chevreul a medal which had been procured by a subscription among his *confrères*. M. Dumas in a speech "à la manière anglaise," as the President expressed it, touched upon the chief services rendered by M. Chevreul to science in acknowledgment of which this medal was presented to him. Each subscriber is to receive a copy of the medal, and according to a slip inserted in the *Comptes Rendus*, the subscription list is still open.

It is with great regret that we have to record the death, at the early age of 38, after a long and painful illness, of Mr. John Cargill Brough, F.C.S. He was a man of most accomplished mind and great general culture, and had personally endeared himself to all his acquaintances. Mr. Brough had filled, for about two years before his death, the office of secretary and librarian to the London Institution in Finsbury Circus, and had brought new life into its management.

We hear from Paris of the death, at the age of 42, of one of the most promising of the younger generation of French botanists, M. Gris. He had written largely on both systematic and physiological botany, and held the post of assistant in the botanical department of the *Jardin des Plantes*.

The inaugural address of the winter session of the Birmingham and Midland Institute will be delivered on Oct. 7, by Canon Kingsley, who is the president for the year.

Mr. G. F. Rodwell, F.R.A.S., &c., has just been appointed Lecturer on Natural Philosophy at Guy's Hospital, still retaining his position as science teacher in Marlborough College.

The Royal Polytechnic Institution appears, under its new management, to be assiduously encouraging the cultivation of Science. We have received a prospectus of classes held in the Institution in quite a number of branches of Natural and Physical Science.

We notice from the *School Laboratory of Physical Science*, published in Iowa, U.S., that the total number of pupils who have attended one or more courses of lectures at the physical laboratory of the State University during the school-year of 1871-2, has been 340, representing all the departments of the University. Of these students, 270 have practised at the stands of the laboratory from two to ten hours a week each, and from the reports of the work done and the results, carefully calculated, of the examinations, it would appear that the teaching is varied and thorough. The high importance of laboratory work in the teaching of students is becoming more and more widely recognised in practice in the United States, and from this Report we learn that the great majority of the students themselves like the laboratory practice very much; those who do not, we are told, are those who are not fond of any serious mental work. As the opinion of the writer of the *Laboratory News* in the above work we quote the following note:—"One of the principal drawbacks to the perfect success of the Laboratory has been the admission of some students of advanced standing in the dead languages; we find these students almost invariably less careful in their work, and more hasty and illogical in their conclusions, than the regular beginners; they also have made the greatest blunders in calculation. As a result, such juniors have failed in competition with common sub-freshmen. I should not refer to these facts, if it were not so frequently asserted that the study of the dead languages constituted an auxiliary to the study of science."

The Marlborough College Natural History Society has issued its Report for the half-year ending Midsummer 1872. In the Preface praise and blame are impartially dealt out to the members of the Society; the zeal and industry of individual members are commended in not undeserved terms; while the apathy and want of energy of the majority of the Society come in for severe censure. In the Botanical department some good work appears to have been done, and the president, the Rev. T. A. Preston, continues his Flora of Marlborough, the present instalment embrace the Calyciforæ. In Geology nothing has been done; in Ornithology a few of the members have shown active interest in "*genuine* Ornithology, not merely the taking of eggs, but observations of the birds themselves and their habits." The greatest triumph has been, however, in Entomology, where, thanks to the energy of two or three individuals, upwards of thirty moths have been added to the Society's list. Of the papers printed we may notice a useful one on Shells, by F. J. H. Jenkinson, and one on Thermo-Electricity and a new Thermo-Electric Battery, by Mr. Rodwell; others, however, are alluded to in the Preface. We cordially encourage the Marlborough College Natural History Society to continue its work.

Mr. Gould is now engaged on the preface to his great work on the "Birds of Great Britain," and will issue the last two parts, completing the whole, in 1873.

A very good "Flora of Liverpool" has been published by the Liverpool Naturalists' Field Club. The area included is within fifteen miles of Liverpool and two of Southport, and embraces some very interesting districts. The work has been performed by a committee of the society appointed for the purpose, with the assistance of amateurs and previously published records, which have all, when possible, been verified. It appears to have been carried out with great care, and some valuable notes are appended to the records of some of the species.

Among the most recently-published foreign flora we may note Dr. J. A. Knapp's "Plants of Galicia and the Bukowina," just published by Braumüller, of Vienna, in one thick volume.

The last number of the *Quarterly Journal of the Meteorological Society* contains a letter from M. Hoffmeyer, Director of the recently established Meteorological Institute of Denmark, giving some details of the work it is intended to accomplish. The sphere of the Institute embraces all the branches of Meteorological Science, and it is especially intended to establish in favourable situations a series of stations, furnished with accurate instruments, by which it will be possible, every morning, to send telegraphic communications to the chief station at Copenhagen, and from that, according to agreement, to foreign societies. When the stations are fairly in working order, observations will be published monthly. It is also proposed by the Institute to establish about ten complete meteorological stations at the Faroe Isles, Iceland, and in Greenland; half of these are expected to be in trim by next winter. Besides the general interest attaching to these stations, it is hoped they may tend to foster a system of international meteorology, and pave the way for the laying down of a northern telegraphic cable between Europe and America. The observations at these stations will be specially published. The establishment of this Institute is likely to be of the greatest service to general meteorology.

In "Railways or No Railways; the Battle of the Gauges Renewed," those who take an interest in the subject will find the case on behalf of the narrow gauge fully and ably set forth.

A "Dissertation on the Use of the Stethoscope in Obstetrics," by Æneas Munro, M.D., read before the Royal Medical Society of Edinburgh, seems to be a valuable contribution to the science of the subject to which it relates.

We have received a pamphlet, "Irrigation not necessary in Upper India," by Major A. F. Corbett, Superintendent Budaon Police, in which the author attempts to prove that irrigation, instead of fertilising that country, will inevitably render it an almost barren waste. The statements he adduces, and the opinions of eminent scientific men and others that he quotes, certainly appear to bear out the writer's theory, and on that account his pamphlet deserves the attention of all who take an interest in the welfare of India.

The "dead season" has brought up its usual crop of reports of the re-appearance of the sea-serpent, mostly easily resolvable into masses of floating sea-weed. The following extract from an evening contemporary well illustrates the hazy ideas prevalent as to the extinct Saurian monsters of which the sea-serpent is supposed to be a descendant:—"If the sea-serpent continues in its present sociable state of mind, we may perhaps have an opportunity of deciding the vexed question regarding the formation of that portion of his figure which, according to English observers, he keeps concealed under the water. The legend of the Lambton Worm, a popular tale in the North of England, describes the worm as a serpent of enormous size, who used to coil himself round a hill overhanging the River Wear, just as thread is wound round a reel, but a very ancient stone effigy of the creature which lately existed at Lambton Castle, represents it with ears, legs, and a pair of wings. If this effigy was made, as it probably was, *from some recollection* or recent tradition of the Lambton Worm, these adjuncts would indicate that the beast was one of the *winged land monsters* which existed at the same time as the *Ichthyosaurus*, but would naturally become an extinct species far sooner than the *fish lizard*, which can conceal itself in the depths of the ocean from the curiosity and violence of man."

It is not for want of good examples that the British Government is so backward in encouraging deep-sea dredging; other governments seem to think it their interest or duty to do so. The United States, as we know, have fitted out an expedition under MM. Agassiz and Pourtales, to explore the Gulf Stream, the Straits of Magellan, and the Pacific Ocean. A second American expedition will, in the same way, explore the northern regions of this ocean; the German Empire has undertaken to search the depths of the Atlantic; while Sweden has sent to Baffin's Bay two ships fully equipped for deep-sea sounding.

THE BRITISH ASSOCIATION

SECTION A—Mathematical and Physical Science

Fifth Report of the Committee for investigating the Rate of Increase of Underground Temperature downwards, and in various localities of dry land and under water, by Prof. Everett.

In December last, intelligence was received from Prof. Sismonda that the administration of the railway owning the Alpine tunnel had given permission to Father Secchi to carry on a series of observations in the tunnel concerning terrestrial magnetism, and that this distinguished observer was willing at the same time to conduct observations of temperature in accordance with the plans of your Committee. Two maximum and two minimum thermometers were accordingly placed in Father Secchi's hands; but it appears that the arrangements for commencing the magnetic observations are not yet completed, and that accordingly no observations of temperature have as yet been taken.

Prof. Lubimoff of Moscow, on receiving a copy of last year's report, wrote to the secretary, correcting a mistake in the description of the thermometer used in taking observations in the Moscow well. The thermometer was enclosed in a hermetically sealed case containing air, and was therefore completely protected against any possible effect of pressure. Prof. Lubimoff at the same time asked to be furnished with a thermometer of the new pattern described in the report (the upright-Negretti pattern), and one of these instruments was accordingly sent.

Dr. Wild of the Central Observatory, St. Petersburg, wrote in January, requesting that two thermometers for observations in bores might be ordered in his name. At this time, the Secretary was in correspondence with Sir Wm. Thomson, who entertained doubts as to the successful working of the new thermometer, and expressed a preference for the Phillips pattern (which has been described in preceding reports) and the Casella-Miller pattern (a modified Six) which has been extensively used for deep sea temperatures. Thermometers of these two patterns were accordingly ordered and despatched to Dr. Wild.

A letter was received from Prof. Henry of the Smithsonian Institution, Washington, in April, stating that the Chief Engineer of the Hoosac Tunnel had promised to have observations of temperature taken in the tunnel, if thermometers were sent. Its total length will be $4\frac{3}{4}$ miles, about two-thirds of which has been penetrated, by working from both ends and from a central shaft 1,028 feet deep. The mountain has two ridges, under which the tunnel passes, and their heights above it are respectively 1,720 and 1,420 feet. Four thermometers have been sent, viz.: two large minimum Rutherfords, for observations in the tunnel, and two upright Negrettis, for observations in the shaft.

The Council of the School of Mines at Ballaarat, Australia, have, in compliance with a request addressed to one of their number by our observer, Mr. David Burns, C.E., consented to take charge of these thermometers, and furnish observations from the bores and shafts in that important gold-mining district. Most of the principal mining managers are connected with the school. Four thermometers have accordingly been sent, viz.: two upright Negrettis for observations in bores, and two simple mercurial thermometers, of large size, for observations during the sinking of shafts.

Some exceedingly deep Artesian borings have been undertaken in France in recent years; and the President of the Geological Society, Mr. Prestwich (who has allowed his name to be added to your Committee) has furnished your Secretary with introductions which will probably lead to the obtaining of very numerous and valuable observations from these wells.

The largest of them all is one which is now sinking for the municipality of Paris, at La Chapelle, St. Denis, a northern suburb of Paris, and has already obtained a depth considerably exceeding that of the Puits de Grenelle. It is expected that its final depth will be about 2,300 feet. Application was made by the Secretary to the eminent firm of well-borers, Messrs. Mauget, Lippmann, and Co., who are sinking the well, and these

gentlemen at once in the most obliging manner consented to take observations of temperature in it. An upright Negretti thermometer was accordingly furnished; and about the 20th of June your Secretary had the pleasure of receiving from them two complete sets of observations taken on the 14th and 15th of that month with their own hands, at every 100th metre of depth, and also at the bottom of the well, 660 metres deep.

Depth in Metres.	FIRST SERIES. June 14, 15. Temp. Fah.	Time down. h.	m.	SECOND SERIES. June 17, 18. Temp. Fah.	Time down. h.	m.
100	58·0	0	35	58·0	3	30
200	61·1	0	30	61·0	2	0
300	65·0	0	30	65·0	2	0
400	69·0	3	10	69·0	11	20
500	72·6	0	30	72·6	2	0
600	75·8	0	30	75·4	2	0
660	83·25	15	45	83·25	2	0

The observations are given in the subjoined table, in which the third column shows the time that the thermometer was allowed to remain at the depth specified before hauling up and reading. The temperature at which the thermometer was set before letting it down is also given in Messrs. Mauget and Lippmann's report, but is not here inserted.

The agreement between the first and second set of observations is remarkably close; and as the time of leaving the thermometer in the water was about half-an-hour in most of the observations of the first set, and two hours or more in all the observations of the second set, it is obvious that half-an-hour is a sufficient time to give a correct observation. This conclusion is satisfactory both as regards the reliability of the observations themselves, and also as establishing the fact that this pattern of thermometer is not unreasonably slow in its working. The exactness of the agreement also serves to show that the thermometer can be depended on to the tenth of a degree, and that we may henceforth use it with confidence.

Before proceeding to discuss the observations, it will be convenient to give a few particulars respecting the well, which have been kindly furnished by Messrs. Mauget and Lippmann.

It was commenced by the municipal authorities as a masonry well, by the ordinary method of digging, until it had reached a depth of 34·5 metres. The intention was to carry it in this way to the depth of about 135 metres, the estimated depth of the tertiary strata covering the chalk; but the difficulties and dangers which were encountered, from the want of tenacity in the soil (*la nature essentiellement ébouleuse des terrains*), and latterly from the insufficiency of the pumps, rendered it necessary to abandon this intention; and in May 1865 the task of completing the well by boring was assigned to Messrs. Degousée and Laurent, the predecessors in business of the gentlemen to whom we are indebted for these observations. A small trial bore (0·2m. in diameter) was commenced, and continued till January 1866, by which time the machinery for the heavier work was ready. In order to support the masonry, which showed signs of giving way, it was tubed through its whole length with a tube 1·8m. in diameter and 0·02m. thick, cemented externally. From the bottom of this tube, at the depth of 34·5m., a bore 1·7m. in diameter was carried to the depth of 68·7m. from the surface of the ground. A second tube 1·58m. in internal diameter was inserted to the depth of 121·6m., and a third tube of internal diameter 1.39m. was carried down into the chalky marls and the upper portion of the chalk at the depth of 139·15m. from the surface. From this point downwards, the bore has been driven through the chalk, and tubing has been unnecessary, its diameter at the depth of 662m. being still 1·35m.

The thickness of the tertiary strata is 137m., and the elevation of the surface of the ground above sea-level is 48m. or 157ft.

The springs which were met with in the tertiary strata correspond to those found in other parts of the basin in which Paris is situated, and have not sufficient strength to spout above the surface of the ground at this elevation. They were encountered at the depths of 19·2m., 34·5m., 86·0m. and 97·0m., and the water now stands in equilibrium in the central tube at 16·5m. below the surface of the ground.

It was not practicable to take observations of temperature during the regular progress of the boring, but an interruption occurred on the 12th of June, and the tool was not at work from this date till after both sets of observations were finished. In reference to this point, Messrs. Mauget and Lippmann, say, under date April 29, "To obtain the natural temperature, it will be necessary to select a time when the work has been interrupted for several days; for the boring being executed by the fall of a heavy tool upon the bottom of the well, the percussion developes a considerable amount of heat, as we perceive by the mud (*les boues*) which we extract, and which in coming to the surface is found to have still a temperature of from 48° to 90° C. (118° to 194° F.)." In their letter of June 19, containing the report of the observations, they remark :—

"You will observe that though the water at the bottom of the well is still some degrees above its natural temperature owing to the action of the drill (*trépan*), the latter has not been in operation since the 12th of the month. At a convenient time, we intend to observe the temperature of the mud as it lies at the bottom of the well, immediately after the withdrawal of the drill, when the latter has been working constantly, a temperature which will probably be found to depend upon the hardness of the rock."

The following table exhibits the successive increments of temperature showed in the second series, which purports to be more accurate.

Depth in Metres.	Increase in deg. Fahr.	Metres per deg. Fah.	Feet per deg. Fah.
100 to 200	3·00	33·3	109
200 to 300	4·00	25·0	82
300 to 400	4·00	25·0	82
400 to 500	3·60	27·8	91
500 to 600	2·80	35·7	117
600 to 660	7·85	7·6	25

The last two columns of this table show that the rate of increase is about four times as rapid in the last 60m. as in the rest of the well, a circumstance which naturally suggests the explanation given by Messrs. Mauget and Lippmann. There are however some difficulties in the way of accepting this view. Comparing the two sets of observations, one taken on the second and third day after the withdrawal of the tool, and the other on the fifth and sixth day, we have precisely the same temperature at the bottom of the well on both occasions, although the observations were sufficiently precise to detect a difference of a tenth of a degree where such difference existed. It seems difficult to believe that a temperature $2\frac{1}{2}$ degrees above the normal temperature could have remained for two days without sensible diminution. In connection with this question, the apparent cooling to the extent of 0°·4 at the depth of 600m. between the first and second observation demands attention, and is not very easily explained.

If the observed temperature at 660m. is to be taken as the normal temperature, the average increase from 100m. to that depth is at the rate of 1° F. in 22·1m. or in 72·5 ft. If the observed temperature at 600m. in the second series is adopted, the increase from 100m. to that depth is at the rate of 1° F. in 28·7m. or in 94·2 feet.

The observations prepared by Messrs. Mauget and Lippmann in the paragraph above quoted will be eminently calculated to assist in showing the correct interpretation.

Mr. G. A. Lebour, F.G.S. of H.M. Geological Survey, has furnished observations taken in a bore hole executed at the bottom of South Hetton Colliery, Durham. The observations were taken by Mr. J. B. Atkinson, a student at the Newcastle College of Physical Science, and appear to have been carefully made. Thanks are also due to the viewer of the colliery, Mr. Matthews, for granting the requisite facilities.

The hole is $2\frac{1}{4}$ inches in diameter, and was bored out of the pumping side of the South Hetton shaft, in order that the bore rods might be the more readily altered. The depth of the shaft is 1,066 feet; that of the bore hole 863 feet from the bottom of the shaft, or 1,929 feet from the surface of the ground. The section of the boring (not including the shaft) consists of 123 alternating beds of shale and sandstone,* with occasional thin seams of coal and some fire clays. The bottom of the boring has reached a very coarse white grit, which is supposed to be the topmost bed of the millstone grit series.

The bore was dry at the time of its execution; but has since become filled with water, probably derived from the shaft above it. Streams, in fact, pour down the shaft, and play about the hole.

* A complete list of the strata has been furnished, and will be preserved by the Secretary, with a view to future reference if required.

Two thermometers, one of them an unprotected Phillips, and the other a protected Negretti, were supplied by the Secretary to Mr. Lebour, as it was not certainly known at that time whether the bore was dry or wet. Mr. Lebour indeed believed it to be dry, but nevertheless selected the Negretti thermometer, as it was thought that the Phillips could not be read off accurately with the poor light which in the position of this bore hole was alone available.

The following table exhibits the results of all the observations which have been taken in the bore, including three which were taken in 1869, while the boring was going on. The boring was stopped, in the case of each of these three observations, only about 20 minutes before the observations were made; and the heat due to friction appears to have produced abnormal elevation of temperature, amounting to about 2° at the depth of 288 feet, to about 6° at the depth of 582 feet, and to considerably more than this at 858 feet. The other observations in the table are Mr. Atkinson's, taken with the Negretti thermometer.

Depth from bottom of shaft, in feet.	Depth from surface of ground, in feet.	Temperatures observed during boring, April 1869.	Temperatures observed April 1872.
100	1166	—	66
200	1266	—	$68\frac{3}{4}$
288	1354	72	—
300	1366	—	70
400	1466	—	72
500	1566	—	$74\frac{1}{2}$
582	1648	82	—
600	1666	—	$76\frac{1}{8}$
644	1710	—	75
670	1736	—	$77\frac{1}{8}$
858	1924	96	

The temperature 75° at the depth of 644 feet, a temperature lower than either of the two between which it stands, was taken on the first day of Mr. Atkinson's observations, and was confirmed by repeated trials at that time. This was the lowest depth that could then be reached, the remainder of the boring being apparently plugged up with "sludge." A spike was subsequently attached to the thermometer case, which enabled it to pierce deeper into the sludge; but the lowest depth which could be reached (670 feet) is still far from the bottom of the bore.

It is intended to take a fresh series of observations at every 50th foot of depth, and especially to re examine the temperatures at about 650 feet, where the reversal of temperature was observed.

The following are the rates of increase deduced from Mr. Atkinson's observations, omitting the temperature 75° at the depth of 644 feet.

Depth in feet.	Increase in deg., Fahr.	Feet per deg.
100 to 200	$2\frac{3}{4}$	36
200 to 300	$1\frac{1}{4}$	80
300 to 400	2	50
400 to 500	$2\frac{1}{2}$	40
500 to 600	$1\frac{5}{8}$	62
600 to 670	1	70
		51·2
100 to 670	$11\frac{1}{8}$	

The average increase between the depths of 100 and 600 feet is 1° in 51·2 feet. These depths are reckoned from the top of the bore hole, which is 1,066 feet below the surface of the ground. Mr. Lebour assumes that the temperature at the depth of 600 ft. from the surface of the ground is 48°. Accepting this estimate, we have a difference of $29\frac{1}{8}$° in 1,676 feet, $(1,066 + 670 - 60 = 1676)$ which is at the rate of 1° in 57·5 feet.

Mr. David Burns, F.G.S., reports that, from changes in the management of the mines, and other causes, it has not been possible as yet to carry out the dry observations at Allenheads mentioned in last year's report.

Only one other shaft has been met with at all suitable for observation. It is called Brandon Walls shaft, and belongs to the Rookhope Valley Mining Company, to the courtesy of whose agent we are indebted for liberty to take observations. This shaft is some 6 miles east of those reported on last year, and is situated in the very bottom of Rookhope Valley. The mouth is covered over with a wooden shed, the shaft itself is free from all obstruction, and the water in it has not been disturbed for some ears. The shaft is 333 feet deep, and is full of water to within 25 feet of the surface of the ground. Observations (by Mr. Burns and Mr. Curry of Bolkburn) were taken in it on five different days in July of the present year; but though agreeing well with one another from day to day, they are so irregular that they throw little light on the rate of increase of underground temperature. At the depths of 83 and 133 feet from the ground, the temperature was 48°·5. In the next 50 feet there was an increase of about 3°, the temperature at 183 feet being about 51·4, and from this depth to the bottom (an interval of 150 feet) the temperature was nearly constant. The best determination of the temperature at the bottom was 51°·7.

It may be remarked that all observations in shafts thus far have exhibited irregularities of this kind. The water in such large openings seems to have its temperature governed by springs and other extraneous causes, rather than by the temperature of the surrounding soil.

The observations at every fiftieth foot of depth in the Kentish Town well, as given in previous reports, are so complete that it has not been thought necessary to continue them. A very delicate thermometer, reading by estimation to the $\frac{1}{100}$ of a degree, has however been procured, for taking observations from year to year at one constant depth (1,000 feet). It was constructed ten months ago, and being enclosed in a partially exhausted glass tube will probably not undergo much change of zero. It has been four times tested by comparison with standards, and has been found to have no error amounting to nearly so much as 0°·1. In consequence of Mr. Symons' illness, no observation has yet been taken with it in the well.

A thermometer which, through the breaking of a rope, had fallen into the mud at the depth of 1,090 feet from the surface of the ground, was extracted by Mr. Symons last November, more than a year after its fall. It had sustained no damage, and its indication when hauled up was 69°·4, nearly agreeing with the temperature previously observed at that depth.

In addition to the large numbers of thermometers above mentioned as having been issued during the past year, one has been furnished for observations which are to be made in the projected boring through the Wealden and underlying strata. With the exception of Mr. Symons' observations at Kentish Town (London, N.), we have as yet no observations of temperature from the Southern parts of England.

SECTION B—CHEMICAL SCIENCE

Mr. Alfred Tribe read a paper *On the Precipitation of Silver by Copper*. In the course of experiments made in conjunction with the President, Dr. Gladstone, it was found that the silver obtained by precipitating the metal from the nitrate by means of copper always contained more or less of the latter metal. When an excess of silver remained in a solution only minute traces of copper were found, but as the silver solution became exhausted the proportion of copper rapidly increased. This co-precipitation of copper was shown to be due to the presence of atmospheric oxygen. In one experiment as much as 15 per cent. of copper was obtained after 48 hours exposure. When carbon dioxide was caused to bubble through the solution during the precipitation the quantity of copper deposited was greatly diminished. The author showed an eudiometric apparatus in which this property of absorbing oxygen was applied to determine the proportion of that gas in the air.

Mr. Gladstone gave a brief account of the physical and chemical characters of the *Volcanic Dust* recently ejected from Vesuvius. In some localities the fall of this dust was very heavy and extended over a considerable area: the sample examined was collected at Ischia, upwards of twenty-five miles from the mountain. It consisted essentially of a mixture of quartz and magnetite. No trace of titanium could be detected. Dr. Thorpe stated that he had recently examined the volcanic sand found in the neighbourhood of Etna, and its agreement in chemical and physical properties with the sand from Vesuvius was very striking. It also contained no titanium.

Dr. Schenck read a paper *On the Amount of Heat required to raise Elementary Bodies from the absolute zero to their state of fusion*. If we assume that a body at — 273° is completely deprived of heat it is possible to calculate the total heat in it at any other temperature provided that the specific heats of the body in its three states of aggregation, its latent heats of fusion and vaporisation, and its melting and boiling points are known. Such calculations are limited from the fact that only in the case of one

body—water—are the data sufficiently well known. In the course of the paper the author pointed out a remarkable coincidence between cadmium, tin, and lead, in the amount of heat required to raise gram-equivalents from — 273° to the state of fusion.

Mr. W. Lant Carpenter made a communication respecting the presence of *Albumen in Fats, and on a new method of obtaining Stearic and Palmitic Acids.* The paper mainly consisted of an account of Dr. Bock's remarkable process for the decomposition of Fats which is now being generally adopted on the Continent, in the manufacture of improved stearin candles. When fats are decomposed in the ordinary process by alkali, a considerable excess of the alkali above the theoretical quantity is required unless the operation is conducted under great pressure, when the risk of explosion increases the disadvantageousness of the process. When the fats are decomposed by oil of vitriol, or other strong acid (the method usually adopted in England), a considerable proportion of the fat is lost by being charred and burnt, and that which remains is so blackened that it is necessary to distil it, an operation of expense and of danger owing to the risk of fire or explosion. All these advantages are obviated by the use of Prof. Bock's process. Dr. Bock has shown that most neutral fats are made up of minute globules surrounded by albuminous envelopes, which form from 1 to 1·5 per cent. of the weight of the fat, and he considers that the action of the alkali, acid, or of heat or pressure was to break up these albuminous envelopes. The destroyed envelopes had a remarkable power of attracting the colouring matters contained in the fat or produced therein during the action of the acid or alkali. The existence of the albumen may be demonstrated by dissolving the fat in ether or benzol and adding water to the solution, or by boiling the fat with a strong solution of oxalic acid. In each case the albumen envelopes collect at the plane of juncture between the two liquids. In the new process the envelopes are broken up by the action of a small quantity of strong sulphuric acid for a limited time only and at a given temperature. The fat is then poured away from the destroyed envelopes and is ready for decomposition by water in open tanks. This operation requires some time for its completion; its progress may be readily determined by a microscopic examination of the crystallised fatty acid formed by slowly cooling a thin layer upon a glass slide. When the process of decomposition is at an end, the solution of glycerine is drawn off purified and concentrated for sale. The fatty acids thus obtained amount to 34 per cent. of the original fat: they are however far from pure and contain more or less brownish or black matter. By submitting the fatty acids in open tanks to the action of a dilute solution of certain oxidising agents, the dark coloured matters are partially oxidised and their specific gravity is so far increased that when the oxidation has proceeded far enough, they readily subside together with the envelopes to the bottom of the tank, and the supernatant fatty acids are rendered comparatively good in colour. After two or three repetitions of this process the resultant stearin is hot and cold pressed in the ordinary manner. The acid thus obtained is of a better quality, has a higher melting-point, and is yielded in greater quantity than that obtained in the ordinary way.

Mr. J. F. Walker contributed a paper *On Dinitrobrombenzene*, and Dr. Wright gave an account of the continuation of his experiments on *New Derivatives from Morphine and Codeine.*

Mr. John Williams described an improved method of preparing Guaranine, the active principle of *Guarana*, the fruit of the *Paulina sorbilis*, which is used by the Amazonian Indians for an infusion. This principle was isolated by Stenhouse, and pronounced by him to be identical with theine or caffeine, the active substance contained in tea and coffee. In the author's process the guarana is reduced to fine powder mixed with one-third of its weight of hydrate of lime and moistened with water It is then allowed to stand for a couple of hours and thoroughly dried at a gentle heat. The mixture is exhausted with boiling benzol filtered, the benzol distilled off, when a small quantity of light coloured oily matter remains. This is treated with hot water and heated for some time over the water bath, filtered through a moist filter, and after concentration, the solution is set aside to crystallise. In about twenty-four hours the guaranine separates out perfectly pure. The same process is applicable to tea, but the author is inclined to believe that guaranine differs in several particulars—taste, solubility in water, &c.—from theine.

Mr. Wanklyn described a method of analysing the *Compound Ethers*—acetic ether, for example. It consisted in determining the amount of alcohol liberated in the decomposition of the ether by the known methods of alcoholimetry. The complete proximate analysis of a compound ether is thus rendered possible.

Prof. Crum-Brown made a brief communication on the subject of *Chemical Nomenclature.* Setting aside the trivial or proper names (names which are simply arbitrary words or marks each indicating in virtue of a convention applicable to each individual case, a particular substance), there are two systems or kinds of systems of chemical nomenclature. These may be distinguished as 1st, the composition system, and 2nd, the functional or relational system, or class of systems. In the first the name of a compound indicates the elements or radicals contained in it, and sometimes their proportions. Thus Chlornatrium, Chloriod, Dreifach chloriod, Silicium wasserstoff, &c. In English we have few names so distinctly compositional in form (we have indeed, Zinc methyl and all the other allied names) but many of our names, although apparently functional in form, are really compositional. Thus, chloride of A means with us nothing more than, or different from, a compound containing the elements chlorine and A: and chloride of sodium, chloride of iodine, ter-chloride of iodine, siliciureted hydrogen, not only represent the same substances as the German names just quoted, but tell us neither more nor less about the substances than these German names do. On the other hand, functional names present the chemical relations between substances. We may take as examples such names as the anhydride, the amide, the aldehyde, the nitride of acetic acid. These derivatives of acetic acid contain no acetic acid, but they stand in certain definite relation to that substance, and he anhydrides, amides, aldehydes and nitrides of other acids stand in the same relation to them. What is still, notwithstanding the efforts of modern chemists, the common popular nomenclature of salts, although originally intended as a compositional nomenclature, might, with perfect consistency, be retained as a functional nomenclature. The objection to the term "muriate of soda" was that the substance so named contains no soda. But the amide of benzoic acid contains no benzoic acid. Soda contains oxygen; muriate of soda contains none (unless chlorine be an oxide), but the nitride of benzoic acid contains no oxygen, although the acid itself does. The name muriate of soda originally meant the *compound* of anhydrous muriatic acid, $2HCl - H^2O$, and anhydrous soda $Na^2O - (2HCl - H^2O) + Na^2O$. We may now, if we please, use the name to mean the result of the action $2HCl + Na^2O - H^2O$. If we do so, the name becomes a functional one, and the phrase "muriate of," or, what is neither better nor worse, "hydrochlorate of," expresses the complex operation. Addition of hydrochloric acid and simultaneous separation of water. Similarly, in the case of such names as sulphate of potash, nitrate of oxide of silver, &c., the phrases "sulphate of," "nitrate of" express the complete operations, addition of sulphuric, or nitric acid, and simultaneous separation of water.

While the old view that salts are compounds of anhydrous acids and anhydrous bases is now abandoned by most theoretical chemists, a relic of this view still remains in the most advanced systems of nomenclature, producing an inconsistency really inconvenient to the teacher and student.

The objection taken to the name hydrochlorate of soda was not only that the substance contains no soda, but also that it contains no hydrochloric acid. This objection is perfectly valid against the name as a compositional one, but does it not equally hold against the words sulphate, nitrate, acetate, &c.? If we are to have hydric sulphate and hydric acetate for sulphuric and acetic acids, why not hydric muriate for muriatic acid? That this question is not altogether an absurd one will be obvious if we consider that all chlorides are not muriates. Those substances which are by general consent called salts stand in a definite genetic relation to the corresponding acids (or, the hydric salts of the series), and it is inconvenient to have the same general name —chloride—applied to substances which do stand in this relation to hydrochloric acid, and also to those which do not. We may divide the chlorides into two groups, very different in character in their extreme members, and gradually shading into one another. We may take chloride of sodium as a representative of the one, and the chloride of phosphorus as a representative of the other. Chloride of sodium is a muriate; the chloride of phosphorus might be better described. We may call the acids and acid anhydrides negative, the hydratic bases, anhydrous bases positive—arranged in a series, we find the series a continuous one from the most positive or basic oxides or hydrates to the most negative; it is however convenient to have a zero

point, and it is no disadvantage if this zero point be an arbitrary one. When we come to express numerically the amount of positiveness or negativeness of these oxides and hydrates, it will be necessary to have a zero point, and a very convenient one is that which corresponds pretty nearly to the generally understood limit between bases and acids, and depends upon the direction in which the action takes place.

SECTION C.—GEOLOGY

On the Cambrian and Silurian Rocks of Ramsey Island, St. David's, by Henry Hicks, F.G.S.*

In a report to the British Association in 1866, by the late Mr. Salter and the author, Ramsey Island was mentioned as a part of the district which had been examined and a short description of the rocks exposed there was given. At that time three distinct formations in succession had been recognised, and also correlated by their fossil contents and lithological characters with the Lingula flags, the Tremadoc group, and the Arenig group. Since then the author has further examined these beds, and recently along with Messrs. Homfray, Lightbody, Kirshaw, and Hopkinson.

During these researches numerous new forms have been discovered in these rocks, and many additional and interesting facts observed. In a section at the north end of the island the following rocks occur in succession :—

1. *Lingula Flags.*—A series of hard silicious sandstones with grey flaky slate, about 600 feet in thickness, and containing *Lingulella Davisii* in great abundance but no other fossils save worm tracks and burrows, and some plant-like markings.

2. *Tremadoc Group.*—Bluish grey flag, and earthy grey rock of a tough texture, from 800 to 1,000 feet in thickness. Fossils are very abundant throughout the whole series, and nearly all the species as well as many of the genera are new. They comprise Brachiopods of the genera *Lingula*, *Obolella*, and *Orthis*, and Lamellibranchs of the genus *Ctenodonta*. There are also two species of *Orthoceras*, a *Theca*, a *Bellerophon*, an *Encrinite* and a star fish, and nine species of Trilobites belonging to the genera *Dikelocephalus*, *Conocoryphe*, *Niobe*, *Asaphus*, *Cheirurus*, and *Calymene*, and a supposed land plant named *Sophyton explanatum*. Some of these genera are characteristic of the Cambrian rocks, and others of the Silurian ; and there are several forms which had not previously been discovered in rocks of so early an age. Until the discovery of these rocks at St. David's the Tremadoc group was supposed to be a local formation only.

3. *Arenig Group.*—A series of ironstained slates and flags, having a thickness of 1,000 feet. The fossils comprise Trilobites belonging to the genera *Asaphus*, *Ogygia*, *Oeglina*, *Trinucleus*, *Ampyx*, *Calymene*, and *Agnostus* ; also a *Conularia*, *Theca*, *Orthoceras*, *Bellerophon*, *Lingula*, and *Orthis*, and about 20 species of Graptolites.

In this section the succession from the Cambrian to the Silurian rocks is probably better shown than at any other place in Britain.

SECTION D.—BIOLOGY

DEPARTMENT OF ZOOLOGY AND BOTANY

Second Supplementary Report on the extinct Birds of the Mascarene Islands, by Alfred Newton, F.R.S.

The speaker stated that a portion of the grant unexpended at the last meeting of the Association had been expended by his brother in a renewed examination of the caves in the island of Rodriguez. This has been conducted by Mr. George Jenner, lately Chief Executive Officer of the island. No detailed account could at present be given. Several missing parts of the skeleton of Pezophaps, and of additional remains of the large Psittacine bird, described from a single fragmentary maxilla by Milne Edwards as *Psittacus* (?) *rodericanus*. This may enable its affinities to be more exactly determined, and also allow more light to be thrown on *P. mauritianus* of Owen. A bird described by Leguat, and hitherto believed to be extinct, had been found still to exist, and had been described by himself as *Palæornis exsul*. The remains of a Ralline bird, considered to be allied to Ocydromus Milne Edwards, was disposed to identify with the "Gelinotte" of Leguat, the nature of which had hitherto only been a matter of guess.

Dr. Sclater said it was well to bear in mind that Rodriguez was one of the stations where it was proposed to place a staff of astronomers to observe the transit of Venus, and the opportunity of carrying on ornithological observation at the same time should not be lost sight of.

On the Perforating Instrument of Pholas candida, by Mr. John Robertson.

The author attributed the perforating action of the animal to a rasping effected by the rotatory movements of the shell and also by putting the valves together.

Prof. Allman said that the late Mr. Bryson, of Edinburgh, had observed the habits of the Pholas, and had come to the conclusion that the boring was effected by the foot charged with silicious particles and acting like the leaden wheel of the lapidary.

Mr. Gwyn Jeffreys was of opinion that in the whole of the perforating conchifera and some of the univalves the foot was the instrument of perforation. In *Cardium*, *Mactra*, and especially *Solen*, as well as other bivalve mollusca, the posterior extremity of the shell was shaped to receive the foot which worked like a gardener's dibble. In the case of *Pholas dactylus*, Mr. Caillaud thought that at Nantes the gneiss was perforated by the rasping action of the shell. Man might do this, but it was doubtful whether it could be accomplished in this way by the *Pholas*. In *Teredo navalis* he believed that, as Sellius had shown in 1733 in his work "De Teredine Marina," the foot was the sole instrument of perforation, and in this case the posterior extremity of the shell had a large excavation to receive the foot. Again, *Pholadidea* in a young state excavated by means of its foot, but afterwards the aperture was closed by gelatinous matter, the animal became encysted, and no further excavation took place. The limpet he had seen in Aberdeenshire excavate the rock to the depth of a fourth of an inch, and this could only have been accomplished by the foot. In *Pholas* also no part of the shell can act at the bottom of the excavation. The prickles it was supposed were renewed ; but this could not take place throughout the shell, and many excavating shells had no prickles at all. Deshayes had advocated the chemical theory ; but this too had been exploded, as Deshayes himself admitted.

Summary of Flowering Plants of Sussex, by W. B. Hemsley.

Taking Babington's Manual (5th Edition) as a standard, the Flora of Sussex includes 1,059 species of flowering plants, reckoning Ferns and Horsetails as well. These last amount to only 33, or about 3 per cent. Roughly speaking $\frac{3}{4}$ are Dicotyledons and $\frac{1}{4}$ Monocotyledons ; $88\frac{1}{2}$ per cent of the species are herbaceous, and $11\frac{1}{2}$ woody ; $27\frac{1}{2}$ per cent are annuals, and $72\frac{1}{2}$ perennial ; 12 natural orders include rather more than half the whole number of species ; 76 of the species are maritime, and 56 peculiar to the chalk. *Pyrola media*, *Habenaria albida*, and *Festuca sylvatica* are outliers of Watson's Scottish type not found in adjacent counties. The three species peculiar to Sussex, *Phyteuma spicatum*, *Lonicera Xylosteum*, and *Trifolium stellatum* are probably all introductions, the last being certainly so. In the centre of the county the heath grows as high as three or four feet, and covers considerable tracts of land.

Prof. Lawson in answer to a speaker who had inquired the useful purpose of these investigations into indigenous plants, and who had lamented the want of adequate knowledge how to keep them in their place, pointed out that the researches of Messrs. Lawes and Gilbert were likely to lead to practical methods of developing the useful constituents of pasture and of restraining the growth of the undesirable elements. He was especially struck with the presence of *Centaurea calcitrapa* about Brighton. This he had generally seen as a ballast plant, and thought almost certainly an introduction.

Diversity of Evolution under Uniform External Conditions, by Rev. John T. Gulick.

The terms "Natural Selection" and "Survival of the Fittest" present different phases of a law which can act only where there is variation. Does this variation ever produce from one stock distinct varieties and species, while the external conditions remain the same? When a species is subjected to a new set of conditions, does the change that is brought about in the organism expend itself in producing just one new species completely fitted to the conditions, or may it produce many that are equally fitted? Facts in the geographical distribution and varia-

* The discussion referring to this paper occurs at p. 383 (after Mr. Hopkinson's paper.)

tion of the terrestrial molluscs of the Sandwich Islands seem to throw light on the subject. A forest region on the island of Oahu, 40 miles in length, and 5 or 6 miles in breadth, furnishes about 175 species, represented by 700 or 800 varieties. The average area occupied by each species is about 5 or 6 square miles, though many are restricted to half that area. The valleys that lie on one side of the mountain range that traverses this district preserve, as far as we can observe, the same conditions; but the varieties, and in some cases the species, found in each valley, differ from those found in any other.*

If we would account for these facts on the hypothesis of evolution, it seems necessary to suppose: First, that these molluscs possess an inherent tendency to variation, so strong that all that is needed to ensure the divergence of type in the descendants from one stock is to prevent, through a series of generations, their intermingling with each other; and secondly, that either the tendency to variation in this family is very much greater than usual, or their tendency to migrate weaker, and their opportunities fewer than usual. An investigation of the conditions under which that species exist leads me to believe that the smallness of the areas occupied by each is due to freedom from that competition that retards variation in Continental species, rather than to any deficiency in the means of transportation. On the continents, "Natural Selection" arising from severe competition with species that have a wide range, tends to prevent the development of varieties, and to give a wider diffusion of forms, that would otherwise be limited in their range, and variable in their type.

Mr. Wallace agreed with the Rev. J. T. Gulick in his interpretation of facts which appeared to be exceedingly remarkable. He had had the opportunity of working at a limited group of organisms in a small part of the world. The results he had described were a type of what took place over whole continents, and exhibit an example of variation and geographical distributions, perhaps the most remarkable that occurs on the surface of the earth. With the general principle that variation does not depend on difference in external condition, he altogether agreed. He thought in this matter that there was a confusion of two distinct things, even in some cases by Mr. Darwin himself. Variation was confounded with the formation of varieties. That it was not dependent on the change of conditions was evidenced by the fact that the varieties of domestic animals and plants were not due to this cause, but only to advantage being taken of spontaneous variation and identical conditions. Horticulturists obtained new varieties of any plant that was introduced into cultivation by growing it upon a very large scale, and selecting the sports which were sure to occur. In this case variation was accumulated by artificial selection, just as it is accumulated in nature by natural selection. This requires, as a condition of its action, a change of external conditions. We all know that closely allied, though distinct species, were found inhabiting distinct areas—for example, islands; and with large continental areas it was the same. This had led to the very general idea that it was variation of condition over those areas which had produced the varieties, whereas it had merely selected them. In the Sandwich Islands there was no difference of physical conditions adequate to produce this result. This was seen in the number of intervening forms which existed. It seemed due to the absence of any weeding-out effect. The land molluscs had hardly any competitors to struggle with, and no enemies, quadrupeds and reptiles being absent, and birds few. The rivers were small and would only distribute any form through the same valley. All these conditions favoured this remarkable persistence of closely linked forms.

SECTION G—Mechanical Science

On Rolling in a Seaway, by Mr. W. Froude, F.R.S.

This was a description of an apparatus for automatically recording the rolling of a ship in a seaway and the slopes of the waves.

The fundamental principles on which the performance of the apparatus depends are (1) that when waves act on a ship or other floating body which would stand stably upright in still water, she will be for the moment in equilibrium if upright or normal to the mean or effective slope of the wave which she occupies; and if she possess a given righting force when inclined to a given angle in still water, she will be urged by approximately the same righting force towards the normal position in wave water, if she at any moment deviate from it by the same inclination. (2) A plumb line or pendulum, if its point of suspension be at or very near the ship's centre of gravity, will be for the moment in equilibrium if it occupy the normal position, and if it have a very short period of oscillation it will instantly assume that position throughout the changes of the wave slope. These two propositions are but expressions of the interdependence which exists between the change of translatory motion which at any moment affects a mass or particle of matter, and the direction at the same moment proper to any force-direction-index carried by the man, whether it be a plumb-line, which lies in the direction, or a spirit level, which lies at right angles to it; the direction being simply the resultant of gravity, and of the disturbing forces which at the moment affect the mass. Mr. Froude described his apparatus as follows:—A revolving cylinder covered with paper and turned by rough clockwork receives the marks made by several pens. One of these pens records time, jerks being given it at successive equal intervals by an exact clock. The apparatus being placed at the centre of gravity of the ship, a pendulum of very short period and considerable power, oscillating in the plane transversely with the keel, records continuously by a second pen the angles made at each moment by the ship, with the mean or effective wave slope, that is to say, her relative inclinations. Another pen, actuated by a rocking arm kept level by the observer on deck, who points it to the horizon, records the angle made at the same moment by the ship with the horizon, that is to say, her absolute inclinations. From the records thus obtained, the amount of the roll of the ship with regard to the wave slope is at once shown, and the form of the wave can be easily worked out graphically, the wave slope at each moment being simply the difference between the records produced by the pendulum pen and the horizon pen respectively. But the graphic integration of the results supplied by the pendulum pen, if correctly performed, supplies what might be called the theoretical measure of the oscillations, which the ship ought to have performed with regard to the horizon during the period embraced in the record. For the pendulum record itself supplies, throughout, a measure of the accelerating force by which the ship's oscillation is governed; so that the integration of this gives a diagram representing the angular velocity which the ship should theoretically have acquired under the operation of that force. And the integration of the velocity diagram in turn gives the sequence or total of motions which the varying velocity involves. The performance of these integrations involves indeed a correct knowledge of the ship's dynamic constants, but these, so far as they are not already known by calculation, may be readily obtained by a single experiment with the ship in still water, where, if she be artificially brought into oscillation (an operation easily performed), and the instrument be made to record the oscillations as they subside under the influence of resistance, the natural period of her oscillation is at once known, and the coefficient of resistance is deducible in a shape which is approximately applicable to the ship's seaway oscillation. All the conditions required for the integration are thus supplied. Several series of diagrams thus obtained by the oscillation of ships in a seaway have been thus integrated, and the theoretical oscillations accord so completely with the recorded oscillations that the fundamental elements of the theory of rolling have been most satisfactorily verified. Mr. Froude said he had more recently contrived and executed an apparatus which would substitute an automatic record of the ship's absolute inclinations for that supplied by the observer on deck, as above described. For this purpose he employed a heavy stationary wheel, which was so delicately supported as to be incapable of receiving any rotation from the motion of a ship. This wheel, if placed transversely in the ship, would remain still at rest—that is to say, without rotation—and would thus, while the ship performed oscillations of rotation under it, communicate to one of the tracing pens a virtual motion along the record cylinder, so as to form a continuous record of the ship's absolute inclinations. The wheel is 3 ft. in diameter and 200 lb. in weight. Through the boss is carried out a strong steel axis, the prolonged ends of which are coated with hardened steel. The axis thus prolonged rests between two pairs of rocking arms, the ends of each pair forming a kind of V. The ends of the arms are, in fact, hardened steel plates, forming segments of circles struck from the axes or centres on which the arms rock, so that they are virtually portions of the circumferences of very large friction rollers. In order still further to reduce the friction of the working parts, the axes of

* A fuller statement of the fact has been given in an article on "Variation of Species related to their Geographical Distribution," in Nature July 18th, 1872.

the rocking arms have been finally reduced to hardened steel pins of small diameter, and so mounted that their motions, when of small range, should be rolling not sliding motions, and great delicacy is thus obtained. The centre of gravity is brought to within 0·0065 in. of the axis of suspension, and the time of a single swing is over thirty-five seconds. Yet so great is the delicacy of the suspension, a weight of $\frac{1}{250000}$ part of that of the wheel itself, if placed at its extreme radius, will produce an oscillation of $1\frac{1}{4}$ in, in range, and which will continue for many minutes; or if the wheel be moved 90° from its position of rest, the oscillations will continue for nearly twenty minutes, the movement being so slow and solemn as to impress on the mind of an observer who had not seen it put in motion that the action was self-originated, or induced by some mysterious agency. The oscillation of a ship can scarcely communicate any motion at all to the wheel, and any minute rotation which is, in fact, communicated will assume the form of an oscillation, having so long a "period" that its effects will be easily separable from those proper to the oscillation of the ship. Thus the indications will be more exact than those produced by the rocking arm on deck. This improved apparatus has not yet been tried, but is ready, waiting a suitable day for trial on board a ship at Plymouth.

Mr. Froude stated that though the apparatus he had described was purely his own invention, it had interested him greatly to learn recently that an arrangement substantially identical with that combination which he first described had about two years previously been invented and successfully used by an able French naval architect (M. Bertin, of Cherbourg), with whom, partly in virtue of this circumstance, it has since been his good fortune to become acquainted and to correspond. It was, however, a satisfaction to him that he was at the present time ahead of his friendly competitor in the race, so far as regarded the delicately-hung heavy fly-wheel which was to furnish an automatic constant record of the angles or absolute rolling or deviations from the horizontal assumed at each moment by the ship.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, Aug. 5.—Prof. Cayley presented a memoir on Orthogonal Surfaces.—M. E. Becquerel communicated a spectroscopic analysis of the light emitted by the phosphorescent uranium compounds.—M. Daubrée presented a note on the discovery of a second meteorite, which fell on the 23rd of July last, in the canton of St. Amand (Loir-et-Cher). This appears to have formed part of the fall noticed at the meeting of the Academy on July 29.—A long letter, illustrated with figures, from Father Secchi, on the solar eruption observed on July 7, and on the phenomena which accompanied it, was communicated. In this paper the author referred to the phosphorescent light emitted by certain animals, and upon this subject MM. de Quatrefages, Milne-Edwards, and E. Becquerel made some remarks.—M. Dumas read an important memoir on alcoholic fermentation, and a note on the ferments belonging to the diastase group.—MM. Favre and Valson presented a continuation of their researches upon crystalline dissociation.—M. G. Ville presented a memoir on the quick quantitative determination of phosphoric acid.—A note by M. Houzeau, on the decolorising power of concentrated ozone, was read, and upon this M. P. Thenard made some remarks.—M. Wurtz presented a note by M. E. Grimaux, on some derivations of tetrachloride of naphthaline.—A note was read by M. Sirodot on a bone-deposit situated at the foot of Mont Dol, containing bones and teeth of elephant, horse, ox, rhinoceros, and other mammals, generally broken and often calcined, with a few fragments of flints and at least one stone implement.—M. C. Sainte-Claire Deville presented a note by M. Gorceix, containing a summary of the phenomena presented by the volcano of Santorin at the close of the eruption of 1866, or from December 1869, to October 1871.—M. T. Lestiboudois presented a note on what he calls heterogeneous Dicotyledons, or those which do not produce their new tissues exclusively in the generative zone between the wood and the bark. —M. Duchartre communicated a note by M. J. Duval Jouve on a form of epidermic cell which appears to be peculiar to the Cyperaceæ.—M. de Quatrefages read a memoir on the Mincopies and the Negrito race in general, containing a discussion of the characters of the Andaman islanders, and of their relations to the other black races of man.—M. Blanchard presented a note by M. J. Kunckel on the development of the striated muscular fibres in insects, in which the author maintains that the primitive element of the muscle is a cell, which, by its elongation, forms the fibrilla, the fibre or primitive bundle being a secondary formation.—M. Blanchard also communicated a note by M. A. Tillot on the embryonic form of the Hairworms (*Gordius*), in which the development of those parasites from the egg is described, and they are shown to possess, in the embryonic state, some analogy with the *Echinorhynchi*.—A note by M. J. Gerbe on the formation of the adventitious products of the ovum of the Plagiostomi was presented by M. C. Robin.

August 12.—Prof. Cayley communicated a continuation of his memoir on orthogonal surfaces.—M. Yvon Villarceau presented a further memoir on the applications of his new theorem of general mechanics to the equilibrium of gases.—General Morin presented a report upon a memoir by M. Graeff, on the action which the breakwater of Pinay exerts upon the floods of the Loire at Roanne.—A note on the vibrations of cords and rods in liquids, by M. E. Gripon, was read.—M. Pasteur presented a note, by M. E. Branly, on the measurement of the intensity of currents by means of the electrometer.—A note, by M. Broun, on magnetic variations observed at Trevandrum during the eclipse of December 11, 1871, was presented; as also a note containing observations of meteors at various stations on August 9, 10, and 11, by MM. Le Verrier and Wolf.—A short note on the observations relating to presence of magnesium in the chromosphere of the sun, by M. Tacchini, was transmitted by M. Faye.—MM. Favre and Valson presented the continuation of their thermo-chemical researches upon crystalline dissociation.—M. Berthelot presented a note on the partition of a base between several acids in solutions, in which he treated of the monobasic acids; and M. Pasteur communicated a note, by M. E. Jungfleisch, on the conversion of right tartaric acid into racemic acid by exposure to heat in the presence of water.—M. Dumas called attention to some researches, by M. Latimau, on *Phylloxera vastatrix*.—M. Brongniart presented a detailed report upon a most important memoir, by M. Grand-'Eury, on the Carboniferous flora of the Department of the Loire.

BOOKS RECEIVED

Foreign.—Through Williams and Norgate—Alexander von Humboldt, 3 vols.: Karl Bruhns.—Etudes sur les Facultés des animaux comparés à celles de l'homme: J. C. Houzeau, 2 vols.—Oeuvres des Verdet, Tome vii—Théorie mécanique de la chaleur: E. Verdet, Vol. i. and Vol. ii., Parts 1 and 2.

American.—Report of the Palæontology of Eastern Nebraska: T. B. Meek.

CONTENTS

Errata.—Vol. vi., p. 382, Section C. Geology, line 7, for "graptolite" read "graptolites;" line 20, for "*T. serrus*" read "*T. serra*;" line 25, for "*Dictyograptus*" read "*Dichograptus*;" line 31, for "*Phyllograptus*" read "*Ptilograptus*;" line 35, for "not" read "two."

THURSDAY, SEPTEMBER 19, 1872

THE POTATO DISEASE

II.

THE habits of the fungus which produces the potato disease, *Botrytis* or *Peronospora infestans*, have been closely investigated by Montagne, De Bary, and Berkeley. The latter gentleman has described its life-history in the *Gardener's Chronicle*, and the editor of that paper kindly permits us the use of the accompanying woodcuts, which illustrate Mr. Berkeley's paper. The fungus bears abundance of spores on the tips of the branches, the mycelium, or spawn, burrowing amongst the cellular tissue of the leaf and causing rapid decomposition, while the vertical threads which branch and bear the spores, find their way through the stomata, or leaf pores. The spores themselves, falling on different parts of the plant, germinate, and, penetrating the tissues, pro-

duce a brown tint, not only in the cells with which they are in immediate contact, but also in the adjacent cells. In addition to these spores, or, more correctly speaking, conidia, the fungus produces also zoospores, or moving spores, furnished with the well-known movable threads or processes, and which are differentiated from the contents of some of the ordinary spores. These bodies, like the ordinary spores, germinate and penetrate the tissues, producing the same brown tint, and in the same way as the kind already mentioned.

The fungus was unknown to the older mycologists, having, at all events, never attracted attention before the first great outbreak of the potato-blight in 1845. It is not quite peculiar to the potato, being found also occasionally on other plants belonging to the natural order Solanaceæ, especially on the fruit of the tomato. The first indication is the well-known brown spots on the leaves of the plants; but by the time it manifests itself in this manner, its mycelium has already made deep inroads into the cellular tissue of the leaf and stem, and cure is well-nigh hopeless. The cutting-off of the haulm close to the ground will generally prevent the spread of the disease to the tubers, but this remedy is at the risk of destroying the quality of

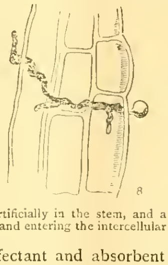
the crop, since it is impossible for the tubers thoroughly to mature after the entire removal of the vegetative organs. The growth of the fungus is greatly promoted by wet weather, and the "sowing" over the crop of lime, which acts as a powerful desiccant, is therefore a natural remedy, as also is the application of soot, the properties of



8. Zoospores sown artificially in the stem, and after twenty-four hours penetrating the tissues and entering the intercellular spaces.

carbon as a disinfectant and absorbent of gases being so well known. Prof. Gardner states that the diseased tuber is strongly alkaline, from the presence of ammonia, the sound potato having an acid reaction. Since, also, we are commonly visited by heavy showers during the latter part of July and early part of August, the period when the disease generally first decidedly manifests itself, it is probable that the advice of the *Gardener's Chronicle* is sound, to plant chiefly early varieties, and lift early, though this will involve some loss to the productiveness of the crop. On all these points, however, we are greatly in want of the authoritative opinion of practical men, the result of a careful series of experiments from which all accidental causes have been eliminated. The Royal Horticultural Society has a fine opportunity of performing

a most important service to practical agriculture by the institution of a series of crucial experiments in its experimental grounds at Chiswick.

Dr. Hooker's statement that the starch of the diseased potatoes is not affected by the parasite, but retains its nutritive properties, is worthy of more attention than it has yet received. He recommends rasping the peeled tubers upon a grater into a tub of cold water. In a few minutes the starch will be found to have sunk to the bottom, and the diseased matter, woody fibre, &c., will be suspended in the water, and should be poured away with it. Fresh water should then be added, the starch stirred up, and again allowed to settle. Two or three of such washings will remove all impurities, and render the starch fit for use. If thoroughly dried it will keep for any time, and can be used as arrowroot for puddings and cakes, and for mixing with flour as bread. This plan is open to obvious objections, both from its tediousness, and from the fact that when the disease has made any considerable progress, the smell is so offensive as to render both the peeling and the grating alike impossible to those possessed of ordinary olfactory perception. Dr Hooker, however, states that the plan was successfully pursued in 1845 and 1846 by the villagers of Hitcham under the direction of the late Rev. Prof. Henslow; and it seems incredible that chemical science should be unable to devise some practical and economical method for separating a wholesome substance of such enormous value in the bulk from the noxious ingredients.

Although the immediate cause of the potato disease has been clearly determined, as has been stated above, to be the attacks of a parasitic fungus, yet we are by no means prepared to agree with the conclusion of a distinguished writer,* that it "seems quite absurd, when the whole *rationale* of the potato disease has been so carefully explained, to look for an explanation in mere climatic conditions, exhaustion, weakness of constitution, or any of the empirical causes which are so often brought forward." The *Peronospora* is undoubtedly the proximate cause of the disease; for the ultimate cause we may have to look to a very different set of circumstances. It is probable that many epidemic diseases, both of men, animals, and plants, are caused by parasitic fungi; yet the attacks of the parasite may be favoured by special climatal or other conditions. We know that many animal plagues can be absolutely eradicated by the removal of the conditions which favour the propagation of the pest. The idea hinted at in our article last week that epidemic diseases may be expected in periodically recurring cycles is at least one deserving further investigation, and is supported by some curious facts. No reason has been given why the potato blight should have broken out so violently in 1845, when we had experienced before that many as ungenial summers during which it did not make its appearance, nor why it should have appeared simultaneously in so many remote countries—in St. Helena and Canada as virulently as in Europe—where the climatal conditions are altogether different; 1860 and 1872 are also not the only wet and thundery summers we have known during the last twenty years. It is quite possible that cosmical conditions may at definite intervals favour the disease, but that it may be developed only when certain other special conditions co-operate with these. We refer in another column to the systematic investigation now being carried on in France and Portugal as to the cause of the vine disease.

* Rev. M. J. Berkeley, in *Gardener's Chronicle*, Nov. 4, 1871.

The period of maximum sun-spots of between eleven and twelve years, as shown by the researches of De La Rue, Stewart, and Loewy, falls in 1848, 1860, and 1872; and it is very singular that history seems to point to nearly the same approximate period for great national epidemics. Thus, according to Hecker's "Epidemics of the Middle Ages," the dates of the five great visitations of the sweating sickness in this country were 1485, 1506, 1517, 1528, and 1551, the epidemic being accompanied on almost every occasion by other pestilences in man and beast in this and other countries, or by general failure of crops. We have, of course, no means of ascertaining the condition of the surface of the sun during those years; but it is at least a singular coincidence that 29 cycles of 11·1 years bring us from 1551 to 1872.

We do not wish to lay more stress on these curious facts than they deserve, but simply to indicate the number of points of view from which the subject may be investigated. To have ascertained accurately the immediate cause of the potato disease is no doubt a great step gained; but the scientific method will not allow us to stop here. We must do our best to penetrate further into the arcana of Nature, and bring all the resources of Science to bear to investigate the conditions which appear to favour the appearance and spread of the invader, and the means which promise the greatest chance of success to repel his attacks.

GLADSTONE'S LIFE OF FARADAY

Michael Faraday. By J. H. Gladstone, Ph.D., F.R.S., &c. (London: Macmillan and Co., 1872.)

THERE can be no doubt that a life of Faraday suitable for the general public was much needed. Dr. Bence Jones's work, though full of interest to scientific men, and to those who knew Faraday personally, was too voluminous and too lacking in cohesion to be very widely read. Dr. Tyndall's brilliant sketch fascinated the reader with the scientific aspect of the life it recorded, but left one longing to know "the inner supplement to that noble outward life" of Faraday. Dr. Gladstone's memoir very largely meets the wants we express.

There are few men better fitted to write a life of Faraday than Dr. Gladstone. Not only was he the personal friend of Faraday, associated with him in the management of the Royal Institution, and in scientific inquiries connected with the Trinity House, but, what is more important, their pursuits and sympathies ran in nearly parallel paths. And so with a loving hand Dr. Gladstone has gathered the materials for his memoir. These are drawn only to a small extent from sources with which we are already familiar, for the author gives us the benefit of his own recollections, and also numerous incidents from the many private sources of information to which he has had access. A delightful freshness and personal interest are thus given to the narrative. Here, for example, is an anecdote that will be new to most of our readers, and which illustrates the quiet humour which Faraday possessed One evening at the Royal Institution, when a lecture on

the English language was being delivered, the lecturer mentioned as a common vulgarism the habit of using "don't" in the third person singular, and cited, as an instance, "He don't pay his debts." Faraday, who was sitting in his usual place to the right of the lecturer, immediately exclaimed aloud, "That's very wrong!"

A very striking story was related to Dr. Gladstone by Cyrus Field. It is a sequel to the very circumstance that Dr. Tyndall has chosen as an example of Faraday's wonderful insight into nature, so like "a divining power." When Mr. Field was making the preliminary arrangements for that great enterprise with which his name will always be associated, he sought Faraday's advice on the electrical questions involved in a transatlantic cable. Faraday told him that he doubted the possibility of getting a message across the Atlantic. Mr. Field saw that this fatal objection must be settled at once, and begged Faraday to make the necessary experiments, offering to pay him properly for his services. The philosopher, however, declined all remuneration, but worked away at the question, and presently reported to Mr. Field—"It can be done, but you will not get an instantaneous message." "How long will it take?" was the next inquiry. "Oh! perhaps a second." "Well, that's quick enough for me," was the conclusion of the American; and the enterprise was proceeded with. This is an important incident, for not only does it show the readiness with which Faraday, when appealed to, freely lent himself to aid any scientific work, but it also indicates the confidence with which he applied the results of the laboratory to the grandest practical operations.

There are many other parts of Dr. Gladstone's memoir that we have marked for quotation, but our space will not allow us to do justice to the book by extracts. With pleasure we refer our readers to the volume itself, which is distinguished throughout by the modesty and self-forgetfulness of its author, its earnest tone, and the entire absence of all technicalities.

Dr. Gladstone will, however, permit us to indulge in a little friendly criticism on the arrangement of his materials. The memoir is divided into five parts—first, "the story of Faraday's life" is told us; then comes a "study of his character;" after which we have "the fruits of his experience," followed by "his method of working;" and in the last section we are shown "the value of his discoveries." With all deference to the reasons—no doubt well considered—which induced Dr. Gladstone to arrange his memoir thus, we venture to think that such a division is inartistic, and at first sight apt to repel a thoughtful mind. For is it not a slight upon the intelligence of his readers if an author presumes they cannot draw the study of a man's character nor "the fruits of his experience" from "the story of his life." Moreover, after having read the first part, which every one must agree is admirably done, we come upon a collection of incidents in Faraday's life, and anecdotes illustrating his character, that lose much of their force, by being massed together for a predetermined effect. It is the very spontaneousness and unobtrusiveness of the words and actions of a noble character that constitute their real claim to our admiration. And therefore we think it would have been far better if the author had woven into the life of Faraday the numerous incidents he has collected, rather than have let them lose their charm by a process of classification.

But if the arrangement is, in our humble opinion, not quite perfect, it certainly is the only blemish we can find in the work. It is a biography that will be read with interest by every intelligent person, and can be thoroughly enjoyed by those who are quite ignorant of science. It is a capital book for the youth of the present day, and among many of them we trust it will arouse a noble enthusiasm.

Now let us turn from the book to the man. Our readers do not need us to remind them of the history of Faraday, a history, which viewed in the grand achievements of his life, is so simple as to be almost sublime. Everyone knows that from a bookbinder's apprentice he lifted himself to the highest position in the scientific world. Here we may remark that we doubt whether a truly heroic nature has ever been quite covered up by the crowd of humanity. A great soul is a hero anywhere, and will win the recognition and often the worship of mankind, in spite of every obstacle. Faraday was an example of this. For the first twenty years of his life who knew him? What was his residence but a mere number in a back street? But before his death who did *not* know him? Every scientific society had laid a tribute of admiration at his feet, and he received letters inscribed to "Professor Faraday, member of all Academies of Science, London."

As his fame grew, and it became possible for him to make his name profitable, and realise thereby a considerable fortune, he permitted no selfish consideration to influence his career. Promptly rejecting that income which came from the sacrifice of his investigations, he obeyed the voice that said to him, "*Wisdom* is the principal thing, therefore get wisdom." So for fifty years one lofty idea animated his thoughts and sustained his indefatigable labour. His life became the ideas of what a philosopher's life should be, written only in the imperishable work he has done. Accepting no reward for his labours, declining any title or elevation of rank, seeking no public applause, living and dying in retirement and comparative poverty, Faraday consecrated himself to his work, and freely left to the world the magnificent revelations of a genius devoted to Nature. This surely is the life of a hero: noble devotion combined with utter unselfishness, the characteristics of a Cromwell, a Bruce, or a Garibaldi.

Though Faraday lived in retirement, and spent most of his hours in the laboratory, few men have passed a happier lifetime. No doubt the orderly and sustained simplicity of his daily life was one cause of the perpetual gladness of his heart. He confined his thoughts chiefly to his work and his home, and he regulated his life in the most methodical and natural manner. This may be seen from a little incident mentioned to the writer by Mr. Faraday's early friend, the late Mr. Benjamin Abbott. Some thirty years ago Mr. Abbott called to see Mr. Faraday, whom he had not met for many years. On inquiring at the Royal Institution the hall-porter told him that Mr. Faraday was at work, and could not be seen by anyone, indeed, that he dare not even take a visitor's card down to him. On Mr. Abbott's explaining that he was an old friend, the hall-porter suggested, with an obliging politeness which is conspicuous there still, that, as

it was near one o'clock, Anderson (Faraday's faithful assistant) would soon be going to his dinner, when probably he might catch sight of Mr. Faraday coming upstairs. Mr. Abbott waited; punctually at one Anderson emerged from the laboratory, Mr. Faraday followed, and, recognising his old friend at once, begged him to join them at dinner. "For," added Faraday, "I am a Goth you know, and always dine in the middle of the day." At dinner Faraday told Mr. Abbott a characteristic story about Anderson; how one morning during his glass experiments he found his assistant had been stoking the furnace all night long. Faraday had told him to keep the fire up, and omitting to release him in the evening, Anderson, with his soldier's excellent experience, stuck to his post till he received the next orders from his master. The fact that this simple obedience was all the assistance Faraday ever had increases the astonishment with which one regards the extent of his labours. The secret of the massiveness of Faraday's work was no doubt that he felt he had *one* aim before him, and therefore he rigidly kept from himself everything that would fritter away his time; political and commercial matters were passed by; he had his warfare to accomplish, and "no man that warreth entangleth himself with the affairs of this life."

Whilst Faraday found it necessary to shut out society, he enjoyed a social gathering, especially a family of children, whom he would amuse by dexterous experiments in glass-blowing, or with other less scientific manipulation. He liked occasionally to take his nephews to the pantomime, himself enjoying, as he said, "the immense concentration of means which it requires." Or he would attend in his early days, as Dr. Gladstone tells us, "the artistic and musical conversaziones at Hullmandel's, where Stanfield, Turner, and Landseer met Garcia and Malibran; and sometimes he would join this pleasant company at supper and charades, at others in their excursions up the river in an eight-oared cutter."

His delight in giving others pleasure showed itself continually. He was considerate and courteous to the lowest servant at the Royal Institution. The writer can testify to the enduring impression made by his words of kind encouragement and acts of thoughtful friendship towards the assistants in the laboratory. As Dr. Bence Jones well remarks, his humility had a living root in his religion. Of the intense earnestness of the religious aspect of his nature, it does not become us here to speak; he did not talk, but he lived Christianity. He rose above his peculiar creed. In no sense contracted or censorious, he shed a warm radiance on all with whom he came into contact. It was impossible to dwell in his presence without feeling all that was best in one's nature rising to the surface. Most tender and touching were the words he addressed to sorrowing friends. What a depth of affection is revealed by the following letter, written to a lady who had recently lost her husband :—

"Believe that I sympathise with you most deeply, for I enjoy in my life-partner those things which you speak of as making you feel your loss so heavily.

"It is the kindly domestic affections, the worthiness, the mutual aid in sorrow, the mutual joy in happiness which has existed, which makes the rupture of such a tie as yours so heavy to bear; and yet you would not wish it otherwise, for the remembrance of those things brings solace with the grief. I speak, thinking what my own trouble would be if I lost my partner, and I try to comfort you in the only way in which I think I could be comforted."

We are reminded by this and other letters of Faraday, that the inner life of a man is best seen in the letters to his intimate friends never meant for publication. In Faraday's exquisite letters, exquisite because so utterly artless, are revealed the happy, loving spirit, and, as Mr. Ruskin would say, the "*fineness of nature*" he possessed.

Another striking characteristic of Faraday was the quiet and unostentatious manner in which he did everything. His style of lecturing was so simple and easy as to appear effortless. This apparent absence of effort is, however, the climax of self-culture. A man only does that perfectly well which he does without the evidence of exertion. Faraday had reached this point through the mental discipline to which he habitually subjected himself. He translated into practice the words in which he expresses his own "strong belief that that point of self-education which consists in teaching the mind to resist its desires and inclinations until they are proved to be right, is the most important of all, not only in affairs of natural philosophy, but in every department of life."

With all this stern reality there was also a fine poetic fancy in Faraday. To him the Universe was no machine. His was "a face-to-face, heart-to-heart, inspection of things," and this, as Carlyle says, is "the first characteristic of all good thought in all times." Scientific phraseology never hid from him the grandeur and mystery that at bottom lies in everything. A thunder-storm was to him no mere affair of positive and negative electricity, no mere discharge of electric potential, but something infinitely beyond all this—"a window through which he looked into Infinitude itself." Dr. Gladstone tells us "he would stand gazing at the lightning, a stranger to fear, with his mind full of lofty thoughts, or perhaps of high communings. Sometimes, too, if the storm were at a little distance, he would summon a cab, and in spite of the pelting rain, drive to the scene of awful beauty." A friend thus met him once at Eastbourne, "in the thick of a tremendous storm, rubbing his hands with delight because he had been fortunate enough to see the lightning strike the church tower."

We are told that a new fact "seemed to charge him with an energy that gleamed through his eyes and quivered through his limbs." The writer remembers an illustration of this, when Dr. Tyndall brought Mr. Faraday into the laboratory to look at his new discovery of calorescence. As Faraday saw for the first time a piece of cold, black platinum raised to a dazzling brightness when held in the focus of dark rays, a point undistinguishable from the air around, he looked on attentively, putting on his spectacles to observe more carefully, then ascertained the conditions of the experiment, and repeated it for himself; and now quite satisfied he turned with emotion to Dr. Tyndall and almost hugged him with pleasure. And so on another occasion, when Prof. Plücker was showing in the laboratory some lovely experiments with vacuum tubes, Faraday literally danced with delight round the electric discharge, exclaiming, as he gazed at the moving arches of light, "Oh! to live always in it!"

We have said enough. Our readers will forgive us for recalling a character which many of them know far

better than the writer. But we are never tired of contemplating a nature so singularly beautiful as that of Faraday. Whether we think of him as pourtrayed by Dr. Bence Jones, Dr. Tyndall, or Dr. Gladstone, or by Prof. Helmholtz, Dumas, or De la Rive, the picture is still the same ;—

"His life was gentle ; and the elements
So mix'd in him, that Nature might stand up
And say to all the world, 'This was a Man !'"

W. F. BARRETT

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

American Stone Arrowheads

I AM glad to perceive that Dr. Abbott has called attention to the variations in form among North American stone arrowheads, although he cannot admit the correctness of some of the remarks I have incidentally made on this subject in my "Ancient Stone Implements of Great Britain." At the time when that work went to press, I was not in possession of Dr. Abbott's "Stone Age in New Jersey," if, indeed, it had appeared, and in describing the various North American forms, for want of other authorities I principally referred to Schoolcraft, Squier and Davis, and Prof. Daniel Wilson, some of whom Dr. Abbott appears to consider as somewhat antiquated.

It is not to be supposed that my acquaintance with the collections in the United States should in any way approach that of Dr. Abbott, as I have never visited America. My views as to the prevalence of different types were, however, mainly founded, not on printed descriptions, but on actual specimens preserved in collections in this country, my own among the number ; and with all deference to Dr. Abbott, who has kindly promised to send me the specimens on which he bases his remarks, I think it will be found that his views, even if completely applicable to New Jersey, will hardly hold good throughout the northern part of the United States and Canada. The principal points on which he disagrees with me are—

1. As to the arrowheads with a notch at the base on either side constituting a prevailing type in North America.
2. As to the leaf-shaped form being very rare.
3. As to the chipping being for the most part but rough, as compared with that exhibited on the arrowheads found in Britain.

1. As to the first point, Dr. Abbott does not appear to appreciate the difference between "a" and "the ;" and though it is possible that other forms of arrowheads are found in America in equal numbers with those such as I have mentioned, yet I think he would agree with me, if he were comparing a series, from North America with one from some other country, in recognising those with a notch at the base on either side as offering one of the prevailing types.

2. As to the leaf-shaped form being very rare, I may observe that among the thirty-eight figures of arrowheads given by Dr. Abbott in his "Stone Age in New Jersey" only one is leaf-shaped, though he mentions the plain leaf-shaped form as the prevailing variety of the leaf-shaped arrowhead and its modifications. In my own collection, comprising upwards of 160 North American arrowheads, there are only six that can be termed leaf-shaped, and but two of these are really typical specimens of the form. These two have come into my possession since my book was written. If not "very rare" I think the form must be regarded as comparatively rare.

3. Lastly, as regards workmanship, Dr. Abbott seems not to have observed that my statement as to the roughness of chipping was qualified with the words "for the most part." Anyone comparing a collection of stone arrowheads from North America with one formed in Britain or Ireland would, I think, at once admit that, as a whole, the latter were more finely and delicately chipped. Or, again, comparing Dr. Abbott's illustrations with mine the same general conclusion will be attained. Even the most elegantly formed American specimens that I have seen cannot compete in delicacy of workmanship with some of the English examples, such, for instance, as those represented in my Figures 317, 318, 319. I can only say that if Dr. Abbott or any other American collector will kindly send me some specimens equally well-chipped, I shall be proud to add them to my collection, and not too proud to acknowledge any errors into which I may have been betrayed through insufficiency of knowledge.

Nash Mills, Hemel Hempsted, Sept. 14

Botanical Terminology

BOTANY is now being taught to large numbers in public and middle-class schools ; its admission as a subject of general study can only be justified by its high educational value, not so much as an end, but as a means. Many of the boys who work at it will have no time to continue the study in detail, and the little they know of it will be what they learn at school.

Upon all these grounds it is desirable that there should be no unnecessary or conventional impediments placed in the way of as much education as possible being given in the short time allotted to it. I am desirous of eliciting an opinion as to whether the botanical terminology is or is not an impediment, diminishing the educational value and restricting the scope of the subject. For some years at Rugby I have felt myself hampered with a weariness of names. Is a terminology as polyglot in its derivation as the tower of Babel, and often involving questionable hypotheses of function, or incorrect ideas of morphology, the best instrument for making young pupils observe accurately or reason accurately on observed results ? And yet a teacher cannot select the terms he will use, (1) because the books, and especially the English and local floras, imply in their readers a knowledge of a wide terminology ; and (2) because, as in the fight against Euclid, so here the teacher is subject to the examiner, and at present the examination papers of the Science and Art Department, Cambridge Local, &c., are incomprehensible to a boy not bristling with terms.

Allow me specially to call attention to some of what appear to me unnecessary faults in the terms used, and to suggest one or two remedies. The names chosen to denote parts are mainly derived from Latin or Greek, or both, or have no received derivation. Well, even supposing that the words do, by their derivation from the dead language, suggest to those who know it some clue to their meaning, yet how few boys can keep these derivations in their heads, especially in schools in which Latin is not much and Greek not at all taught. Why on earth, when the promoters of science are driving out Greek to let in science, should a knowledge of Greek be a necessary "open sesame" to the correct remembering and spelling of botanical terms ?

But the above supposition is seldom correct, the words when translated expressing either a fanciful resemblance, or some pre-adamite stage of botanical knowledge. If the opening through which the pollen-tube passes is already called "little gate," perhaps we must submit to the name, but why call it "micropyle." ?

And here perhaps is the place to make a protest against such words as were flooded into the science at the time when the sexuality of plants was first established.

The usefulness of insisting on the generalisation that gamogenesis was common to plants and animals only exists in teaching those who know what gamogenesis in animals means. Does that usefulness exist in the case of boys and girls who learn botany. ? In teaching Human Physiology, some subjects are omitted and rightly omitted, from such text-books as Huxley's Elementary Physiology ; why then should a knowledge of such subjects be assumed in our botanical terms ? The facts of botany can all be taught, as far as my experience of boys and girls goes, without the slightest difficulty; the generalisation will follow of itself, as soon as it is wanted ; I only object to its being gratuitously, and almost pruriently, forced on the attention. Who can approve of the use in our elementary floras of the term "hermaphrodite," or the same symbols for pistillate and staminate plants being used which the boys are taught in their astronomy as the recognised symbols for Venus and Mars ? To this class belong the tribe of words ending in *—androus* and *—gynous*, which must either be taught as unintelligible gibberish, or explained on gamogenetic analogy. I do not wish to be misunderstood : if you are teaching the physiological subjects in animals, let "honi soit" be your motto, and call a spade a spade ; there are worse evils than we dream of arising from obscurantism ; but if you are teaching botany, keep to your subject, and do not go out of your way to call a club a spade.

Lastly, many words are utterly confusing: either they seem by their jingling similarity to make the learner and indeed even

older botanists sure to confuse them, as *loculicidal* and *septicidal* and the troop of words which end in —*tropous*; or they convey a morphologically impossible idea, as *inferior* and *superior* as applied to the ovary. To see how these faults can be avoided, let us inquire why an unusual amount of names are required at all.

(I.) Popular names being vaguely used require to be restricted in their meaning by accurate definition.

(II.) A new name is required for any part to which no name is popularly assigned, either because the thing to be named escapes popular observation, or because two or more things are included in the connotation of the popular term.

(III.) New adjectives, or adjectival-periphrases, are required to express characteristics, or relations of part to part.

Let me briefly suggest some principles, which, while remedying the faults of the old terminology, seem not to clash with these three necessities of the subject.

(*a*) Names for new things to be given in English, *ex. gr.*, the names *calyx* and *corolla* to be taught as *cup* and *crown*: in this we should be only following the German use of Kelch and Krone.

(*b*) Where a part of a thing already named requires a fresh name, the preference to be given to a name framed like the German double words—Kelch-blatt, Staub-blatt—so as to indicate the relation of part to part, thus *cup-leaf*, *leaf-stalk*, *flower-stalk* to be taught instead of *sepal*, *petiole*, and *peduncle*.

(*c*) Short expressions involving English (not Greek) prepositions to be used for adjectives: thus *splitting by mid-ribs*, *on seed-vessel*, *united by dust-pouches*, to be used for *loculicidal*, *epigynous*, *syngenesious*.

(*d*) Where the definitions of the terms is given in numbers, numbers or fractions be used instead of those terms: thus in æstivation, $\frac{2}{5}$ to be used for quincuncial; in cutting of leaves the fraction of the leaf cut to be stated instead of *omnia quæ exeunt*, *in-fid*, *-sect*, and *-partite*.

But it will be said—how will pupils taught thus get on afterwards? The answer is, either they will do no more of the subject than they do at school, in which case they will have got the idea without the obstructions of the terms; or they will care to go on further with the subject, in which case they will learn the terms very quickly, being now familiar with the facts and ideas. In neither case will time have been lost, and the scope of botanical subjects which may be treated in the time will have been doubled.

I must apologise for the length to which this letter has run.

Rugby, September 16

Hutton's Trigonometrical Tables, for Arcs expressed as portions of the Radius

AT the end of the preface of the first edition of Hutton's Mathematical Tables (1785) is the following postscript:—"P.S.—Since my History of Trigonometrical Tables in the following Introduction was printed, there has been published in the 'Philosophical Transactions' for the year 1784, a paper of mine concerning a project for the trigonometrical tables to be constructed on a new plan, namely, in which the arc of the quadrant is divided into aliquot parts of the radius, or according to the real lengths of the arcs, which construction is now in some degree of forwardness, as myself and several assistants have been closely engaged in the execution of it ever since." And in the succeeding editions, down to the sixth, 1822, there occurs on p. 2 of the Introduction the following remark:—"But the complete reformation would be to express all arcs by their real lengths, namely, in equal parts of the radius decimally divided, according to which method I have nearly completed a table of sines and tangents." Hutton died in 1823, and I can find no further reference to the table in question. I feel pretty certain that it has never been published, and there is no other paper on the same subject (except that in the Phil. Trans., 1784) of Hutton's referred to in Watt's "Bibliotheca" or the Royal Society's Catalogue.

The table was intended to give the sines, tangents, &c., of $\frac{1}{100000}$, $\frac{2}{100000}$, &c. (the unit being the arc equal to radius) to seven decimal places, and would be very useful. If it has not been published, perhaps some reader of NATURE might be able to say what has become of the manuscript that was nearly completed.

I may mention that the calculation of such a table was under the consideration of the Tables Committee of the British Association, but it was thought that some other tables were at present more urgently needed.

Cambridge, Sept. 16

THE "HASSLER" EXPEDITION

WE are indebted to the courtesy of the Editor of the *New York Tribune* for early communication of the following information from Prof. Agassiz's expedition:—

OFF GUATEMALA, July 29, 1872

To Prof. Benjamin Peirce, Superintendent U.S. Coast Survey.

MY DEAR PEIRCE:—Do not be surprised at my few messages. It is about all I can do to take advantage of every opportunity that offers for study and collecting; but I rarely feel sufficiently collected to do any connected writing. I have another new chapter concerning glacial phenomena, gathered during our land journey from Talcahuano to Santiago, but it is so complicated a story that I do not feel equal now to recording the details in a connected statement, while the whole may be put in a few words.

There is a broad valley between the Andes and the coast range, the Valley of Chillan extending from the Gulf of Ancud, or Port Montt, to Santiago, and farther north. This valley is a continuation, upon somewhat higher level, of the channels which, from the Strait of Magellan to Chiloe, separate the islands from the main land, with the sole interruption of Tres Montes, which gives the clue to the whole, as we have here in miniature a valley between the Andes and the coast range. Now this great valley, extending for more than 25 degrees of latitude, is a continuous glacier bottom, showing plainly that for its whole length the great southern ice-sheet has been moving northwards in it. I could find nowhere any indication that glaciers descending from the Andes had crossed this valley and reached the shores of the Pacific. In a few localities only did I notice Andean, *i.e.*, volcanic erratics upon the loose materials filling the old glacier bottom. Between Currillo and Santiago, however, facing the gorge of Tenon, I saw two distinct lateral moraines, parallel to one another, chiefly composed of volcanic boulders, resting upon the old drift, and indicating by their position the course of a large glacier that once poured down from the Andes of Tenon, and crossed the main valley, without, however, extending beyond the eastern slope of the coast range. These moraines are so well marked that they are known throughout the country as the Cerillos of Tenon; but nobody suspects their glacial origin; even the geologists of Santiago assign a volcanic origin to them.

What is difficult to describe in this history are the successive retrograde steps of the great southern ice-field, that, step by step, left to the north of it larger or smaller tracks of the valley free of ice, so that large glacial lakes could be formed, and, in fact, seem always to have existed along the retreating edge of the great southern glacier. The natural consequence is that there are everywhere stratified terraces, without border barriers (as these were formerly the ice that has vanished), resting at successively higher or lower levels, as you move north or south, upon unstratified drift of older date, the northernmost end of these terraces being the oldest, while those farther south belong to the latter steps in the waning of the ice-fields. From these data I infer that my suggestion concerning the trend of the striæ upon the polished and glaciated surfaces of the vicinity of Talcahuano, alluded to in the postcript of my last letter, is probably correct.

I was much grieved on reaching Valparaiso to hear of the mishaps of the dredging apparatus. The subsequent departure of Pourtales has been a great loss to us all, for notwithstanding his silent nature, he is a powerful standby.

Our visit to the Galapagos has been full of geological

and zoological interest. It is exceedingly impressive to see an extensive archipelago, of most recent origin, inhabited by creatures so different from any known in other parts of the world. Here we have a positive limit to the length of time that may be granted for the transformation of these animals, if they are in any way derived from others dwelling in different parts of the world. The Galapagos are so recent that some of these islands are barely covered with the most scanty vegetation, itself peculiar to these islands; some parts of their surface are entirely bare, and a great many of the craters and lava streams are so fresh that the atmospheric agents have not yet made an impression upon them. Their agent does not, therefore, go back to earlier geological periods; they belong to our time, geologically speaking. Whence then do their inhabitants come from—animals as well as plants? If descended from some other type, belonging to some neighbouring land, then it does not require such unspeakably long periods for the transformation of species as the modern advocates of transmutation claim; and the mystery of change, with such marked and characteristic differences between existing species, is only increased and brought to a level with that of creation. If they are autochthones, from what germs did they start into existence? I think that careful observers, in view of these facts, will have to acknowledge that our science is not yet ripe for a fair discussion of the origin of organised beings.

Our stay in Panama has allowed us to make very extensive collections in the Bay and across the Isthmus. I was surprised to find so little difference in the character of the flora and of the terrestrial fauna between the two oceans. Marked peculiarities are only to be found among the marine animals, and even among them the American character of the Atlantic and Pacific marine fauna is unmistakable; we are not surrounded by animals recalling by their peculiarities the many groups of islands of the Pacific. I expect that our visit in Acapulco will confirm these impressions. L. AGASSIZ

CAPTAIN HALL'S ARCTIC EXPEDITION

THE *Washington Chronicle* of August 26 contains the following interesting account of the progress and position of this important expedition:—"The Navy Department has received later despatches from Captain Hall, by the way of Tydskland and Copenhagen, completing his official record up to the moment of final departure from North Greenland. These despatches, which are quite full, bear date off Tossak, Tussuissuk, N. lat. 73° 21', W. long. 56° 5', August 24, 1871, and are, therefore, only four days later than Hall's Upper Navik despatch, August 20, 1871, which reached the department within three months by the way of Copenhagen. The explanation of this long delay *in transitu* is that there is no regular communication between Denmark and these far-off colonies but once a year. Hall's Upper Navik despatches were timed to reach the Danish brig just then sailing, and this present letter sent back by native pilots, as he notes in concluding, may have had near a year's detention in Disco. It seems to have reached the American Minister at Copenhagen about July 30. Although thus divested of any special value as news, the present despatch is of much intrinsic interest. All on board the *Polaris*, officers, scientific corps, and men, were well and in excellent spirits. The seagoing qualities of the vessel had been tested and found admirable; the engines and machinery were in perfect working order, coal and rosin in good supply, and the ship's crew abundantly provisioned. For the long Arctic night before them they had books, games, instrumental music, &c.—in a word, everything that the thoughtful care of the department could supply, or letters of credit at Newfoundland and in Greenland furnish, had been laid in to complete their outfit, and of all this Captain Hall makes characteristic and thankful acknowledgments. Governor Elberg, of the Navik district, had accompanied the *Polaris* as far as Tossak, the extremest northerly limits of Danish jurisdiction as well as of civilised life, and was to the last moment assiduous in his exertions to further the interests of the expedition. Mainly through his co-operation Hall was fortunate enough at Tossak to make up his complement of Esquimaux dogs—sixty strong, healthy animals—a matter of almost vital importance. He likewise laid in a large supply of dog food, and considerably augmented his stock of reindeer-furs, sealskins, &c., for the adventurous voyage. At Upper Navik the expedition had shipped Hans Christian, a famous native hunter and dog-driver, with his wife and three children. Jensen, the Dane, who was under promise to join the expedition at Tossak, backed out at the last moment. Governor Elberg, of whose many kindnesses Hall speaks with full heart, awaited at Tossak the return of the native pilots, bearing this despatch to him, and it closes with the prow of the *Polaris* northward in the early morning of August 24, with a complete roster of all on board, thirty-three souls, and a fervent, hopeful prayer for success. It will be remembered that Captain Hall's previous despatches speak of his good fortune in meeting at Holsteinburg the returning Swedish expedition, and that the commander, Baron van Otter, kindly furnished him copies of log, deep-sea soundings, &c., assuring him that the season was more than usually favourable, and extremely wide iceberg-channels, &c. Of the same purport was the information received of Governor Rodolph, thirty years resident in North Greenland, who declared the year to be more favourable for any northern voyage than many years agone or to come. Acting on this information, and under discretionary power vested in him by the Navy Department, Captain Hall had abandoned the Jones's Sound route, and had decided before he left Upper Navik that after stopping at Tossak he would cross Melville Bay to Cape Dudley Digges, and from that point steam direct to Smith's Sound, thence make all possible attempts to find a passage on the west side of the Sound from Cape Isabella up to Kennedy Channels, wintering there probably in about the same latitude or a little higher than Kane's winter quarters, and thence on and up to the North Pole. The letter published in the *New York Times*, April 25, purporting to narrate a disaster to the *Polaris* and her return last February to Disco, was a *canard*. Not one word of it has ever been credited at the Navy Department. It is not believed that any disaster has overtaken the Expedition, or that any ground for apprehension exists."

*THE BLIND FISHES OF THE MAMMOTH CAVE AND THEIR ALLIES**

THE *Amblyopsis spelæus* undoubtedly has quite an extensive distribution, probably existing in all the subterranean rivers that flow through the great limestone region underlying the Carboniferous rocks in the central portion of the United States. Prof. Cope obtained specimens from the Wyandotte Cave and from wells in its vicinity, and in the Museum of Comparative Zoology at Cambridge there is a specimen labelled "from a well near Lost River, Orange Co., Ind.," which, with those from the Wyandotte Cave, is conclusive evidence of its being found on the northern side of the Ohio† as well as on the southern, in the rivers of the Mammoth Cave. I have been able to examine a number of specimens from the Mammoth Cave, and have carefully compared with them the one from the well in Orange Co., Ind., and find that the specific characters are remarkably constant.

* Reprinted from the *American Naturalist*, a sequel to "The Blind Crustacea of the Mammoth Cave." See NATURE, vol. v. pp. 445, 484.

† I have also been informed by Mr Holmes of Lansing, Mich., that *blind fishes* have been drawn out of wells in Michigan.

In 1859* Dr. Girard described a blind fish, received by the Smithsonian Institution from J. E. Younglove, Esq., who obtained it "from a well near Bowling Green, Ky." The general appearance of this fish, which was only one and a half inch in length, was that of *Amblyopsis spelæus*, but it differed from that species in several characters, especially by the *absence* of ventral fins. Dr. Girard therefore referred the fish to a distinct genus under the name of *Typhlichthys*† *subterraneus*. Dr. Günther‡ considers this fish a variety of *Amblyopsis spelæus*, and records the specimen in the British Museum "from the Mammoth Cave," as half-grown.§

By the kindness of Prof. Agassiz, I have been enabled to examine nine specimens of *blind fish without ventrals*, in the Museum of Comparative Zoology. Seven of these were collected in the Mammoth Cave by Mr. Alpheus Hyatt, in September 1859. One was from Moulton, Lawrence County, Alabama, presented by Mr. Thomas Peters; and another from Lebanon, Wilson Co., Tennessee, presented by Mr. J. M. Safford. It is not stated whether these latter came from wells or caves, but probably from wells. They are all of about one size, one and one-half to two inches in length, and are constant in their characters. Moreover, four of the seven specimens from the Mammoth Cave were females with eggs. These eggs were as large in proportion as those from *Amblyopsis*. The ovary was single, and situated on the right side of the stomach, as in *Amblyopsis*. The difference in the number of eggs was very remarkable, each of the four specimens examined having but about thirty eggs in the ovary, while in three females of *Amblyopsis* (all, however, of nearly three times the size of *Typhlichthys*) there were about one hundred eggs in each. As in both species there were no signs of the embryos in the eggs, it is not probable that any of the eggs had been developed and the young excluded, nor is it at all likely that the great variation in the number of eggs would simply indicate different ages. For these reasons, taken in connection with the absence of ventral fins, I have no hesitation in accepting Dr. Girard's name as valid for this genus, of which we thus far know of but one species, with a subterranean range from the waters of the Mammoth Cave, south, to the northern portion of Alabama. In this connection it would be most interesting to know the relations of the "blind fishes" said to have been found in Michigan. For thus far we have *Typhlichthys* limited to the central and southern portion of the subterranean region, *Amblyopsis* to the central, and the species in the northern portion undetermined.

In 1853, on his return from a tour through the southern and western states, Prof. Agassiz gave a summary of some of his ichthyological discoveries in a letter to Prof. J. D. Dana.‖ In this letter are the following remarks:—

"I would mention foremost a new genus which I shall call *Chologaster*, very similar in general appearance to the blind fish of the Mammoth Cave, though provided with eyes; it has, like *Amblyopsis*, the anal aperture far advanced under the throat, but is entirely deprived of ventral fins; a very strange and unexpected combination of characters. I know but one species, *Ch. cornutus* Ag. It is a small fish scarcely three inches long, living in the ditches of the rice fields in South Carolina. I derive its specific name from the singular form of the snout, which has two horn-like projections above."

This is the only information ever published regarding this interesting fish, and the only specimens known are those on which Prof. Agassiz based the above remarks.

The only specimen known of this second species was drawn from a well in Lebanon, Tenn., and presented to the Museum by Mr. J. M. Safford, Jan. 1854. It is a more slender fish than *C. cornutus*, but the intestine follows the same course, and the four pyloric appendages are present as in that species.

In the genus *Chologaster*† we have all the family characters as well expressed as in the blind species, though it differs from *Amblyopsis* and *Typhlichthys* by the presence of eyes, the absence of papillary ridges on the head and body, and by the longer intestine and double the number of pyloric appendages, as well as by the position of the ovary; and agrees with *Typhlichthys* by the absence of ventral fins. *Amblyopsis* and *Typhlichthys* are nearly colourless, while *Chologaster Agassizii* is of a brownish colour, similar to many of the minnows, and *C. cornutus* is brownish yellow, with dark, longitudinal bands.

Among the most interesting points in the history of this genus is the fact of its occurring in two widely different localities, *C. Agassizii* having been found in a well in the same vicinity (probably in the same well) with a specimen of *Typhlichthys*, and undoubtedly belonging to the same subterranean fauna west of the Appalachian ridge, while *C. cornutus* belongs to the southern coast fauna of the eastern side of that mountain chain, and is thus far the only species of the family known beyond the limits of the great subterranean region of the United States.

Having now given an outline of the structure, habits, and distribution of the four species belonging to the family and recapitulated the known facts, we are better able to consider the bearings of the peculiar adaptation of the blind fishes, in the Mammoth and other caves, to the circumstances under which they exist.

Prof. Cope, in stating, in his account of the blind fish of the Wyandotte Cave, "that the projecting under jaw and upward direction of the mouth renders it easy for the fish to feed at the surface of the water, where it must obtain much of its food," suggests that:—

"This structure also probably explains the fact of its being the sole representative of the fishes in subterranean waters. No doubt many other forms were carried into the caverns since the waters first found their way there, but most of them were like those of our present rivers, deep water or bottom feeders. Such fishes would starve in a cave river, where much of the food is carried to them on the surface of the stream. . . . . . The shore minnows are their nearest allies, and many of them have the upturned mouth and flat head. . . . . . Fishes of this, or a similar family, enclosed in subterranean waters years ago, would be more likely to live than those of the other, and the darkness would be very apt to be the cause of the atrophy of the organs of sight seen in the *Amblyopsis*."

This suggestion was undoubtedly hastily made by Prof. Cope when writing the letter which was printed in the *Indianapolis Journal*, and were it not that the article has been reprinted in the "Annals and Magazine of Natural History," I should not criticise the statement made in an off-hand letter for publication in a newspaper; for with Prof. Cope's knowledge of fishes it could simply be a hasty thought which he put on paper, when he suggests that it is because the *Cyprinodontes* have a mouth directed upwards and are surface feeders that they were better adapted to a subterranean life than other fishes, and hence maintained an existence, while other species, which he supposes were introduced into the subterranean streams at the same time, died out.

If the fishes of the subterranean streams came from adjoining rivers, why were not many of the Percoids, Cyprinoids, and other forms, that are as essentially surface feeders as the *Cyprinodontes* (many of the latter are purely "mud feeders"), as capable of maintaining an existence in the subterranean waters as any species of the latter? Neither is it necessary for us to assume that the structure of the fish should be adapted to feeding on the

* Literally "bile-stomach;" probably named from the yellow colour of the fish.

surface, for not only have we in the blind cat fish described by Prof. Cope himself from the subterranean stream in Pennsylvania, an example of a fish belonging to an entirely different family of bottom feeders thriving under subterranean conditions, but the blind fishes of the Cuban caves are of the great group of cod fishes which are, with hardly an exception, bottom feeders. The fact that the food of the blind fishes of the Mammoth Cave consists in great part of the cray fish found in the waters of the cave, as shown by the contents of several stomachs I have examined, and also that one blind fish at least made a good meal of another fish, as already mentioned, shows that they are not content with waiting for what is brought to them on the surface of the water, and that they are probably as much bottom as surface feeders.

Again, in regard to sense of sight, why is it necessary to assume that because fishes are living in streams where there is little or no light, that it is the cause of the non-development of the eye and the development of other parts and organs? If this be the cause, how is it that the *Chologaster* from the well in Tennessee, or the "mud fish" of the Mammoth Cave, are found with eyes? Why should not the same cause make them blind if it made the *Amblyopsis* and *Typhlichthys* blind? Is not the fact, pointed out by Prof. Wyman, that the optic lobes are as well developed in *Amblyopsis* as in allied fishes with perfect eyes, and, I may add, as well developed as those of *Chologaster cornutus*, an argument in favour of the theory that the fishes were always blind, and that they have not become so from the circumstances under which they exist? If the latter were the case, and fishes have become blind from the want of use of the eyes, why are not the optic lobes also atrophied, as is known to be the case when other animals lose their sight? I know that many will answer at once that *Amblyopsis* and *Typhlichthys* have gone on further in the development and retardation of the characters best adapting them to their subterranean life, and that *Chologaster* is a very interesting transitionary form between the open water *Cyprinodontes* and the subterranean blind fishes. But is not this assumption answered by the fact that *Chologaster* has every character necessary to place it in the same family with *Amblyopsis* and *Typhlichthys*, while it is as distinctly and widely removed from the *Cyprinodontes* as are the two blind genera mentioned?

If it is by acceleration and retardation of characters that the *Heteropygii* have been developed from the *Cyprinodontes*, we have indeed a most startling and sudden change of the nervous system. In all fishes the fifth pair of nerves send branches to the various parts of the head, but in the blind fishes these branches are developed in a most wonderful manner, while their subdivisions take new courses and are brought *through* the skin, and their free ends become protected by fleshy papillæ, so as to answer, by their delicate sense of touch, for the absence of sight. At the same time the principle of retardation must have been at work and checked the development of the optic nerve and the eye (which probably exists externally in the young fish), while acceleration has caused other portions of the head to grow and cover over the retarded eye.

Now, if this was the mode by which blindness was brought about, and tactile sense substituted, why is it that we still have *Chologaster Agassizii* in the same waters, living under the same conditions, but with no signs of any such change in its senses of sight and touch? It may be said that the *Chologaster* did not change because it probably had a chance to swim in open waters, and therefore the eyes were of use, and did not become atrophied. We can only answer, that if the *Chologaster* had a chance for open water, so had the *Typhlichthys*, and yet that is blind.

If the *Heteropygii* have been developed from *Cyprinodontes*, how can we account for the whole intestinal canal becoming so singularly modified; and what is there in the difference of food or of life that would bring about the change in the intestine, stomach, and pyloric appendages, existing between *Chologaster* and *Typhlichthys* in the same waters? To assume that under the same conditions one fish will change in all these parts and another remain intact, by the blind action of uncontrolled natural law, is, to me, an assumption at variation with facts as I understand them.

Looking at the case from the standpoint which the facts force me to take, it seems to me far more in accordance with the laws of nature, as I interpret them, to go back to the time when the region now occupied by the subterranean streams was a salt and brackish water estuary, inhabited by marine forms, including the brackish water forms of the *Cyprinodontes* and their allies (but not descendants) the *Heteropygii*. The families and genera having the characters they now exhibit, but most likely more numerously represented than now, many probably became exterminated as the salt waters of the basin gradually became brackish and more limited, as the bottom of this basin was gradually elevated; and finally, as the waters became confined to still narrower limits, and changed from salt to brackish, and from brackish to fresh, only such species would continue as could survive the change, and they were of the minnow type represented by the *Heteropygii*, and perhaps some other genera of brackish water forms that we have not yet discovered.

In support of this hypothesis we have one species of the family, *Chologaster cornutus*, now living in the ditches of the rice fields of South Carolina, under very similar conditions to those under which others of the family may have lived in long preceding geological times; and to prove that the development of the family was not brought about by the subterranean conditions under which some of the species now live, we have the one with eyes living with the one without, and the South Carolina species to show that a subterranean life is not essential to the development of the singular characters which the family possess.

That a salt or brackish water fish would be most likely to be the kind that would contine to exist in the subterranean streams, is probable from the fact that in all limestone formations caves are quite common, and would in most instances be occupied first with salt water then with brackish, and finally with fresh water so thoroughly impregnated with lime as to render it probable that brackish water species might easily adapt themselves to the change, while a pure fresh water species might not relish the solution of lime any more than the solution of salt; and we know how few fishes there are that can live for even an hour on being changed from fresh to salt, or salt to fresh water. We have also the case of the Cuban blind fishes belonging to genera with their nearest representative in the family a marine form, and with the whole family of cods and their allies, to which group they belong, essentially marine. Further than this, the cat fish from the subterranean stream in Pennsylvania belongs to a family having many marine and brackish water representatives. As another very interesting fact in favour of the theory that the *Heteropygii* were formerly of brackish water, we have the important discovery by Prof. Cope of the Lernæan parasite on a specimen of *Amblyopsis* from the Wyandotte cave; this genus of parasite crustaceans being very common on marine and migratory fishes, and much less abundant on fresh water species.

Thus I think we have as good reasons for the belief in the immutability and early origin of the species of the family of *Heteropygii*, as we have for their mutability and late development, and, to one of my, perhaps, too deeply rooted ideas, a far more satisfactory theory; for, with our present knowledge, it is but theory on either side.

F. W. PUTNAM

*PASTEUR'S NEW PROCESS FOR THE MANUFACTURE OF BEER**

DURING the last few years several improvements have been introduced into the manufacture of beer; in Germany especially, land of sauer-kraut and hops, much attention has been devoted to this spicy and delicate question. In general, however, the apparatus for this manufacture leaves much to desire, and to this day brewers are far from being in possession of a process anything like perfect. Scientific men have given scarcely any attention to the question, which, perhaps, they consider unworthy of their study; while, like the rest of mortals, overcome by the heat and burden of the day, they perhaps have not disdained at times to raise to their lips the golden beverage, which even the most dainty prefer to the ancient and divine nectar.

Happily, we have commenced to review our past errors; the great masters of science have consented to descend from the ethereal heights of their empire, and to bring to bear upon industrial art their precious co-operation. For my part, I prefer a result to a formula, an application to a cloudy theory. Should some, losing themselves in impenetrable mists, turn away their attention with alarm from the useful pursuits of these men of science who approach with satisfaction the vulgar necessities of this world, let them do so, so long as M. Liebig is willing to be the world's cook, and M. Pasteur its brewer! It is an established fact in the eyes of earnest men, that "science," as Flourens said, "ought not merely to remain a source of self-satisfaction to the soul who has acquired it, and been elevated by it above the crowd, and that it becomes false as soon as it ceases to be profitable to that crowd." Dunoyer said with justice that "he who is a man of science, and nothing more, knows only how to make science useless to himself."

M. Pasteur is one of those men essentially scientific and keensighted, who understand the saying Geoffroy St. Hilaire one day made to re-echo through the Institute, "The social question is the first with which to occupy ourselves at the present day." But it was in that same room that Bert exclaimed, "Let us continue to study Nature in her most secret processes, to discover, to measure, to calculate the forces that she brings into action, having no thought of any useful applications we can put our studies to." Without doubt, with his friend Gay-Lussac, the great mathematician would reproach Pellegrini-Savigny with having degraded Science in occupying himself with questions as to alimentation. But on the other side we have the names of Berthollet, Monge, Chaptal, Conté, d'Alembert, Franklin, Geoffroy St. Hilaire, Arago, and especially Pasteur, for whom posterity will undoubtedly have a profound respect. M. Pasteur has added to his other fruitful inventions a new process for improving the manufacture of beer, for which he asked a patent in June 1871 in the following terms:—

"I desire to take out a patent for five years for a new mode of manufacturing beer, which consists essentially in fermentation sheltered from all contact with air.

"The wort, after being boiled, is turned into vessels of wood or iron, cooled in a current of carbonic acid gas; and then put to ferment.

"This process is founded upon new scientific data which I have expounded elsewhere, and from which it follows that contact with air is most injurious to the manufacture of beer. It is applicable to mild and strong, brown or pale ales.

"I wish the beers made by my process to bear in France the name of *Bières de la Revanche Nationale*—I shall say why elsewhere—and abroad that of *Bières françaises*.

"The disuse of cooling *bacs*.

"No loss by evaporation, &c.

"The abolition of store cellars, for future use.

"An increase of the quantity produced, and, at the same time, an increase in the strength of the beer.

"The development of a very agreeable 'bouquet.'

"No further use for ice-houses, for fermentation at a low temperature.

"Such are some of the principal advantages to be derived from the application of my process, and some of the qualities that will mark the beers *de la Revanche*."

On Nov. 4, 1871, an additional certificate, accompanied by the sketch here reproduced, was deposited at the Prefecture of the Department of the Seine.

"The annexed sketch," says M. Pasteur in this addition, "represents the construction of the apparatus for the application of the new process of beer manufacture. A description of the design accompanies it.

"The size of this apparatus varies with the importance of the manufacture. It can be made of any size, from one hectolitre to 100,000 hectolitres. When the apparatus is of a somewhat considerable size, the employment of carbonic gas is indispensable to prevent the formation of deleterious ferments—lactic ferment, butyric ferment, injurious alcoholic ferment, &c. The employment of air, previously purified by calcination, by passing it through cotton, or by any other mode, is also a remedy for this drawback. A very small quantity of air is not injurious, perhaps even ultimately improves the quality of the beer. The beer can absorb all the flavour which malt and hops can give it; it can acquire a thoroughly free taste, sparkling limpidity, great strength, and in general all its characteristic qualities, only if we can totally, or in a very large measure, suppress the combustion which takes place in the ordinary process.

"We can also fill up the void which is made in the apparatus during the cooling of the wort, by bringing the apparatus into connection with a vessel full of warm wort, to kill the seeds of disease in the wort and in the beer which is the ultimate result.

"A man-hole is necessary at those parts of the apparatus marked F, F, when they are of great size.

"The cylinders should be surrounded with a muffler of flannel."

On November 25, 1871, M. Pasteur added a new improvement to his invention.

"The facility with which my apparatus may be applied will be increased by the employment of carbonic acid gas, after a more convenient fashion.

"The carbonic gas produced during fermentation, after having passed through a washing-flask, to be freed from any froth it might hold, is delivered into a zinc or tin reservoir, placed a little below the fermenting apparatus. At the lower part of this reservoir are arranged a number of sockets or taps. When it is desired to cool the wort in presence of the carbonic acid, as it is useless to mix up this gas with the liquid, it is sufficient to put one of the taps of the reservoir in communication with one of the tubes of the apparatus F, F, F′. This arrangement enables us to do without a gasometer, and obviates all the difficulties that could result from the movement of a gas which ought to overcome the resistance of liquid. Moreover, as the reservoir always keeps itself full, its capacity need not be very large.

"With a rapid cooling we can dispense with the use of carbonic acid; we can even allow ordinary air to enter in proportion as the bulk of the wort diminished while cooling."

The germs of disease in the wort are killed in the boiling wort, and those which the volume of free air just mentioned may carry, will not have time to develop in the wort, if the cooling process has been prompt—a condition always easy to bring about by having a suitable flow of water, and by having the bulk of wort always comparatively small.

"In reference to these assertions, it may not be useless to recall the proof I formerly gave of the remarkable fact,

* Translated from an article by M. A. Jouglet, in the *Moniteur Scientifique* for September 1872.

that liquids the most variable, even common household broth, preserve their limpidity for years by being kept from contact with air, provided that they be deprived of their germs. In the ordinary processes for manufacturing beer, all these germs are carefully accumulated in the wort, and even in the beer; and besides, the aromatic part

E, E, E'. Pipe for receiving cold water which is distributed by the nozzles P into the fermenting apparatus F, F, F, F'. M, M. Apparatus for manufactured carbonic acid. C, C, C. Discharge-pipe for the water which is thrown out by the troughs *g*, *g*, *g*', where it collects very warm at the outset of the operation. F'. Another arrangement of the fermenting apparatus in which the moveable cover closes the cylindrical apparatus by means of the exterior trough *g*'', *g*'', with which the border of the cover dips. G. An ordinary gasometer, with a receiving and egress pipe. The fermenting gas of various apparatus can easily be turned into this gasometer, which afterwards supplies this gas when a new process is set agoing. *t*, *t*, *t*. Thermometers to indicate the temperature for putting in the yeast.

of the hops is utterly destroyed by the oxygen of large masses of air; hence a deterioration of the product and a difficulty in keeping it.

"The cooling of the wort can be hastened by various arrangements. One of the most simple consists in having serpentine or cylindrical tubes placed vertically in the

interior of the vessels F, F′, where cold water circulates. The boiling wort can be turned into the fermenting vats themselves, to which the cooling tubes alluded to have been added, besides covering over these vats with a tin cover by hydraulic pressure, or else the boiling wort will cool in a large apparatus F or F′, fitted with cooling tubes for the circulation of water; then, at the moment when fermentation begins, the wort is turned into the fermenting vats closed by their hydraulic covers. It is even possible to make the common refrigerators serve by enclosing them in a vessel full of carbonic acid gas, or of air deprived of germs, and even ordinary air, if the vessel is of small capacity.

"To recapitulate:—the main and altogether novel principle of my process consists in the employment of vats of tin or wood, into which the wort is run as hot as possible, and is cooled by a current of water outside, or outside and inside at once, without any evaporation, over which there is absolute control; so much is this the case that, according to the terms of my patent, nothing is more simple than to transport the wort without danger to the greatest distances. With regard to the action of the air, we can limit it at pleasure, in so far as it is noxious, for we can always annihilate the mischievous influence of the germs it contains. The brewer has, moreover, the control over the action of free oxygen gas, so far as it consumes the aromatic or other very delicate principles. Besides, my process allows the temperature to be kept steadily at any height for the purpose of fermentation. In short, its advantages are valuable for the fermentation of German beer, or for mild fermentation, for we can proceed to the employment of ice or any other powerful means of cooling during the process of fermentation. There, is, however, no distinction between strong and mild fermentation, except in so far as the greater or less specific differences of two yeasts, strong and mild, are concerned. The two yeasts can be kept equal; the fermentation will be accomplished in the cold vats.

"Ere long I shall indicate how we may obtain at pleasure, at all seasons, and in all places, the two yeasts in a state of purity, without having recourse to those of the brewer.

"The ferment which is deposited at the bottom of the vessels, F′, is of a brown colour, because it is mixed with the deposit characteristic of the wort during the cooling process. It will be easy to collect it almost white, and without mixture, either by scraping the surface of the cake which it forms at the bottom of the apparatus, or by introducing at the outset into the apparatus, at the moment when we place the cover on the boiling worts, circular plates, attached to a bar which passes through the cover. This upright bar should terminate in the quadrant of a circle, round the extremities of which it can be turned, and moved up or down. While the wort is cooling, the plate of each apparatus will have its plane in a vertical position, and thus it will remain during the first days of violent fermentation. Then, when the ferment begins to settle down, the plate should be gently lowered until it is horizontal. After the product has been drawn off, a cake of ferment will be found upon the plate."

M. Pasteur made still another addition to this process, which was added to his patent in January 1872. It is as follows:—

"When the yeast in one pan is spoiled from any cause, it is necessary to have recourse to yeast taken from another pan. It then becomes a matter of importance to be able to prepare for one's self in any kind of vessel whatever a yeast deprived of all deleterious germs. I have solved this problem by discovering that the *Mycoderma vini* can be made the nucleus of a mild yeast. It can be made to develop itself in the wort of beer sheltered from contact with the air. I have also discovered that the fermenting principle of the grape is a mild yeast. It is a source to which breweries established according to my process can resort."

This addition is, in my opinion, of great importance. M. Pasteur's researches will not probably end here. Every day brings with it a new idea. At all events, from this time the manufacture of beer has received such valuable improvements as will tend to its increased production and use. The process has not yet received the sanction of long experience, but it appears to have fulfilled all that was expected of it. Some have asserted that M. Pasteur's system involves an enormous expense. I do not believe it; experience will show these objections to be unfounded.

After all I know very well that M. Pasteur may yet be the victim of envy. It will be remembered what annoyance an enemy gave him in connection with his process for improving wines.

M. CHEVREUL

A VERY interesting episode took place at the *séance* of the French Academy of Sciences of September 2, on the occasion of what may be regarded as the academic jubilee of the Dean, the famous chemist, M. Chevreul. The fiftieth year of his membership does not strictly occur till 1876; but it is well known that he would have been elected in 1816, had he not urged the Academy to give the vacant place to M. Proust, his compatriot, and a celebrated chemist, who was old and infirm, and could not afford to wait. M. Faye, as president of the Academy, intimated that the members had resolved, as a token of their estimate of his works, and their regard for his personal character, to present the venerable Dean that day with a medal, without waiting for the arrival of the formal jubilee. The medal represents the features of the illustrious chemist, who bears the weight of his 86 years much more lightly than many of his fellows who are considerably younger than himself. M. Dumas, the celebrated chemist, and permanent secretary of the Academy, in an eloquent and gracefully-worded speech, recounted the many valuable services rendered by M. Chevreul, who modestly styles himself "le doyen des étudiants français," and at the same time bore warm testimony to the personal character of the man. After M. Elie de Beaumont, who had been a pupil of M. Chevreul, had added a few words of veneration and respect for his old master, the latter attempted to respond, but had simply to express his inability to do so. It was in 1806 that M. Chevreul published his first most important work. He was collaborator of Vanquelin: and he has just completed a volume, entitled "Mémoires de l'Académie," a most interesting work, which throws light upon many of the most scientific questions of the day. M. Chevreul is one of the most distinguished chemists of the age; and, besides being Dean of the Academy of Sciences, is Director of the Museum of Natural History at the Jardin des Plantes. He has chosen for his motto that beautiful maxim of Malebranche, which indeed affords a true key to his life, his works, and his discoveries, "*Chercher toujours l'infaillibilité, sans avoir la prétention de l'atteindre jamais.*"

NOTES

It is stated, on the authority of a private telegram from Bombay of Tuesday last, that letters from Dr. Livingstone, dated July 2, 1872, have been received at Zanzibar. He was still at Unyamyembe, was well, and waiting the arrival of Stanley's second expedition.

The fourth three-yearly meeting of the French Institute will take place on the 2nd of October, and the yearly public meeting on the 25th of October.

At the sitting of the French Academy of Sciences, on Sept. 9, a number of communications on the subject of the ravages of the *Phylloxera vastatrix* in the vineyards of France were read by M. Dumas, and referred to the "*Phylloxera* committee" of the Academy. It appears that the disease is making fearfully rapid advances in Provence, threatening the speedy entire destruction of the crop. In the department of Vaucluse it is also rapidly increasing; while in that of l'Hérault it is rather diminishing. All the correspondents agreed that when once a plant is attacked cure is hopeless, and that it is almost impossible to prevent the parasite spreading to neighbouring plants by any other means than complete submersion under water, though the application to the roots of a soil composed of sand, manure, and some insecticide, will delay it for some years. There is no doubt that the wingless insect migrates above ground from the diseased to the healthy plant, and is carried in great quantities by the wind. M. d'Armand, of Marseilles, demanded that a prize of 500,000 fr., or, if necessary, 1,000,000 fr., be offered by the State to any one who shall discover a means of arresting the disease. The pest has made great advances also in Portugal, especially in the neighbourhood of Porto, Villa Réal, Douro, and Santarem; and a Royal Commission has been appointed to investigate fully the causes of a disease which threatens the destruction of one of the most important branches of national wealth, and the best means of curing it.

We have received from New York copies of the *Tribune*, containing full reports of the A. A. A. S.—the transatlantic expansion of the British Association—contributed by one of the editors of that journal. There can scarcely be imagined a more striking indication of the root that Science is taking in America than this, for the report has necessitated some 2,400 miles of travel, and the white heat of a political contest is raging; and yet it appears: in other words, knowing the cleverness of our transatlantic cousins—it pays!

The present excessive price of coals is stimulating the wits of every one concerned to endeavour to discover some means of reducing it. Certainly one of the best means would be to increase the supply from beneath the soil of our own country; how this may probably be accomplished is suggested in a letter to the *Liverpool Daily Post* of Sept. 16, by Mr. T. M. Reade, C.E. His suggestion is that in all likelihood coal would be found by boring the district immediately around Liverpool. The whole of the rock on which the town stands, and in fact the whole country, from a fault passing near and west of Neston, under the estuary of the Dee, to the Croxteth fault, just beyond West Derby, belongs to the Trias, which in this locality consists only of two members, the Bunter and the Keuper, the third, or Muschelkalk of Germany, being absent. Eastward the Triassic formation extends as far as Manchester, from which it follows an irregular line as far south as Shrewsbury; but as this portion of the district is deeply covered with the red marls of the Keuper, and as it would take deep sinking to reach the underlying coal (assuming it to be present), Mr. Reade confines his proposition to the district enclosed by lines drawn through Liverpool, Warrington, Chester, and West Kirby, at the mouth of the Dee. The whole of this district has been let down as in a trough, by which the Trias has, to a large extent, been preserved from denudation, and the underlying coal formation is consequently, in places, at a considerable depth below the surface; whether at a workable depth is the question which must be considered. Leaving out of account the red marls, which only occupy a small patch by Upton, in Cheshire, and again by the Weaver opposite Frodsham, the highest rock in the series is the Keuper sandstone, which forms the surface at Oxton, Wallasey, Heswell, and Stourton, in Cheshire, and under a portion of Liverpool, west of what is called the Everton fault—a strip of Keuper sandstone running almost due north from Toxteth Park. The remainder of the Triassic formation consists entirely of the Bunter sandstone, which is itself divided into Upper soft red sandstone, the pebble bed, and Lower soft red sandstone. Under these again, before we reach the highest members of the carboniferous rocks, it is an open question whether we should or should not have to penetrate Permian strata. The Permians have been proved in a few places, principally occurring on the northern boundary of the Trias in a narrow strip, and the total depth being but small. At Croxteth, where coal was formerly worked, the New Red sandstone or Trias is said to be directly superposed upon the coal measures; but a well-boring at Winwick, after penetrating 150 feet of red sandstone, the upper part of which is placed with the pebble beds in the geological survey sheet, was sunk 210 feet through strata consisting of hard red rock, stiff red marl, red and white sandstone, with a zone of limestone bands at the base, the boring terminating at 360 feet from the surface in hard rock. These beds, Mr. Reade is inclined to think, belong to the Permians rather than to the Upper coal measures; but it is doubtful if the Permians would be found under the whole area, as they have evidently been subject to denudation before the New Red sandstone was laid down. If coal is to be bored for at Liverpool, it should be at one of the several places where the Lower red sandstone is thrown up to the surface, the probability being, Mr. Reade thinks, that the upper members of the coal-measures would be reached at the depth of 400 or 500 feet, while the workable coal, or commencement of the middle coal-measures, would probably be found at a further depth of 1,200 feet. If the shaft were sunk near a fault, it would soon be seen whether it were worth while to sink deeper. Mr. Reade suggests a patch of Lower sandstone, about half a square mile in extent, at Eastham, and a less one at West Kirby, in addition to that about Croxteth on this side of the river. The depth conjectured by Mr. Reade is very much under some of the depths which have been canvassed in estimates of the increased difficulty and costliness of meeting the industrial demand for fuel.

A great international exhibition of fruit will be held at South Kensington, in connection with the Horticultural Department of the London International Exhibition, 1872, on Wednesday, Nov. 6, in which all home and foreign growers of fruit are invited to take part, and for which occasion a liberal schedule of prizes has been issued by the Council.

The discovery of a new planet, No. 124, by M. Prosper Henry, on the night of September 11-12, is announced from Paris. Its position and motion are as follows:—September 11, $15^m 47^h 35^s$, Paris M.T.; R.A. $23^h 59^m 35^s$; Decl. $-0° 55' 57''$; horary motion in R.A. $-1^s \cdot 9$, in Decl. $-20''$. Magnitude about 11·7.

During the closing hours of the last Congress of the United States an appropriation of 150,000 dols. was made for the purpose of introducing salmon, shad, and other valuable food fishes into the rivers and lakes of the United States, and its expenditure was placed in the hands of Professor Baird, the United States Commissioner of Fish and Fisheries. The late period at which this appropriation was made rendered it difficult to accomplish much in reference to shad, as the season for their hatching was very nearly over; but, notwithstanding this, a very satisfactory beginning to the enterprise is announced by the commissioner.

Dr. Augustus Krantz, of Berlin, the well-known dealer in specimens of geology and mineralogy, died on the 6th of April last, in the sixty-second year of his age. This gentleman was well known throughout Europe and America for the immense

collections kept for sale by him, and many colleges and other cabinets in the United States contain series purchased from him, furnished at very reasonable prices.

THE Newcastle-on-Tyne College of Physical Science has issued its prospectus for the Session 1872-73. The first Session closed with 70 day and over 100 evening students, and considerable accessions are hoped for. The teaching of Biology is still conspicuous by its absence; but there is so strong an element of Natural History on the governing board of the College that we may hope the just claims of this branch of science may not be disregarded much longer. Why is the obsolete term "Natural Philosophy" retained among the subjects taught? It is here apparently meant to embrace Mechanics, Hydrostatics, and Optics. An examination will be held on October 7 and 8 for four exhibitions of 15*l.* each, tenable in the College for two years, in Arithmetic, Algebra, and Euclid, and either Geology, Heat, or Chemistry.

IN 1871 the important papers of Dr. Petermann upon the Gulf Stream, with their accompanying maps and charts, were translated into English and published by the United States Hydrographic Office, under the direction of Captain R. H. Wyman. Since then two supplements have been issued by the office, including additional information obtained by Dr. Petermann, the second one accompanied by a map of the northern regions of Europe and Asia east of Greenland. This, which is on quite a large scale, gives us the results of the discoveries made up to the end of 1871, including the work done by Lamont, Mack, Johannesen, Payer and Weyprecht, Rosenthal, &c. The text of this supplement contains reports of the cruises of Smith and Ulve, and of Captain Torkildsen, papers on the sea north of Spitzbergen, and on Gillis's Land and King Charles's Land, &c. Petermann is of the opinion that, as far as the discoveries of land go, the results of Smith and Ulve are more important than those of any cruise between Greenland and Siberia for many years past, as they show that the north-east line of Spitzbergen extends across $10\frac{1}{2}$ degrees of longitude instead of the $7\frac{1}{2}$ previously assigned, this extension including the southern coast as well as the northern. The easternmost point reached by this expedition was a little beyond the 28th degree of east longitude.

AT no previous period (says *Harper's Weekly*) has there been so much activity displayed on the part of the United States Government in the way of thorough explorations of its territories, the liberality of Congress at the last session in authorising such having been very great. The operations of the Coast Survey have been largely extended, including the commencement of a triangulation between the coasts of the Atlantic and Pacific. Arrangements have been made for extended surveys by the Navy Department of the North Pacific, and an appropriation also made for the expense of making the observation of the coming transit of Venus. Under the War Department are progressing the new survey of the northern boundary of the United States, between the Rocky Mountains and the Lake of the Woods, the geological survey of Mr. Clarence King along the fortieth parallel, and the surveys in Utah and Nevada by Lieutenant George M. Wheeler; while Dr. Hayden's work in the Interior Department is advancing satisfactorily in its two main divisions, as also that of Major Powell along the Colorado.

THERE are at this time four chemical laboratories in Japan, where the science is taught, three of them being presided over by Germans and the fourth by an American. The chief one is at Osaka, where there are nearly 100 students. The rest are at Kaga, Shidzoka, and Fukuwi. A fifth will soon be opened at Jeddo. The students are said to be fairly intelligent, but their minds are at present encumbered with astrology and other kinds of spurious philosophy.

THE BRITISH ASSOCIATION

SECTION A—MATHEMATICAL AND PHYSICAL SCIENCE

On the Application of Photography to Copy Diffraction Gratings, by the Hon. J. W. Strutt.

GREAT interest has always attached itself to the beautiful phenomena discovered by Frauenhofer, which present themselves when a beam of light falls on a surface ruled with a great number of parallel and equidistant lines. Their unexpected character, the brilliant show of colour, and the ready explanation of the main point on the principles of the wave theory, recommend them to all; while the working physicist recognises in them the key to the exact measurement of wave-lengths, which has been so splendidly used by Angström and others.

The production, however, of gratings of sufficient fineness and regularity is a matter of no ordinary difficulty. Indeed, the exactness required and obtained is almost incredible. The wave-lengths of the soda lines differ by about the thousandth part. If in two gratings, or two parts of the same grating, the average interval between the divisions differed by this fraction, the less refrangible soda line of one would be superposed on the more refrangible corresponding to the other. In point of fact the gratings ruled by Nobert, to whom the scientific world has been greatly indebted, are capable of distinguishing a difference of wave-length probably of a tenth part of that above mentioned. But in order that the D lines may be resolved at all, there must be no average error (running over a large part of the grating) of $\frac{1}{1000}$ part of the interval between consecutive lines. When it is remembered what the interval is (from $\frac{1}{1000}$ to $\frac{1}{6000}$ of an inch, or even less), the degree of success which has been reached seems very remarkable.

A work requiring so much accuracy is necessarily costly—the reason, probably, why gratings fit to be used with the telescope for the purpose of showing the fixed lines are comparatively rare. The hope of being able to perfect a process for the reproduction of gratings at a comparatively cheap rate has induced me to return at the first opportunity to the experiments described in a preliminary note read before the Royal Society in June last. Although the subject is as yet by no means exhausted, I have thought it worth while to bring before the Section an account of the progress that has been made, with specimens of the results.

The method of procedure is very simple. A dry plate prepared by any photographic process on a *flat* surface of glass or other transparent material not affected by the fluid media employed, is brought into contact with the ruled surfaces of the grating in a printing frame, and exposed to light. In my first experiments I used exclusively as a source of light the image of the sun in a lens of short focus placed in the shutter of a darkened room; but so small a source is not necessary. The light from the clouds or sky, reflected by a mirror through a hole several inches in aperture, will be sufficiently concentrated if the frame be a few feet distant. I have not as yet specially investigated the point, but I believe that if the light were too much diffused the experiment would fail. Much would, no doubt, depend on the perfection of the contact—an element very likely to vary.

The variable intensity of diffused daylight, which it is almost impossible to estimate with precision, has induced me to use exclusively in my later experiments with ordinary photographic plates the light of a moderator lamp. This, with globe removed, is placed at a distance of one or two feet from the printing frame, the distance being carefully measured. Working in this way there is little difficulty in giving consecutive plates any relative exposures that may be required. A collateral advantage is the possibility of operating at any time of the day or night.

With regard to the preparation of the plates, I have latterly been using the tannin process introduced by Major Russell. A preliminary coating with dilute albumen is generally advisable, as any loosening of the film from the glass must be avoided, on account of the distortion that it might introduce. In some states of the collodion, an edging of black varnish put on after the exposure is sufficient to hold the film down. The glasses, after being coated with collodion (I have used Mawson's), are immersed as usual in the silver bath, and then allowed to soak in distilled water, best contained in a dipping-bath. They are then washed under a tap for about half a minute, and put into the tannin solution (about 15 grains to the ounce) held, in my practice, in a small dish. I usually prepare my plates in the evening, standing them up to dry on blotting-paper. In the morning they are in a fit state for use. Artificial heat might no doubt be used if a more rapid drying were desired.

At a distance of one foot from the lamp the exposure required is four or five minutes. The development is the most critical part of the process. The pyrogallic solution should contain plenty of acid (acetic or citric), and its action must not be pushed too far, the mistake which a photographer accustomed to negative work is most likely to make. At this stage the spectra given by a candle flame are not very brilliant, on account of the iodide of silver still covering the parts which are to be transparent. Any trace of fog is especially to be avoided. I have experienced advantages in many cases from a solution of iodine in iodide of potassium applied to the film previously to fixing; but its action must be carefully watched, or too much silver will be converted. The iodide of silver is then cleared away with hyposulphite of soda or cyanide, followed by a careful washing under the tap.

With regard to the gelatine copies, I have not much to add to the account read before the Royal Society. The process is very simple, and some of the results very perfect; but I have not hitherto succeeded in sufficiently mastering the details. Plates apparently treated in precisely the same manner turned out very differently. That difficulties should arise is not very extraordinary, considering the novelty of the method; but it is curious that some of the very first batch prepared are among the best yet produced. The value of the results is so great that I have no intention of abandoning my attempts, and perseverance must at last secure success.

I will now say a few words about the performance and prospects of the new copies. Their defining power on the fixed lines in the solar spectrum is all that could be desired, being, so far as I can see, in no way inferior to the originals. In the third spectrum the 3,000 to the inch gratings show the line between the D's, if the other optical arrangements are suitable. The fourth line of the group, *b*, is distinguished with the utmost ease. I am not sufficiently familiar with spectroscopic work to make an exact comparison, but I presume that two prisms of 60° at least would be required to effect as much. I am here speaking of photographs on worked glass. With ordinary patent plate, although very good results may be obtained, if tested by the naked eye only, it is a great chance whether the magnifying power of a telescope will not reveal the imperfect character of the surface.

With direct sunlight the light is abundantly sufficient, but it is here in all probability that the weak point of gratings lies. It should be distinctly understood that where light is deficient gratings will not compete with prisms. There are cases, however, where the scale might be turned by the opacity of all highly dispersive substances to the rays under examination. Even if glass be retained as the substratum, it may be used in a very thin layer, while prisms are essentially thick. The immense advantage of a diffraction spectrum for the investigation of dark heat need not here be insisted on. Taking all things into consideration, it is probable, I think, that photographed gratings will supersede prisms for some purposes, though certainly not for all.

The specimens in the hands of Mr. Ladd are copies of two gratings by Nobert, each of a square inch in surface, the one containing 3,000 and the other 6,000 lines. The latter cost about twenty pounds.

SECTION C.—GEOLOGY

Monday, Aug. 19.—On the Occurrence of Erect Bases or Trunks of Psaronius in the Devonian Rocks of New York, U.S.A., by Prof. James Hall.

During the year 1870 some excavations were made in beds of fine sandstone, referred at that time to the upper part of Hamilton's group, but which probably belong to beds higher in the series. In these beds several thousand trunks of tree-ferns were found in an upright position, with their bases resting in and upon a bed of clay, in which they appear to have originally grown. In the clay, and in the sandstone above, to the height of two or three feet, great quantities of vegetable substance occurred. Principal Dawson refers these trunks to the genus *Psaronius*, and he has determined two or more species from the locality.

These facts were held to indicate a point of comparatively dry land upon the eastern margin of the Devonian Sea. Receding from this ancient shore we find the sands and slates to become finer, and the latter to change into calcareous muds. For some distance the shells occurring in these beds are all Lamellibranchs, and it is only when we have travelled a considerable distance to the westward that Brachiopods appear. The author then entered into some detail as to the mode of accumulation of these beds, which are admirably exposed along a line of outcrop 300 miles in length.

Sur les Animaux Fossiles du Mont Leberon, Vaucluse, by Prof. A. Gaudry.

The author remarked that the fossils found by him and others in this place bore a striking similarity to those he had before collected in Attica. In comparing the 4,940 bones from the latter place with the 1,200 from the former, he had been much struck with the great variations exhibited by animals that seem to descend from the same parent. The presence of numerous and large herbivores proves the existence of a considerable extent of meadow-land during the Miocene period.

Brief Notice of the Present State of our Knowledge in connection with the Brachiopoda, by Thomas Davidson, F.R.S.

The object of this paper was "not to trouble you with details, but to mention, in general terms, what has been the advance effected in this portion of palæontology since 1853, the period at which I first published my general introduction." Mr. Davidson first alluded to the general question of classification, dissenting from the views of Prof. Morse, who wished to remove the Brachiopoda from the Mollusca, and to place them with the Annelides. The great importance of the Brachiopoda to the palæontologist was then dwelt upon, and the author remarked that "many instances are on record where the sight of a few specimens of Brachiopoda have enabled a palæontologist to determine accurately the age of a rock in some distant land to which he had no access." Mr. Davidson stated that the number of so-called species of recent forms amounted to about 100, but that probably the number would have to be reduced to about 60. "The number of so-termed species of *Lingula* had been greatly exaggerated, and a certain number of the others are known only by a single specimen."

Tuesday, Aug. 20.—Mr. H. Woodward read his *Sixth Report on Fossil Crustacea*. The report was illustrated by a large number of diagrams, and announced the discovery of new crustacean forms in Silurian, Coal Measure, and Permian rocks.

Remarks on the Genera Trimerella, Dinobolus, and Monomerella, by Thos. Davidson and Prof. W. King. The authors proposed to group these three genera into a new family to be called Trimerellidæ. It was shown to be structurally allied to the Lingulidæ, and it was inferred that the two families were genetically related. This is a point of great interest, inasmuch as the Lingulidæ are the earlier forms, occurring in Cambrian rocks, whilst the Trimerellidæ first appear in the Silurian strata. The Cambrian Lingulas have a horny shell, and so too have generally the animals associated them. In later formations the Brachiopods and other animals have much more calcareous shells; and from these facts it was inferred that lime was less abundant in the Cambrian sea than during later periods. As the result of long labour in this field of research, the authors were led to adopt the doctrine of evolution of species "effected mainly through the operation of Divine laws, and not by purposeless or accidental modifications." The paper concluded with detailed descriptions of the structure of the Trimerellids.

The Rev. John Gunn's paper was then read *On the Prospect of Finding Productive Coal Measures in Norfolk and Suffolk, with Suggestions as to the Places best adapted for an Experimental Boring*. The author controverted the views expressed by Sir R. Murchison as to there being no coal beneath these counties, and on the following grounds:—The "Anglo-Belgian Basin," in which the forest bed was deposited, is bounded by the chalk on the west and south, and by older rocks on the east. It was contended that this area has been characterised by vegetable growths at several successive periods; and that as regards the coal-growths, these were accumulated in a basin bounded by the carboniferous limestone, just as the forest-bed was accumulated in a basin bounded by the chalk. Hunstanton was suggested as the best place to bore; because there the cretaceous rocks have been denuded, and there too some of the oolites are absent. Probably the bore would not exceed 1,000 feet in depth.

An interesting paper was then read by the Secretary, forwarded from Bonn by G. vom Rath, *On a remarkable Block of Lava ejected by Vesuvius during the great Eruption of April* 1872, *proving the Formation of Silicates by Sublimation.* This was a block of old lava which it is assumed had been floating in the melted lava of the late eruption, and was subsequently ejected by the volcano. It shows that in its interior there were formed crystals of pyroxene, mica, sodalite, specular iron, and magnetite;

whilst at the exterior the pyroxene was melted and the leucite destroyed.

The author particularly pointed out that sodalite, which was found sublimed in the interior of the block, is the silicate most rich in sodium. This he contended was not an accidental circumstance, but resulted from the percolation of sea-water charged with chloride of sodium. The author remarked that the study of such matters is conducting us to the conclusion that the quantities of water, hydrochloric, and sulphuric acid, &c., exhaled by craters and streams of lava, are not only an accompanying phenomenon in the production of volcanic rocks and mineral aggregates, but that they are essentially co-operating at their origin. If once we succeed in proving and explaining the origin of minerals through vapours, or under the co-operation of vapours, then the key to many problems relating to the plutonic rocks and their minerals will be found.

A few Remarks on Submarine Explorations, with Reference to M. Delesse's work entitled "Lithologie du fond des mers," by J. Gwyn Jeffreys, F.R.S.

The lithology of the sea-bottom is not only a vast subject in its various relations to natural history and physical science, but is especially interesting in a geological point of view, because every part of our globe has been at one period or another covered by the sea. Mr. Jeffreys contended that it is almost impossible to ascertain with any degree of certainty what stratified formations are marine, unless we find in them such remains of marine animals as were capable of being preserved. Exceptions doubtless occur, *e.g.* where the stratum had been subject to the action of carbonic acid, produced by the subsequent passage of rain or fresh water; in which case all cretaceous organisms might have been dissolved before they became silicified or petrified. He then gave a short account of submarine explorations, from the time when O. F. Muller first used a dredge for scientific purposes (about 1772), to the present day; and he summarised the results of the expeditions conducted by his colleagues and himself on board H.M.S. *Porcupine*, under the auspices of the Royal Society in 1869 and 1870. But next to nothing is known of the enormous tracts of sea-bed which underlie the depths of the ocean in both hemispheres. He attributed the diffusion and geographical distribution of the marine invertebrate fauna to the action of currents, and not to voluntary migration.

M. Delesse's work was recently published at Paris, and consists of two octavo volumes, besides an atlas of charts and maps. The precise date of publication does not appear; the dedication is dated December 1, 1871. It forms part of a series called "Publications scientifiques industrielles," and purports to have been published with the sanction of the Ministers of Marine and Minister of Public Works.

While giving M. Delesse full credit for the laborious and conscientious manner in which he has evidently performed his great task, Mr. Jeffreys regretted that he had omitted to notice the reports on deep-sea explorations published by the Royal Society in 1869 and 1870, or the Address of Mr. Prestwich (the late President of the Geological Society), which was published in May 1871, and particularly treated of those reports. M. Delesse is a foreign member of the Geological Society. By consulting what had been published on the subject, M. Delesse would have been able not only to give fuller information, but to correct errors which unavoidably occur in an extensive compilation. For instance, his map of France during the tertiary epoch does not show the communication which has been proved by naturalists and geologists to have then existed between the Bay of Biscay and the Gulf of Lyons. According to M. Delesse, there has been no communication since the Liassic period between the Atlantic and the Mediterranean north of the Pyrenees. His division of the French marine fauna into three provinces (Celtic, Lusitanian, and Mediterranean) does not agree with modern observations. Zoophagous mollusca do not, as stated by him, live on those which are phytophagous; pebbles ("*galets*") are not everywhere unfavourable to mollusca, even on coasts exposed to a stormy sea; and foraminifera never crawl at the bottom of the sea. But it is to be hoped that these omissions and errors will be rectified in another edition of a work so desirable and important to scientific inquirers.

Mr. W. Boyd Dawkins, F.R.S., then read his paper *On the Physical Geography of the Mediterranean during the Pleistocene Age.* The author showed from the researches of M. Gaudry that during the late Miocene period it is probable that there was some communication between Attica and Africa. During the Pliocene period a similar communication must have existed at some part or parts of the Mediterranean area. The object of this paper was to show that a like union existed during the Pleistocene age. The palæontological evidence was first gone over. It was shown that African mammalia are found at Gibraltar, in river gravels near Madrid, in Sicily, Malta, the Morea, and in Candia; particular reference was made to the occurrence of a small species of Hippopotamus (*H. Pentlandi*) in these localities, and it was contended that there must have been communication between them and with Africa.

An examination of the soundings makes this probable. It is found that the Mediterranean consists of two deep basins, separated from each other by comparatively shallow water, one barrier extending from Africa, past the Straits of Gibraltar to Cadiz, and the other reaching from Tunis, past Sicily and Malta, to join Italy. An elevation of 2,000 feet would effect this. It was pointed out that the existence of such a mass of high land in the south of Europe must have had an important effect upon the climate of the period.

Mr. Charles Moore's paper *On the Presence of Naked Echinodermata (Holothuria) in Oolitic and Liassic Beds*, was then read. Soft-bodied animals, such as these, are rarely found in a fossil state; but the author had fortunately discovered some minute wheel-like plates, somewhat resembling those of a recent Greenland species, and which he referred to at least four different species of Holothuria. Some of these plates indicate structures not hitherto seen in recent species.

Mr. J. E. Lee read a *Notice of Veins or Fissures in the Keuper filled with Rhætic Bone-bed, at Goldcliff in Monmouthshire.* There are exposed on a scarf of Keuper marl, bare at low water, a number of rounded masses of irregular form, but of great length, consisting wholly of bone-bed. The author presumed that these projections are the casts of fissures in the marl which were afterwards filled up with bone-bed. Mr. C. Moore afterwards made some remarks on the extraordinary richness of the bone-bed.

Wednesday, August 21.—Mr. J. H. Judd communicated through Mr. Hughes, a note *On the Discovery of Cretaceous Rocks in the Islands of Mull and Inch Kenneth.* In the former they are seen a several places, and the author supposed that they would be found underlying a great part of the volcanic area of this district. The rocks are all of upper cretaceous age and lie unconformably upon the Jurrassic series and older rocks. Like all other rocks of these islands the cretaceous beds are penetrated by intrusive dykes and sheets of trap. Mr. Judd observed, that this discovery gave great confirmation to Prof. Geikie's views as to the Tertiary age of the volcanic rocks of the Hebrides.

Mr. T. A. Readwin's paper, *On the Coal and Iron Mines of the Arigna District of the Connaught Coal Measures, Ireland*, was then read in abstract.

The shales overlying the Upper Limestones of district were surmised by the author to belong to the Yoredale Series. Over these there are grits and shales with three seams of coal which the author referred to the Gannister Series, remarking that a bed of true "gannister" occurred there.

The coal field was divided into three districts, each of which was described by the author. He noticed at some length the clay-ironstone bands and nodules which occur over a much larger area than do the coals. The ironstone is richer and purer than most of our English clay ironstone. The author believed that the time had come for a vigorous and scientific exploration of the district, which he felt convinced would soon become, as Sir Robert Kane had long ago predicted, "an important centre of industry for the interior of the country."

SECTION D.—Biology

On Deep Sea Dredging round the Island of Anticosti in the Gulf of St. Lawrence, by T. F. Whiteaves, F.G.S.

Depths of from 100 to 250 fathoms were successfully explored during July and August 1871. The temperature of the deep sea mud was found by using a common thermometer to be almost invariably 37° or 38° F. About 100 species of Invertebrata new to the Gulf of St. Lawrence were collected. These included a remarkable foraminifer, *Marginulina*, with spinous processes from the first chamber, *Grantia ciliata*, a new *Pennatula*, &c. Two rare Echinoderms were collected—the well-known *Schizaster fragilis*, and the curious *Calveria hystrix* of Wyville Thomson. Nearly all the marine invertebrates of the northern part of the Gulf of St. Lawrence are purely Arctic species. Three-fourths

of the mollusca of Greenland range as far south as Gasté Bay. The species which belong exclusively to the deep sea in Canada have a decidedly Scandinavian aspect.

Preliminary Notice of Dredgings in Lake Ontario, by H. Alleyne Nicholson, M.D., D.Sc.

In this communication the author gave a short preliminary account of a series of dredgings carried out in June and July in Lake Ontario. With a praiseworthy appreciation of the value of such researches, the Provincial Government of Ontario had placed at the author's disposal a sum of money to be expended in this investigation, and the results had been very satisfactory. The dredgings were carried on partly in a yacht and partly in a small paddle-wheel steamer, and were prosecuted wholly by hand, the apparatus employed being similar to that used in marine dredging, except that a bag of embroidery canvas was attached outside the ordinary net, an addition rendered necessary by the exceedingly fine nature of the mud at great depths.

Upon the whole, the results obtained in Lake Ontario agreed very fairly with those obtained in Lake Superior in 1871, there being a general conformity in the phenomena observed in both areas. The fauna of Lake Superior, however, so far as deep water is concerned, is decidedly richer than that of Lake Ontario, whilst some of the more remarkable species discovered in the former appear to be altogether absent from the latter. As might have been anticipated, the fauna of Lake Ontario is not extensive, though some forms occur in great profusion. The shallow-water fauna is very rich in individuals, and the number of species is quite considerable for fresh water. Beyond eight or ten fathoms, the fauna becomes very scanty; and when depths of from twenty to fifty fathoms are reached, the list becomes reduced to some Annelides and Amphipod Crustacea. The nature of the bottom, also, at great depths is very unfavourable to life, consisting almost everywhere of a fine impalpable mud or clay, the temperature of which is very low.

Out of thirty-one forms in all discovered by the author in Lake Ontario, the most interesting were the Annelides and Crustaceans. The Annelides were very abundant, and consist of species of *Nephelis*, *Clepsine*, *Saenuris*, and *Chirodrillus*, some of the Leeches presenting phenomena of special interest. Of the *Crustacea*, the most important is a little Amphipod, which occurred plentifully in from thirty to forty-five fathoms, and which the author identified with the *Pontoporeia affinis* of the Swedish lakes. This species, and the Stomapod, *Mysis relicta* of Löven, are found in Lakes Wetter and Wener in Sweden, and it is well known that they have been supposed upon good grounds to support the view that these lakes had been at one time connected with the sea. It is, therefore, a very interesting fact that these crustaceans should both have been found in Lakes Michigan and Superior. The *Pontoporeia* the author had now detected in Lake Ontario; but it was a curious fact that the *Mysis*, which is of common occurrence in Lake Superior, should not have been found to occur at all in the dredgings carried on in Lake Ontario.

On the Flora of Moab, by A. W. Hayne, M.A.

The 250 plants found in Moab from the beginning of February to the middle of March, belong to 58 natural orders, of which by far the best represented are Leguminosæ with 35 species, Compositæ and Cruciferæ each with 26, and Graminaceæ 23. The remainder belonged to Liliaceæ, Scrophulariaceæ, Labiatæ, Boraginaceæ, Umbelliferæ, etc. From the greater abundance of springs the Eastern shore of the Dead Sea is comparatively fertile. The most conspicuous difference which results is the abundance of the date palm, of which on the West only a single clump survives near Jericho.

On the Structure and Development of Mitraria, by Prof. Allman, F.R.S.

Several specimens of the remarkable larval form, to which John Muller gave the name of *Mitraria*, were obtained by Prof. Allman in the Gulf of Spezzia, and were made the subject of careful study of structure and development. Mecznikoff had recently examined another species of the same form, and the author was enabled to confirm the main result arrived at by him, that *Mitraria* was the larval form of an annelide. In some fundamental points, however, regarding the process of development, his observations did not agree with those of the Russian zoologist; while in structure there are some important features which have not been described by either Müller or Mecznikoff, differences which may, in some cases at least, depend on actual differences between the species examined.

The nervous system is well developed, and consists in the principal central portion of a large quadilateral ganglion, formed by the union of two lateral ones, and situated on the summit of the transparent dome-like body of which the larva mainly consists. From this two very distinct chords are sent downwards, so as to form a pair of commissures with two small ganglia, which are situated at the opposite side of the alimentary canal. Besides these, two other small ganglia exist in the walls of the dome, at the oral side of the great apical ganglion, and two similar ones at the ab-oral side. These send off numerous filaments, which dive at once into the walls of the dome, while each sends off a long filament to the region where the alimentary canal begins to bend downwards towards its ab-oral termination. The great apical ganglion supports two sessile ocelli, with pigment and lens, and two small spherical vesicles, each containing a clear spherical corpuscle. These last the author regards as auditory capsules.

A system of vessels was also described. This consists mainly of a sinus which surrounds the great apical ganglion, and sends off three branches, which run in a radial direction in the walls of the dome, two lateral and one ab-oral, and appear to open into a sinus which surrounds its base.

In the progress of development the ab-oral end of the alimentary canal becomes elongated in the direction of the axis of the dome, carrying with it the walls of the base of the dome, which are to form the proper body walls of the future worm, and in this way a long cylindrical appendage becomes developed, and hangs from the central point of the base. At first there is no trace of segmentation, and this is subsequently induced on the cylindrical body of the worm by the formation of consecutive annular constructions.

The process of development as observed by the author in the species of *Mitraria* examined by him thus differs in several points from that observed by Mecznikoff. Among these the most important is that the ventral side of the worm is formed simultaneously with the dorsal instead of subsequently to it and independently of it, as in the case described by Mecznikoff. The development of the worm was not traced to the ultimate disappearance of the dome-like body of the larva.

On the Whales of the Antwerp Crag, by Prof. Van Beneden.

A brief account was given of the great accumulation of bones of fossil cetacea, or rather of whales, which are found in the Antwerp Crag, and of which the greater part belong to species new to science. These primitive whales were all small in size, and in that respect have no existing representative except the Neobalæna of New Zealand. It is only in the Upper Crag that we find representatives of larger species which actually exist such as those of the genera of Balæna, Megaptera, and Balænoptera.

Prof. Flower said that the excavations at Antwerp had revealed a perfect cetacean burial ground. Under the superintendence of a *savant* who had a most intimate acquaintance with the osteology of recent whales, the skeletons of the extinct species had been almost reconstructed in the Brussels Museum. It was a remarkable thing that these ancient whales were all small. It was the reverse of what happened in most other cases where the ancient representatives of any type were generally far larger than those at present existing.

Mr. Sclater inquired what was the relation between the cetacea of the Antwerp and Suffolk Crag.

Prof. Van Beneden replied that they were identical. The English material was not in itself sufficient for independent determination; but with the knowledge he had acquired from the more perfect remains, he was able to identify those from the Suffolk Crag.

Prof. Allman said that there was a parallel to the case of the whales in the dwarf fossil elephant of Malta. This was of the more interest, as the affinities of the elephant and of the whale are by no means remote.

On some points in the Development of Vorticellidæ, by Prof. Allman.

The author described, in a beautiful branched and clustered vorticellidan, a process different from any which had been recorded by those observers who had described the so-called encysting process, and the behaviour of the "nucleus" in the Vorticellidæ.

In almost every cluster some of the zooids composing it had become greatly altered in form. They had increased in size, and instead of the bell-shaped form of the others had assumed a globular shape, and had lost both oral orifice and ciliary apparatus, while their supporting peduncle had ceased to be contractile.

In the younger ones the contractile space of the unchanged zooid was still very evident, but was fixed, showing no tendency to alteration of size, and the so-called nucleus was very distinct and larger than in the ordinary zooids. The whole was enveloped in a transparent gelatinous-looking investment.

In a slightly more advanced stage another envelope, in the form of a brown horny capsule, begins to be secreted between the proper wall of the zooid and the external gelatinous investment. It is at first thin and smooth, but it gradually acquires considerable thickness, and becomes raised on its outer surface into ridges enclosing hexagonal spaces.

In this stage the capsule has become too opaque to admit of a satisfactory view into its interior; but if the capsule be carefully opened its contents may be liberated so as to render apparent their real nature. It will be then seen that these consist of a minutely granular semi-fluid plasma surrounding the "nucleus," which has much increased in size and occupies a large portion of the cavity of the capsule. The condition of the contractile space could not be determined; it has probably altogether disappeared.

In a further stage the "nucleus" has undergone an important change; for, instead of the long cylindrical form it had hitherto presented, it has become irregularly branched, has acquired a softer consistence, and has moreover broken itself up into two or more pieces. This change in the "nucleus" is invariably accompanied by the appearance of nucleated cell-like bodies, which are scattered through the corpuscular plasma which had filled the rest of the capsule. They are of considerable size, of a spherical form, and with their nucleus occupying the greater part of their cavity, and having its nucleolus represented by a cluster of granules.

In other capsules, apparently the more advanced, no trace of the so-called nucleus of the vorticella body could be detected, and it seems to be entirely replaced by the spherical nucleated cells, which had now still further increased in number. It is impossible not to regard these cells as the result of the disintegration of the nucleus, and the conclusion is a legitimate one that they are finally liberated by the natural dehiscence of the capsule, and become developed into new vorticellidans.

On the Structure of Noctiluca, by Prof. Allman.

The author gave an account of some researches he had made on *Noctiluca miliaris*. They were mostly confirmatory of the results arrived at by other observers, more especially by Krohn, Quatrefages, Busch, Huxley, and Webb, while they further served to supplement the observations of these zoologists.

At one end of the meridional depression is the vibratile flagellum with the mouth at its base, and here the depression becomes quite superficial, while the opposite end is much deeper and is here abruptly closed. Just outside of this deep end of the depression there commences, by a funnel-shaped enlargement, a very slightly elevated ridge of a firmer consistence than the rest of the body; it terminates abruptly after running down, in a meridional direction, over about one-third of the circumference of the body. The author had reason to believe that this ridge is traversed in its length by a canal which opens close to the ab-oral extremity of the meridional depression by a funnel-shaped orifice, thus giving support to the opinion of Huxley, who believes that *Noctiluca* is provided with an anal orifice. The mouth leads into a short cylindrical gullet, and the author confirmed the existence of the vibratile cilium contained within the gullet, as originally described by Krohn; and of the ridge, with its projecting tooth, described by Huxley as existing in the gullet walls. The floor of the gullet is formed by the central mass of protoplasm, here naked and in direct contact with the surrounding medium. The vibratile cilium springs from this floor, and near the root of the cilium is a depression in the floor which can be followed for a little distance into the protoplasm.

Besides the well-known branching processes which radiate from the central mass of protoplasm to the walls of the body, there is also sent off from the central mass a broad, irregularly quadrangular, plate-like process, which extends to the outer walls, where it becomes attached along the line of the superficial meridional ridge. The lower free edge of this broad process is thickened in the manner of a hem.

In contact with the central protoplasm is the nucleus, a clear spherical body about $\frac{3}{2000}$ of an inch in diameter.

The body walls are composed of two layers—an external thin, transparent, and structureless membrane, and an internal thin granular layer of protoplasm, which lines the structureless membrane throughout its whole extent, and which receives the extremities of the radiating processes from the central mass. Under the action of iodine solution and other reagents, the protoplasmic layer may be seen to detach itself from the outer structureless membrane, and, along with the radiating bands, contract towards the centre. It admits of an obvious comparison with the primordial utricle of the vegetable cell.

The flagellum, which is given off close to the margin of the mouth, is a flattened band-like organ, gradually narrowing towards its free extremity, and with its axis transversely striated like a voluntary muscular fibre throughout its whole length. It seems to have the power of elevating its edges, so as to render one of its surfaces concave, and thus becomes converted into a semi-tube, which may assist in the conveyance of nutriment towards the mouth.

The nucleus is a spherical vesicle, with clear colourless contents, among which minute transparent oval corpuscles may usually be detected. When acted on by acetic acid, the difference between the contents of the vesicle and its wall becomes very apparent, and the contents may now be seen accumulated towards the centre as a minutely granular mass, with some of the oval corpuscles entangled in it.

The radiating offsets, which extend from the central protoplasm to the peripheral layer, contain well-defined clear corpuscles which slowly change their relative places, as if under the influence of very feeble currents. These offsets, indeed, closely resemble the radiating protoplasm filaments which extend from the protoplasm, surrounding the nucleus, to the walls of the primordial utricle in the vegetable cell. The peripheral layer contains scattered through it numerous minute cell-like bodies. These are spherical and of various sizes; in the larger ones a distinct central nucleus may be detected.

It is scarcely correct to regard the central mass of protoplasm as a true stomach. The author had failed to find any evidence of a permanent gastric or somatic cavity, and he regarded the protoplasm mass to which the gullet leads as representing the "parenchyma" of the Infusoria, and, like this, allowing of the solid food being forced down into it from the gullet and there encysted in extemporaneously formed vacuolæ. The food also frequently forces its way from the central mass into the radiating processes, and diatoms and other microscopic organisms may be seen in these processes enclosed in cyst-like dilatations of them, extemporaneously formed for their reception at various distances from the central protoplasm.

It was considered probable that the canal which seems to exist in the superficial ridge affords exit for certain effete matters, which may be conveyed to it through the process, by which it is kept in connection with the central protoplasm.

Our knowledge of the phenomena of reproduction and development in *Noctiluca* is still very imperfect, and the author saw little which seemed capable of throwing additional light on this subject. He agreed, however, with Huxley in regarding it as probable that the nucleated cell-like bodies which are present in the peripheral layer of protoplasm have a reproductive function, and are destined after liberation to become developed into new individuals.

From the account now given it will be apparent that *Noctiluca* consists essentially of an enormously vacuolated protoplasm, involving a nucleus and enclosed in a structureless sac, the vacuolation taking place to such an extent as to separate the contents into a peripheral layer of protoplasm which remains adherent to the outer sac, and into a central mass which is kept in communication with the peripheral layer by processes of protoplasm which pass from one to the other. The author believed that the nucleus of *Noctiluca* had a significance different from that of the so-called nucleus of the ordinary Infusoria, and that it admitted of a closer comparison with the true cell-nucleus. He was of opinion that the nearest ally of *Noctiluca* would be found in the somewhat anomalous infusorial genus *Peridinia*.

In conclusion the author detailed some observations he had made on the luminosity of *Noctiluca*; and he gave reasons for maintaining that the seat of the phosphorescence is entirely confined to the peripheral layer of protoplasm which lines the external structureless membrane.

On the Structure of Edwardsia, by Prof. Allman.

The structure of this beautiful little actinozoon differs in many important points from that of both the zoantharian and alcyonarian polypes. It was shown that just within the mouth the walls of the stomach sac project into the cavity of the sac in such a way as to form eight complicated frill-like lobes; that the eight vertical, radiating lamellæ which project into the body cavity

from the outer walls, and are composed of parallel longitudinal fibres enclosed between two membranous layers, do not reach the stomach sac in any part of their course, and that eight strong muscular bundles pass symmetrically through the whole length of the body cavity, being attached at one end to the disc which carries the tentacles, and at the other to the floor of the body cavity, while they are free in their intervening course.

Attached along the length of about the posterior half of each muscular bundle is the long sinuous generative band, with its chord-like craspedum loaded with thread cells. Just before terminating at the lower opening of the stomach sac each of the eight generative bands enters a most remarkable pectinated organ, which appears to be quite unrepresented in any other group of the Cœlenterata. It was difficult to suggest the true significance of these organs; their relation to the generative bands might lead to the belief that they are testes, or they may be analogous to the so-called cement glands which exist near the outlet of the oviducts in some of the lower animals. In this case they might supply some additional investment to the ova at the time of extrusion.

The author regarded *Edwardsia* as presenting a very distinct type of actinozoan structure, which occupies an intermediate position between that of the zoantharian and that of the alcyonarian polypes. He also compared it with the extinct rugose corals of the palæozoic rocks to which it corresponds in the numerical law of its body segments, and of which it might in some respects be regarded as a living non-coraligenous representation.

On the Structure of Cyphonautes, by Prof. Allman.

This remarkable little organism, whose structure and ultimate destination have been variously described by different observers, was obtained by the author in considerable abundance in Moray Firth. The animal is enveloped in a mantle, and the whole enclosed in a delicate, transparent, structureless test formed by two valve-like triangular plates which are in contact along two edges, and separated from one another by a narrow interval along the third. Its form is thus that of a very much compressed cone or pyramid. The author distinguishes by the term base the broader edge where the two plates of the test are separated from one another; while the other two edges are distinguished as the anal and ab-anal edges. The apex is the angle opposite to the base, and here a narrow passage exists through which the fleshy walls of the mantle are brought into immediate contact with the surrounding water.

In the base are two large oval openings, one, the larger, situated towards the anal edge, and the other towards the ab-anal. The former leads directly into the cavity of the mantle. Its edges are prolonged by a membranous lobe ciliated on its margin, and uninterruptedly continued round the anal side of the opening, but deficient on the opposite side. The interior of the lobe is occupied by a cavity.

A large part of the mantle cavity is occupied by the pharynx, a spacious thin-walled sac which opens into the mantle cavity by a long curved somewhat S-shaped slit with thickened and ciliated margins, which, at one side, are continued beyond the large opening situated near the anal side of the base in the form of two short ciliated tentacles. Towards the apex the pharynx becomes suddenly narrow, and is here lined by vibratile cilia, and marked by circular striæ which possibly indicate the presence of sphincter fibres. It now turns towards the anal side, and then bends downwards towards the base, and enters a thick-walled sub-cylindrical stomach. This runs towards the base parallel to and a little within the anal edge of the test, and is ultimately continued into a short straight intestine, which terminates by an anal orifice in the mantle cavity near the outer opening of the latter. From the upper part of the walls of the pharynx a narrow bundle of fibres passes to the apex of the mantle cavity.

Upon each side of the pharynx and lying against the stomach and intestine is a large oval mass. Its situation would suggest the probability of its being a hepatic organ, but it is altogether so enigmatical that it would be rash with our present knowledge of it to insist on assigning to it any special significance.

In contact with each of these enigmatical organs is a small tubercle, from which a bundle of short fibres pass off in a radiating direction. The resemblance of these bodies to a pair of nervous ganglia is obvious, but the author was more inclined to regard them with Schneider as indicating points of attachment of the contained animal to the two valves of the test.

The smaller of the two openings in the base, that, namely, which is situated near the ab-anal edge of the animal is, like the other, surrounded by a hollow membranous lobe with ciliated margin. This is uninterruptedly continued round the ab-anal side of the opening, but is deficient on the opposite side. The opening leads into a special chamber entirely shut off from the cavity of the mantle and from the pharynx. The walls of the chamber are lined with cilia, and it has within it, or in immediate connection with its walls, two peculiar structures. One of these is a somewhat pyriform organ which, with one end close to the orifice of the chamber, extends from this point into its cavity; it is composed of a mass of spherical bodies. The other extends over the roof of the chamber in form of a cap; it consists of two portions, one of which lies directly on the walls of the roof, and has a transversely laminated structure, which, however, disappears towards the ab-anal side of the chamber; the other is an oval mass of globular cell-like bodies and lies on the free convex surface of the laminated portion.

Here again this part of the *Cyphonautes* is in the highest degree enigmatical, and yet it is difficult not to believe that in the structures just described we have an ovary and testis with associated accessory structures.

The author observed no further fact which might tend to throw light on the ultimate destination of *Cyphonautes*, and more especially nothing which might tend to confirm the remarkable views lately published by Schneider, who believes that he has traced its devolopment into the polyzoal *Membranipora pilosa.* The structure is considerably more complicated than Schneider seems to be aware of, while the opinion of this observer that the whole of the proper *Cyphonautes* structure becomes absolutely obliterated and the body of the animal converted into an amorphous mass of cells from which the *Membranipora* becomes evolved not by a process of budding but by a differentiation of structure is so startling that notwithstanding the partial assent lately given to it by Nitsche we are compelled to wish for further confirmation of the evidently careful observations of the German zoologist.

If the ab-anal chamber described above with its associated structures really belongs to the generative system—and it is hard to say what else it can be—the view that *Cyphonautes* is a polyzoal larva is scarcely tenable.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, Aug. 19.—M. Faye in the chair. MM. Jamin and Richard read the second part of their paper on the laws of cooling, and the cooling power of gases. The authors have determined the amount of heat abstracted by a gas from a warm solid placed in its midst.—A. and P. Thenard presented a memoir on the action of ozone on indigotic sulphate and on arsenius acid. The authors find that ozone decolourises three times as much indigo as the law of equivalents would lead one to suppose, and that this reaction takes place in two well-marked periods. Two-thirds of the indigo are decolourised, in the first of these periods, almost instantaneously, and one-third in the second period after the lapse of several hours. The authors ascribe this second action to hydric peroxide (*eau oxygenée*) formed by the ozone. The authors are led to doubt whether ozone is really a triple atom molecule, or whether it is simply oxygen in which is condensed a powerful selective force. They intend to thoroughly investigate this question.—M. Daubrée reported his examination of the meteorites which fell at Lancé and at Authon (Loir-et-Cher) on the 23rd July, 1872. The Lancé stone weighed 47 kilogrammes; the one which fell at Authon, 12 kilometres from Lancé, was much smaller. Their structure was granular, and some of the grains acted strongly on polarised light; they were evidently portions of the same mass. Specific gravity, 3·8. Elements found: iron, cobalt, nickel, copper, sodium, sulphur, chlorine, silicon, and oxygen.—Max Marie followed on the determination of the perimeter of the region of convergence of the series of Taylor, &c.—M. Mallard read a paper on the action of silicic anhydride and analogous oxides on sodic carbonate at a high temperature.—On the combined use of morphia and chloroform during surgical operations, and on a new mode of administering the latter. M. Demarquay, the author, convinced of the great danger incurred by the combined use of these agents, has abandoned it and devoted himself to the improvement of the apparatus employed for the administration of chloroform. The apparatus in question consists of a flannel mask stretched on a wire frame; the chloro-

form is poured drop by drop on its surface.—Observations on a note by Prof. Respighi on the solar protuberances, by S. Tacchini. The author asserts that no dependence can be placed on the details of any drawings of the prominences except when made with a telescope of large aperture.—M. Trève, in a paper on the magnet, mentions some experiments from which he deduces that the "transformation" of a bar of soft iron into a magnet requires a mechanical work and a molecular action of a kind as yet unknown.—"On the compressibility of Air and Hydrogen at high temperature" by M. Amgat. The author asserts that up to 320° these gases follow the law of Mariotte. M. Berthelot followed, on the distribution of a base between several acids in solutions. "On the aptitude of certain gases to acquire persistent active properties under the influence of electricity" by M. Chalrier. The author finds that hydrogen when acted on by electricity possesses the power of uniting directly with the nitrogen of the air and of reducing newly precipitated oxide of silver, even after it has travelled some distance from the point where the electricity was allowed to act on it. M. G. Lechartier, in a paper on the reproduction of pyroxene and peridot, stated that he had succeeded in preparing these minerals by heating mixtures of their constituents.—M. P. Bert followed with "Experimental researches on the effects of changes of barometric pressure on the phenomena of life." In a very interesting paper of great practical importance as regards miners and divers working under great pressure, the author cited the case of an English company who in a single year lost ten divers out of twenty-four three of these died suddenly on coming to the surface, *i.e.*, at the moment of sudden release from a high pressure and seven after several months of suffering from paralysis also died. The author concludes (from a series of experiments of cats and dogs) that up to five atmospheres two or three minutes should be allowed for the pressure to decrease, above that much more time must be allowed, and at nineteen atmospheres five minutes per atmosphere at least is required. If the pressure is allowed to decrease more rapidly than this death is certain.—"Comparative researches on the absorption of Gases by the blood: estimation of Hæmoglobin," by M. N. Gréhant. The author describes a method of estimating Hæmoglobin by observing the quantity of carbonic oxide the blood will absorb. Application of Meteoric Metamorphism to the study of the black crust of grey meteorites, by M. S. Meunier.—M. A. Cheux describes a white Aurora Borealis observed at La Baumette near Angers on August 8, 1872, and says that great disturbance was observed on the sun on the morning of the 9th; he gives a view of the sun showing twenty-four spots.—Extracts from two letters from Messrs. Guiscardi and H. de Saussure relative to the late eruption of Vesuvius.—Appearance of a meteor in the department of Vienne, July 23, 1872 (extract of a letter from M. Daubrée). This was the meteor of which portions fell in the Canton of St. Amand, Loir-et-Cher, Vienne is forty kilometres distant from the places where the two portions of the meteorite fell.—M. Tellier read a note on the supersaturation of water. Water may be cooled 3° or 4° below zero in a glass vessel and still remain liquid in which state it may be violently agitated but a very sudden blow often causes its solidification. M. J. Gerard exhibited photographs of the interior of an aquarium.

August 26.—M. Faye, president.—Determination of the mutual actions of Jupiter and Saturn to serve as a base for the respective theories of the two planets, by M. Le Verrier.—In a note on the action of carbon and iron on carbonic anhydride at a high temperature, by M. Dumas, the author refutes a statement lately made by M. Durunfaut that these bodies do no not react un'ess hydrogen is present.—Mr. C. Peters announced the discovery of two new planets, 122 and 123. The planets are of the 11·5 and 12th magnitudes respectively.—New researches on the propyl compounds, by MM. Is. Pierre and E. Puchot.—In new experiments on spontaneous generation, by M. Donné, the author supports the well-known views of M. Pasteur.—Elementary theory of simple integrals and of their periods, by M. Max Marie.—On the physical constitution of the sun, by M. E. Vicaire. The author returns to the old theory of a comparatively cold nucleus which he regards as most probably liquid. He considers that the tremendous explosions of which the sun is the seat could not occur from the midst of a mass of dissassociated gases.—Notes were received from M. Brachet relating to the improvement of microscopes; from M. Lanale, relating to aerial navigation; from M. Clarke, relating to cholera; from M. Roussett, relative to certain questions concerning medicine.—On the spherical representation of surfaces, by M. A. Bibancour.—Letter from M. Gasparis, on a new mechanical theorem.—On ozone and hydric peroxide (*eau oxygénée*). M. F. Le Blanc sent a note relating to the paper by the Messrs. Thenard in No. 8 *Comptes Rendus*, 1872. The author states that in 1854 he discovered that ozone acted on water with the production of hydric peroxide.—Industrial employment of ozone for the destruction of the empyreumatic taste of whisky, and in the manufacture of vinegar, by M. Widemann. The author established a factory at Boston, U.S., where whisky was thus treated at the rate of 12,000 gallons per week. He also converted maize whisky into vinegar by diluting it with seven volumes of water, and then treating it in the same way.—On the divisions of a base between several acids in solution, dibasic acids, by M. Berthelot.—Action of cupric sulphate on normal urine, by M. Ramon de Luna.—M. P. Bert communicated a seventh note on the influence of change of barometric pressure on the phenomena of life.—On noctilucine, by Mr. T. L. Phipson. Noctilucine is the substance which is secreted by the various animals which are phosphorescent in the dark. The author believes that the same substance is secreted by certain plants (*Agaricus*, *Euphorbia*, &c.) and that it is also produced by the fermentation and decomposition of various vegetable and animal matters. The spectrum of this substance lies entirely between the lines E and F of the solar spectrum.—On the iodide of nitrogen, by Husson, *fils*.—M. Le Verrier presented observations of the August meteorites, from Greenwich, Lisbon, and at Volpeglino.—M. Chapelas announced, respecting the meteorites of the 8th, 9th, 10th, and 11th of August, that the mean hourly number was 33·5, a decrease of 6·4 on last year. The number for 1872 was only about one third of that for 1848.—A new communication from M. Pigeon, on the typhus of horned beasts, was submitted to the examination of M. Bouley.

BALFOUR'S PALÆONTOLOGICAL BOTANY

Introduction to the Study of Palæontological Botany. By J. H. Balfour, A.M., &c., Professor of Botany, Edinburgh. (Edinburgh: Adam and Chas. Black, 1872.)

THE mastery of an alphabet by a child depends on his recognising and remembering the differences in form of the various arbitrary signs which we conventionally use to represent different sounds. Perhaps in the face of the alphabetic researches of Mr. John Evans we should withdraw the qualification—arbitrary. He may see a connection between the sign and the sound, and be able to give a reason for the various forms employed, and explain the influence of this horn or that loop superadded to the simple line in modifying the sound. We are, however, at a loss to discover what possible connection of affinity or even of analogy can exist between the signs O and Q and the sounds they represent. Whatever the recondite researches of the antiquarian may discover, the letters of the alphabet are practically recognised and universally received as arbitrary signs for particular sounds. The mastery of the alphabet is only the recognition and remembrance of the different signs and the sounds they represent.

This mnemonic education is not unfrequently the only education which some attain to, or perhaps are capable of. In science not a few are looked up to as masters whose extensive knowledge is nothing more than the faculty of discerning differences joined to a good memory. The rationale of the difference is another matter; perhaps they are mentally incapable of appreciating whether the distinguishing characteristics at once perceived by them are dependent on the absence of affinites or of analogies. The differences exist—that is their goal.

Many entomologists prosecute their labours on this low platform, and in botany the mere herbarium systematist occupies the same position. The one classes beetles, and the other plants as the lexicographer arranges words, by a method that exhibits their differences and permits easy reference.

But in no division of science is this class so common as in geology. The mere perception and memory of differences will give one a high class position as a palæontologist: and much useful work will such a one do—work necessary to the progress of science. True, it is not the highest class of work, and too frequently men who are experts at it aim at something higher. But deficient in the power of appreciating analogies, or recognising affinities in the points of resemblance, or their absence in the points of difference; deficient also in the exact knowledge of zoology or botany, such men have grandiloquently proclaimed and ignorantly and of course obstinately defended the most absurd opinions. Confined to the useful work of separating and recording different forms their services to science are most valuable, but the interpretation of obscure structures, and the higher problems of science, must be left to others able to deal with them.

No greater source of the evils we deprecate exists than the common but erroneous practice of separating palæontology as a science by itself. Palæontology has no grounds for recognition as an independent science. The organisms of an existing geographical province might be excluded from zoology and botany on the same grounds that are employed to exclude the plants and animals of a geological period. Zoologists are far ahead of botanists in getting rid of this error. Extinct forms have their place in every philosophic estimate of the animal kingdom. In botany, on the other hand, the study of fossil forms has been recently characterised as a non-scientific pursuit engaging the attention of the "geologist"; extinct plants are excluded from systematic works, and if dealt with at all in class books, all reference to them is eliminated from the general text, and they are confined to a page or two, or relegated to an obscure appendix.

Great praise is due to Prof. Balfour for introducing a different order of things. His manuals have always to a greater extent than any others published in the English language dealt with fossil plants; and he has now given us a special introduction to botanical palæontology. From the position obtained by the study of structural and systematic botany he deals with the problems presented by fossil plants

The earlier pages of the work are occupied with preliminary considerations as to the difficulties which present themselves in attempting to determine fossil plants, the different conditions of preservation in which their remains occur in the stratified rocks, the accepted classification of the sedimentary deposits, and the like.

The plan of the work itself is to treat of the plants as they are associated in the different recognised formations. Looking at palæontology as a separate section of the science of botany this is no doubt the obvious method of treatment, just as in geographical botany we deal with the different provinces of the surface of the earth and the floras which characterise them. If, however, the stratigraphical aspects had been subordinated to the systematic, a more valuable and instructive exhibition of the past vegetation of the globe would have been before us. For example, had the Coniferæ been traced from the first known occurrence of Abietineous wood in the Devonians, through the anomalous Araucarian wood and the Taxineous fruits of the Carboniferous rocks, the last types represented by the Walchias of the Permians and the Voltzias of the Trias, up to the appearance of the still existing groups in the Oolitic and Cretaceous rocks, an exhibition of extinct forms would have been given which would have conveyed to the botanist a clear and comprehensive view of the Order. In this way important light would be thrown on the present geographical distribution of orders and even genera. Look, for instance, at *Araucaria* and *Sequoia*,—two genera limited in numbers as well as in geographical distribution. We find the first represented by several species in our Secondary rocks, entirely absent from the Tertiaries, and at length banished to the southern hemisphere; while *Sequoia* appears in the Cretaceous strata, persists through the lower Tertiaries, and is now limited to a small geographical province in Western North America.

Nevertheless much may be said for the method adopted by Prof. Balfour. So long ago as the year 1828, Adolphe Brongniart detected a correspondence between the great divisions of the vegetable kingdom and the great epochs

of the earth's history. He correlated the predominance of Cryptogams with the Primary epoch, of Gymnosperms with the Secondary, and of Angiosperms with the Tertiary. The discoveries of the half century that have elapsed since Brongniart published his views have confirmed the broad truth of his generalisations. Recently they have been expounded and illustrated by one who worthily follows his illustrious countryman in this particular field of study,—by the Comte de Saporta in the preface to his Tertiary Flora of the South of France.

Accepting this classification, which is so far both systematic and stratigraphical, Prof. Balfour prepares the student for dealing with the more obscure fossil remains by introducing each epoch with a *résumé* of the leading characters of the great group of plants which are found in it, drawn from their living representatives. The fossils characteristic of the various formations then follow in detail. The most recent observations are given. Look, for example, at the illustrations and descriptions of the fructification of the Cryptogamic plants of the Coal measures—the ferns, club-mosses and mares-tails—brought together here for the first time.

The numerous woodcuts and the admirable plates greatly enhance the value of the volume.

WM. CARRUTHERS

THE BRITISH MUSEUM PHOTOGRAPHS

Photographs from the Collections of the British Museum. Taken by S. Thompson. 1st Series. (London: W. A. Mansell and Co.)

AMONG all the varied purposes to which the art of photography has been applied, there is perhaps none for which it has proved itself more valuable than for the reproduction of ancient works of art. It matters not whether it be the sublime conception of some ancient Greek sculptor, the thorny-looking inscription on a Babylonian brick, or the stone hatchet of some prehistoric troglodyte, in each case the reproduction by the camera, if executed by a competent operator, will give a more vivid and faithful idea of the original than any drawing by however skilful an artist.

In the case of inscriptions, of minute patterns, of delicacy of form, or of the distinctive character of an object, the merely mechanical process, though not entirely without its drawbacks, possesses a great advantage over the skilful artist, inasmuch as it is entirely free from prejudice. The artist, however conscientious, is always prone to draw incorrectly such details as he does not understand, and to attempt some improvement in force and effect in those which he fully appreciates. It is only in the case of coins and of other small objects which it is necessary to hold in more than one light in order fully to discern the details, that a good drawing is preferable to a photograph; and then the question arises, what is a good drawing?

For rendering available to students the contents of a museum, photography is invaluable. By it the objects which, in many instances, it is impossible to study at leisure in their repository, are, as it were, rendered portable, and made available for extended examination at home, and for reference at a moment's notice. It is with great satisfaction, therefore, that we see this series of nearly a thousand quarto photographs of objects in our national collections issued to the public by Messrs. Mansell and Co. It is divided into seven parts—ethnographical and pre-historic, Egyptian, Assyrian, Grecian, Etruscan and Roman, Mediaeval, and Seals, and one great advantage to the student is that he is by means of a comprehensive catalogue enabled to make his own selection of such photographs as come within his own particular province.

That the choice of the objects to be photographed has been judicious may be inferred from the fact that it has been made by the aid of Dr. Birch, Mr. Charles Newton, Mr. A. W. Franks, Mr. Murray, Mr. George Smith, and Mr. Walter de Gray Birch, all well known for their labours in the departments which they represent. Four of these gentlemen have also prepared the catalogue.

The photographs themselves are remarkably well and clearly executed, the figures in all cases being sufficiently large to make the details visible. We have but one fault to find, which it is to be hoped may be easily remedied—the absence of any scale on the photographs, and of any dimensions in the catalogue. In the case of some of the pre-historic and ethnographical objects it would also be an advantage if further particulars were given as to the localities from which they were obtained.

The catalogue is accompanied by an interesting introduction from the pen of Mr. Charles Harrison, giving a good general view of the progress of human civilisation, which the objects photographed illustrate, and also giving the rationale of the whole series. We cordially concur in his hope that each local museum will have its objects photographed, and that the plates like these may be made accessible to the public at a fixed moderate cost. In the meantime we commend these illustrations of our rich national collection to the readers of NATURE.

OUR BOOK SHELF

Autumns on the Spey. By A. E. Knox, M.A., F.L.S. Author of "Ornithological Rambles in Sussex, &c. (London: Van Voorst.)

WE have seldom come across a book in which the *dulce* and the *utile*, science and amusement, are so happily combined as in the modest little volume before us. Mr. Knox's main object, apparently, in spending his autumn on the Spey, was to fish for salmon in that trying river; and some of his wonderful achievements in this exciting occupation are narrated in an almost fascinating, and certainly unpretentious manner, in a few of the chapters of his booklet. But it would be a great mistake to consider this merely a book of sport, and Mr. Knox nothing more than a genial "piscator;" he has already proved what is confirmed by this his most recent work, that his knowledge of British zoology, and especially ornithology, is extensive and thorough. To any one who desires to see the report of a trained and patient observer on the zoology, and even geology, of the basin of the Spey and and of contiguous districts, we would with confidence recommend Mr. Knox's work. It contains much that is valuable and interesting on these subjects, and a good deal that is new to many. Quite charming and very curious is his account of the *modus operandi* of a family of crossbills (*Loxia curvirostris*) which he watched while standing under a tree, a few inches above his head, busily engaged at their marvellous employment of splitting the

fir cones and extracting the seeds. His observations on the habits of the water-ouzel, its procedure under water, and the food it seeks there, quite redeem that lively little bird from the imputation of being a destroyer of salmon-spawn, and prove him to be the salmon fisher's best friend. But, indeed, the charms of Mr. Knox's book are many, and will be deemed an acquisition by all who take an interest in British zoology; to those who are both fishers and naturalists it will afford a rich treat. The tail-piece to the book is a beautiful woodcut of a salmon, having underneath the punning legend, "*In spe vivo.*"

Physical Geography. By Sydney B. J. Skertchley, F.G.S., H.M. Geological Survey. (London: Thomas Murby.)

THIS is one of "Murby's Series of Science Manuals" intended for use in schools. It seems on the whole creditably done, the information conveyed is valuable, and in the main trustworthy, the author occasionally drawing on his own experience for illustration. Amid the many manuals on the same subject competing for favour this deserves to take a place, though the few illustrations introduced are wretched, and there is an occasional attempt at fine writing.

Révue Photographique des Hôpitaux de Paris. Publié par Bourneville et A. de Montméja. 4ème Année. Avril, 1872. (Paris: Delahaye)

THIS enterprising little publication deserves success. The number before us, which, however, is only interesting to our medical readers, contains three photographs (about 4 in. by 3 in.), one of a calcified enchondroma, and two of a remarkable case of encephalocele. One of these exhibits the whole infant, the other the upper part of the trunk. The details are very clearly visible, and there is an account of the case by P. Budin. The *Révue* contains also a good report of recent anatomical physiological and surgical work.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

The Potato Disease

I FEEL very much interested in the attempt you have made to connect the potato disease with cosmical phenomena, and I quite agree with you that although the *Peronospora* may be the proximate cause, yet for the ultimate cause we may have to look to a very different set of circumstances.

The researches of Baxendell, Meldrum, Smyth, and others, go to show that the convection currents of the earth are influenced by the state of the solar surface. Now surely anything that influences the motions of our atmosphere may readily be supposed to influence the distribution and activity of those disease germs that are now believed to be present in the atmosphere. Are not various kinds of blight associated with the prevalence of certain winds?

In referring to the five great visitations of the sweating sickness you say quite truly that we have no means of ascertaining the condition of the surface of the sun during those years. Nevertheless, *indirectly*, we may, I think, come to some sort of conclusion more or less probable regarding the sun's surface in those years.

This may, perhaps, be done by means of records of the Aurora Borealis. I have not access at present to the great catalogue of M. de Mairan, and I will, therefore, confine myself to the list of auroral appearances given by Mr. Jeremiah in your columns for November 17, 1870. Very great and extensive auroral outbursts are known to occur during years of maximum sun-spots, and auroræ are phenomena which appeal too much to the imagination to remain unnoticed in an unscientific age.

If, therefore, we can tell the years of very great auroral outbursts, we can at least approximate to those of maximum sun spots.

Now (quoting from NATURE) "in 1574 Camden and Stow inform us that an Aurora Borealis was seen for *two* successive nights, viz., the 14th and 15th of November, with appearances similar to those observed in 1716, and which are not commonly noticed. The same phenomenon was twice seen in Brabant in 1575, viz. on 13th February and 28th September, and the circumstances attending it were described by Cornelius Gemma, who compares them to spears, fortified cities, and armies fighting in the air." This has every appearance of a widely extended and great series of outbursts, and we may, perhaps, suppose that the maximum was not far from 1575.

Again we learn that "on September 2, 1621, the same phenomenon was seen all over France, and it was particularly described by Gassendus in his 'Physics,' who gave it the name of the 'Aurora Borealis.' Another was seen all over Germany in November 1623, and was described by Kepler." Giving equal weight to these two appearances, we may place the maximum in the year 1622.

Again we learn that "in 1707 Mr. Neve observed one of small continuance in Ireland, and that in the years 1707 and 1708 this sort of light had been seen no less than *five* times." We may in this case place the maximum in the year 1708.

We have thus selected as years of maximum auroral disturbances the years 1575, 1622, and 1708, and if they correspond approximately with years of maximum sun spots, we should expect the distances between them to be divisible by 11·1, which Wolf as well as De La Rue, Stewart, and Loewy, agree in representing as the solar period. Now the difference between 1575 and 1622 is 47 years—a period not very different from four solar periods, or 44·4 years.

Again the difference between 1622 and 1708 is 86 years—a period not very different from eight solar periods, or 88·8 years. Furthermore the difference between 1575 and 1708 is 133 years—a period not very different from twelve solar periods, or 133·2 years.

Finally the difference between 1708 and 1816·8, the period of one of Wolf's well-ascertained spot maxima, is 108·8, which is not very different from ten solar periods, or 111·0 years.

Assuming, therefore, that 1575 is not far from a period of maximum sun spots, and going backwards by steps of 11·1 years, we are led to the following dates:—1552·8, 1530·6, 1519·5, 1508·4, 1486·2, as years of maximum spots, whereas the dates of sweating sickness were 1551, 1528, 1517, 1506, 1485, and the differences between the two sets are as follows: 1·8, 2·6, 2·5, 2·4, 1·2, the mean being 2·1 years, and the difference always in the same direction.

It is, of course, hazardous to place much confidence in these results; nevertheless, it is worthy of remark that the greatest difference between observation and calculation from hypothesis, recorded in the communication, is 2·8 years, whereas it might sometimes have been 5·6 years on the supposition that there is no truth whatever in the hypothesis.

I shall only remark in conclusion that when we have arrived at the position of being able to explain by a probable hypothesis the cause of spot variations, we may perhaps be able to test our conclusions by means of these early notices of the Aurora Borealis.

B. STEWART

HAVING been from home, it is only now that I have read your very interesting article of Sept. 12, on the Potato Disease.

It is certainly most desirable that "an investigation into the origin, cause, and remedies" thereof by the ablest of our scientific men should be promoted; but it appears to me that this is a case for private contributions rather than an appeal to Government. I would, therefore, suggest that a fund be raised by subscription to supply the means of offering three prizes for the above object: the first I should hope would not be less than 500*l*., the second and third 300*l*. and 200*l*.

These sums would offer an inducement to the ablest men to devote to the object a portion of that time and talent which, with many of them, forms the chief (sometimes the only) source from whence their income is derived.

The judges might be appointed by such of the subscribers as could meet at a given place after due notice.

The sum required, including expenses of advertising, &c., would not be large; there ought to be no difficulty in raising it when we consider what a large interest is at stake.

I should be happy to subscribe 5*l*.

Richmond, Surrey, Sept. 23

M. MOGGRIDGE

On the Substance Exhibited at the British Association, Brighton, by Mr. P. L. Sclater, and stated to be the Ossified Notochord of a Fish

NEARLY every one frequenting the Zoological Section at the British Association at Brighton must have seen and been puzzled by a substance exactly resembling in external appearance a slender willow twig when perfect, two feet or more in length, and pointed at both ends.

This substance was exhibited by Mr. Sclater, and pieces of it were freely distributed by him for examination.

I was, unfortunately, not present when he read his paper on the subject; but I gathered that he had said that the substance had been described to him by the person who sent it as occurring in the back of a fish, and that Mr. Sclater called it an ossified notochord. A drawing of the fish was exhibited.

I further heard that Mr. Gray, of the British Museum, regarded the substance as the axis of one of the Pennatulidæ, and that this opinion was held by several other naturalists also.

I first became acquainted with the substance at the Kew Herbarium, where a piece of it was shown me by Mr. Berkeley, it having been given to him by Prof. Thiselton Dyer; and I was told that Dr. Hooker had examined it with the microscope, and rejected it as certainly not vegetable.

It was almost impossible to conceive of the substance being the notochord of a fish. No fish's notochord is composed of longitudinal fibres, nor has a structure at all resembling that of the substance in question; and moreover a notochord in such a fish as a lamprey, in which it is persistent, is much thicker in proportion to its length than are these calcified rods. Further, the tendency is for a notochord to ossify peripherally, and form rings of bone, not a hardened central core.

On reaching Oxford from Brighton, I got Mr. Robertson to give me a specimen of *Funicularia quadrangularis*, one of the Pennatulidæ, which was preserved in spirits. I found it had a long slender flexible core, exactly similar in appearance to Mr. Sclater's substance, but quadrangular in section instead of circular. The core was about two feet and a half long, and pointed at both ends. Microscopical examination of longitudinal sections of the core, when treated with acetic acid, gave off carbonic acid in quantities, and showed a structure almost exactly resembling that observed under similar circumstances in Mr. Sclater's substance.

I then looked into the literature of the subject, which fully confirmed me in the opinion that the substance in question is the core of one of the Pennatulidæ. A few statements, culled from the two works I consulted, may be interesting to the readers of NATURE. The works were "Anatomisch-systematische Beschreibung der Alcyonarien," von A. Kölliker, Erste Abtheilung: Die Pennatuliden. Erste Halfte (Frankfort: C. Winter, 1870). "Icones Histologicæ, oder Atlas der Vergleichenden Gewebelehre," herausgegeben von A. Kolliker. Zweite Abtheilung, Erster Heft. Die Binde-substanz der Cœlenteraten, p. 158 (Leipzig: W. Engelman, 1866).

The Alcyonariæ, a sub-order of polyps, are divided into three groups:—(1) Alcyonidæ; (2) Gorgonidæ; (3) Pennatulidæ.

The Pennatulidæ consist of hard and soft parts. The hard parts appear in most varieties in the form of an inner calcified axis, which in size and position is like that of the Gorgonidæ. It is to be considered as calcified connective tissue, is entirely and completely enclosed within the substance of the polyp colony, and is pointed at both ends.

The Pennatulidæ are thus divided:—

I. Pennatulidæ with polypbearers bilaterally symmetrical.
   A. Polypbearers feather-shaped in Pennatuleæ.
   B. Polypbearers leaf-shaped in Renillaceæ.
II. Pennatulidæ, with polyps arranged radially.

The Pennatuleæ break up into (1) Penniformes; Pennatuleæ with a well-marked feather-shape; (2) Virgularieæ; Pennatuleæ with a long, narrow polypbearer, and small leaves or polyps resting immediately on the axis. To this latter group belongs the genus *Funicularia*, and probably also the genus to which Mr. Sclater's specimen belongs.

With regard to the fine structure of the hard axis of Pennatulidæ, I have gathered the following from Kölliker's "Icones," p. 158.

The axes of Pennatulidæ consist of calcified horny substance, arranged in concentric lamellæ about a central core. The lamellæ are pierced by peculiar soft radial fibres, which, however, are well defined in certain species only. The organic basal substance shows an extremely well marked fibrillar structure. The axes are less firmly calcified than those of the Gorgonidæ, and are thus for the most part able to be cut with a knife and bent.

According to the analyses of Fremy (Ann. de Chimie, 1855, t. xliii. p. 98), the axis of *Pteroides spinosum* contains from 31 to 40 per cent. mineral matter, and that of *Pennatula rubra* from 45 to 48 per cent.

A drawing is given by Kölliker of a transverse section of the axis of a Virgularia (*Lygus mirabilis*) prepared by grinding, which shows a white central core, surrounded by a broad brownish cortex, which is marked with concentric and radial lines.

If the axis of a *Lygus* be treated with acetic acid, a development of carbonic acid takes place. It becomes soft, and allows the following structure to be made out:—

The bulk of the axis consists of a fibrous tissue which resembles ordinary fibrillar connective tissue in the most deceptive manner, and consists of very fine fibrillæ, which run parallel to one another in a wavy fashion, and which can be isolated from one another. On the surface of the axis is a yellowish cuticle.

Drawings are given of longitudinal sections of the axis of *Lygus mirabilis*. It shows the peculiar broad transparent radial fibres crossing the finer longitudinal ones. In another figure of a similar preparation from *Funicularia quadrangularis*, these radial fibres are less marked, but the cavities containing them appear as oval apertures in the section.

Reference is made to Quekett, Lectures on Histology, II., and Histological Catalogue, I., where the structure of the axes of *Pteroides*, *Lygus*, and *Funicularia* is described, but the radial fibres mistaken for canals.

I think any one who has examined Mr. Sclater's substance, and very many have had such an opportunity owing to his kindness in distributing pieces, will find that both in external characteristics and internal microscopical structure, it conforms very closely to the description given here from Kölliker of the axis of the Pennatulid. I have sent the Editor of NATURE some pieces of the axis of *Funicularia quadrangularis* in case any one cares to compare the two substances, and has not the material at hand. In the mean time I cannot but conclude that Mr. Sclater has been misinformed, and that we are very unlikely ever to see that very marvellous fish in the flesh.

H. N. MOSELEY

Ocean Currents

HAVING just returned from a sojourn of nearly two months amongst the White Mountains, I am now for the first made aware of the publication, both of my last note on Ocean Currents, and also of Mr. Croll's reply. I have not been disposed to enter into an extended discussion of this subject, knowing that it cannot be properly treated without the use of mathematics, in short essays suited to NATURE, and doubting whether the discussion could be made either acceptable to its Editor or edifying to its readers. In my last note, therefore, I endeavoured to be as brief as possible, and considered only the more simple form of the conditions of the problem, as expressed by differential equations, showing the relations between the forces, resistances, and the differentials of the motions, and showed that the deflecting force eastward exerted upon a pound of water or any body in moving toward the pole with a velocity of one mile per day, and which must be sensibly the measure of the resistance of friction, is of the same order near the parallel of 45° as the action of gravity on the same body upon a gradient of 6 ft. from the equator to the pole; and from tidal considerations it was inferred that the resistances to the slow motions of ocean currents may be very much less than the action of gravity upon any body upon a gradient of 6 ft. in the distance of a quadrant.

If, instead of considering the differential equations of any problem, and endeavouring to satisfy them directly, we adopt the less simple method, and consider the integrals of these equations, and endeavour to satisfy them directly, the method, though less simple, is entirely legitimate, and we should obtain the same results. This is substantially the method adopted by Mr. Croll; and from considering the problem in this way, he comes to the conclusion that the deflecting force eastward, which is the measure of the resistance, is at least 1,500 times greater than the action of gravity on a gradient of 6 ft. from the equator to the parallel of 60°; and as the velocity of the pound of water eastward, and that toward the pole, are probably about of the same order, and consequently the resistances, he justly infers that the resistance to the motion toward the pole must be overcome by

some other force than that of gravity due to the assumed gradient. But it may be shown by the other method of considering the problem, by assuming a motion towards the pole of one mile per day, that the forces which overcome the resistances in both directions are about of the same order. This very great difference in the results obtained from the two methods of considering the problem, indicates that there is some great fallacy somewhere which needs looking after.

Mr. Croll is misled by adopting the erroneous principle that the amount of work performed by gravity upon a falling or descending mass is in all cases expressed by the mass multiplied into the height through which it descends, or that the foot-pound is a unit of work. The amount of work required to give velocity to any body, or overcome any kind of frictional resistance, is expressed by the intensity of the effort, regarded as constant, multiplied into the time of action. The intensity of the effort of any force, as of gravity, is explained by the mass multiplied into the velocity which such force can produce in a unit of time. If we, therefore, put g, m, t, and v for the force, the mass, the time, and the velocity respectively, we shall have, putting W for the amount of work performed by gravity,

$$(1) \quad W = mgt = mv,$$

that is, the amount of work performed is expressed by the momentum. Now this amount of work is stored away in the moving body, and remains until it is used in overcoming resistance of some kind, as friction or the inertia of other bodies, and W is exactly the expression of the working power which has been communicated to it. But if the moving body has been subject to resistances, as of friction, during the time t, then we shall have

$$(2) \quad W = mv + ft$$

putting f for the coefficient of friction, and supposing it to be constant. In this case mv expresses the amount of work left which has not been expended in overcoming the friction during the time t, and of course in this case we cannot get all the work back again which has been expended, at least mechanically.

If we now suppose a body to fall in a vacuum through the space s, if the amount of work performed by gravity upon it, and the working power communicated to it, is expressed by the mass multiplied into the height through which it has fallen, we shall also have

$$(3) \quad W = ms = \tfrac{1}{2}mgt^2 = \tfrac{1}{2}mvt.$$

Hence, comparing the preceding expressions of W, we have $mv = \frac{1}{2}mvt$, which is impossible; and therefore, if the former expression of W is correct, the latter is not.

Again, illustrating by a special case, if we suppose a body, of which the momentum is mv, to move upon a level plane without friction, and the plane to curve up in the direction of motion, and also suppose another body with half the mass and double the velocity, of which the momentum is $\frac{1}{2}m \times 2v = mv$, m and v being the mass and velocity of the first body, it must be admitted that the amount of labour expended in giving both bodies the momentum mv is exactly the same, in the latter case the intensity of the effort being half as great, but the time of action twice as long; but the momentum will carry the latter up the slope to a height four times greater than that of the former, and after descending again to the plane, both will have the same momentum, and the same amount of labour would be required to bring each to rest, and consequently both have the same power of doing work. But the mass of the latter multiplied into the height through which it has descended is double that of the former, and hence these products do not express the power of doing work which gravity has communicated to them.

In the case in which the descending body is resisted by friction, we have seen (2) that neither the mass multiplied into the height of descent, nor the momentum mv which the body has on arriving at the level plane, expresses the whole action of gravity, and the resistance fv may be so small as not to affect sensibly the amount of work expressed by mv, or it may be so great that mv may be neglected, in comparison with ft. The value of ft may also be so great that the value which mv would have (1) in the case of a free body falling through the space s, would be almost infinitely small in comparison with the whole expression of W (2). In the various cases, therefore, which may be supposed, in which friction may be either very small or very great, so that in the former case the effect of the resistance might be scarcely sensible, and in the latter it might take the action of gravity a long time to drag the body down through the space which it has to descend, we cannot suppose that in all these cases the whole action of gravity is expressed by the same number of foot-pounds, supposed to be units of work.

If, therefore, Mr. Croll's pound of water were moved from the equator to the parallel of 60° by the action of gravity without any resistance, the momentum which it would have on arriving there would express the work done by gravity upon it, and not the six foot-pounds, and the work would be done in a very short time in comparison with the time in the real case of nature; but when it is dragged down there through all the resistance which it suffers, at the rate of a mile per day, as we have supposed, the amount of labour which gravity performs is very many times greater than that expressed by the momentum which the pound of water would have on arriving there without resistance; and with regard to the six foot-pounds, we have seen that the work is no more comparable to them than a surface is to a solid.

Again, if we suppose the gradient upon which gravity acts to be only one foot in the distance instead of six, and the resistance to the pound of water to be as the velocity, then the water would move with only one-sixth of the velocity in the other case, and the water would be six times as long in reaching the parallel of 60°, but the energy of the action of gravity would be only one-sixth as much, and hence the work would be the same, being carried on six times as long in the latter case with one-sixth of the energy. But then the same work would be represented by one foot-pound, if that is a true unit of the work instead of six. In this case also the deflecting force eastward would be only one-sixth as much, but the time being six times as long, the same amount of work would be done, and this would be sensibly the same as that which would be required to give the pound of water a velocity of about 760 miles, as Mr. Croll has it, but really double that amount.

I am well aware that in the action of machines in which force is balanced against force, and consequently the times of action are the same, the amount of work may be expressed by the forces multiplied into the spaces through which they act; but in all cases in which the times differ, the amount of work cannot be expressed by any unit into which the element of time does not enter. The amount of work required to produce a velocity of 760 miles per hour is a function of the time, and proportional to the time where the force is constant, and cannot be measured by foot-pounds.

With regard to the argument based upon M. Dubuat's experiment, the matter briefly and fairly stated stands thus: according to the experiment, water will not flow unless acted upon by a force equivalent to that of gravity upon a given gradient, which makes the force required to move it about fifteen times greater than the horizontal component of the moon's disturbing force which produces the tides. But this force of the moon does move the water of the ocean, and therefore M. Dubuat's experiment is not applicable to water of great depth as of the ocean, and the argument fails. It is true, as Mr. Croll states, that the two cases of motion are somewhat different; in the case of the tides the water from top to bottom flows in the same direction, while in the other the upper and lower strata flow in contrary directions, and the resistances to the lower motions are no doubt greater. Six of the nine feet therefore of Mr. Croll's gradient should probably be given to the lower currents, and only three to the upper ones. But Mr. Croll admits that in the case of the tides a gradient of one inch is sufficient to move the water. A gradient of three feet only, therefore, ought to be sufficient to move the upper half, which would correspond somewhat to the case of tides in an ocean of half the depth. The observations of Col. Graham show that the water of Lake Michigan, about 700 feet deep, readily yields to the moon's disturbing force which causes a tide at Chicago with a range of nearly two inches.

Cambridge, Mass., Sept. 7 WM. FERREL

Spectral Nomenclature

IT seems almost absurd that a subject of such interest, and, as I think, importance, as that of Spectral Nomenclature should be discussed from opposite sides of the globe alone; so it may be hoped that it will not have been allowed to end with Prof. Young's remarks upon the one or two points in which he differs from me, but will have been taken up by others at a less distance. There is a great deal more to be said about it; but probably I should not have troubled you again just yet but for the obligation I feel to disclaim credit which he gives me for what is not mine.

Doubtless it is not necessary, but the obligation is the same; and a mistake into which Prof. Young has fallen is open to others.

The map which he wants—to be based on inverse wave-length or rapidity of vibration or pitch—is, I believe, in course of construction by Dr. Huggins, to whom, and not to me, is due, I think, the first idea and the proposal. Prof. Young has probably associated my name with it through a lecture delivered by my brother at Glasgow, in 1869, in which it was advocated.

I also wish to acknowledge that I was not aware of the fact which has now been so decidedly stated, that the coronal green line is certainly *practically* identical in position with 1474 (K), as tested by direct comparison. Indeed, I was ignorant that such a comparison was possible, having supposed that the line in question was only visible during eclipse. I ought, of course, to have referred to Prof. Young's "Preliminary Catalogue," and probably should have done so had I been in a house instead of in a tent, a few score of miles from the nearest station. But in truth it did not occur to me that there could be any certainty about the position of a line which, as a coronal line, had never been fixed by measurement. I may now venture to ask, What guarantee was there that No. 31 of the "Preliminary Catalogue" was "the coronal line," anterior to the Dodabetta measurement? I do not question it now, but I should like to know if the presumptive identity is supported by any characteristic difference between that line and those which are presumably due to the chromosphere. There is still a link wanting.

However, admitting the identity, and therefore the accuracy of the assigned position, we may still believe what Prof. Young says he would be glad to see proved, that "the apparent coincidence (with the iron line) is merely a very close juxtaposition." More than this: even were a very much higher dispersive power to show no resolution of the identity, should we not still be in nearly the same position as to any inference to be drawn therefrom? Evidence of physical relation between metals which present one or more lines common to both spectra may, indeed, eventually be shown (by the improbability of so frequent an accidental concurrence) to amount to proof. But this must be a prior step. To conceive it taken, and then to apply the like reasoning by analogy to the case of the single coronal line tallying with an iron line, seems to me speculation of the second order. Undoubtedly it would be matter for congratulation to be relieved from the liability to temptation of this kind by definite disproof. In the meantime, I cannot but regret that Prof. Young has half neutralised the good of a plain disavowal of belief in the ferrous interpretation of the coronal green line, by hazarding the query whether it may not "turn out" to be quasi-ferrous.

I am sorry—to return to the subject of nomenclature—that your respondent does not agree to my objection to "D_3." Is it not plain that such a designation is haphazard? The association of idea is with D_1 due to sodium, instead of with the origin or source of the line. It tells nothing beyond the position, roughly, in the spectrum, by reference to a position which we happen to be familiar with, but with the occupant of which it has no connection otherwise. The name, in short, has no foundation in principle; and that, I apprehend, is a lack of the first requisite in a scientific name.

The objection to Greek alphabet letters is of a different character, but not less easily answered. It is very true that, through the exertions of Prof. Young and others, "the whole Greek alphabet would not suffice to name one in three of the lines" already known; but it would nevertheless suffice (as in the somewhat analogous case of the stars) "to express as many as the memory would require to hold." There is ample precedent. The principal lines of the elements, like the principal stars of constellations, are known to some extent by Greek letters; and as for the difficulty in respect of order, there was a time when the "lucid" stars, though very many in number, and having no very clear claims to precedence, were only known individually by personal names. Yet no sooner did a Bayer rank and name them according to apparent brilliancy, by Greek letters (to say nothing of the Roman), than the advantage of a fixed nomenclature was recognised and his work accepted; although observation must have shown that the assigned order was not always strictly correct. So would it happen now if, the lines having been lettered, further knowledge should show that the established precedence was not quite all that could be wished. The evil of slight incorrectness of this kind would be felt to be trifling compared with that which would result from an unsettling of a nomenclature established solely for convenience and involving no theory.

This would not prevent nor conflict with, neither would it render unnecessary, a far more extended tabulation depending on refrangibility. On the contrary, the want of such a classification and means of indication would be felt as soon as precise tabulation should come to be undertaken. In Kirchhoff's solar chart we have, graphically, something like what is wanted in a much more general, numerical, and tabular form—an example of a catalogue of lines. Charts are very useful, but not most handy; and they are not susceptible of such ready improvement and extension. The accumulation of results of spectroscopic research must sooner or later take the form of a catalogue of lines, from all sources, arranged in order of refrangibility; designating individuals (for special reference) where possible, according to their parent element or compound, their physical source, their cosmical habitat, or other characteristic and distinguishing indication, implied under the system of nomenclature which may be adopted; upon which would follow such details as to character (including intensity, width, definition, complexity, variability, &c. &c.) as present knowledge or future research may represent as suitable material for incorporation.

So long as spectroscopic analysis is content to remain in its earliest stages—and it must be allowed to be still in its infancy, though a giant from its birth—the student and experimentalist may to a very considerable extent learn by heart or by practice such spectra as he needs; but this can never suffice for all purposes. Accumulation is continually going on, and products must be stored. Let that be once acknowledged and the task attempted, and it must follow that, no matter how rigorous and precise may be the system of tabulation, there will be not only room, not only gain, but a positive necessity for an intelligible use of that kind of descriptive indication which is only to be found in scientific classification and nomenclature.

A general catalogue such as I contemplate would command, if compiled with even moderate knowledge and care, a very general acceptance. Unquestionably it would be extended, modified, improved upon, by subsequent work; but, so far as nomenclature is concerned, it would probably undergo but slight alteration—the less the better. It would form a basis on which any number of special catalogues might rest, without interfering with its permanence as a catalogue of reference.

I do not pretend to say that the task is a simple one; quite the reverse. But, then, all the more honour to whoever accomplishes it. J. HERSCHEL

Bangalore, July 29

Jeremiah Horrox

I OBSERVED in a number of NATURE some three weeks ago an inquiry relative to J. Horrox, the astronomer. My wife is descended from Horrox, and I knew that one of her friends had his life, but have not been able to find it till now. The book has just been sent to me here.

The Rev. Jeremiah Horrox was born in Toxteth Park, near Liverpool, in 1619, and died in 1641, aged 22.

The life is by the Rev. A. B. Whatton, published by Wertheim, Macintosh, and Hunt, 24, Paternoster Row, 1859, and includes a translation of his discourse on the Transit of Venus.

HENRY HOLIDAY

Millions of Millions

WHY do not Messrs. Ranyard and Co. adopt the late Benjamin Gompertz's most convenient notation of prefixing a circle to the first significant figure, or suffixing a circle to the last significant figure having therein a digit for the number of zeros employed?

Thus: ·⑤718 is ·0000071S

And 718⑥ is 718000000

Analogy of Colour and Music

IN NATURE, No. 150, p. 393, a letter from Mr. G. C. Thompson is headed "Correlation of Colour and Music." As this letter refers to a paper of mine published some time ago, permit me just to say that Mr. Justice Grove has in your journal objected to the use of the word "correlation" employed in this sense. Entirely coinciding with the opinion of the eminent parent of this

work, I wrote as follows in NATURE for February 17, 1870:—"*Analogy* is certainly far more appropriate to express what is merely a parallelism, and not a necessary or complementary relationship between light and sound." In the subsequent letter on this subject you adopted the word "analogy;" pardon, therefore, my pointing out an obviously accidental "reversion to the primitive type" which appeared in your paper Sept. 12.

Sept. 16 W. F. BARRETT

The Fringes on the Lighter Side of the Rainbow

AT the place referred to by Mr. Thompson in NATURE (No. 150, p. 393) I merely followed Sir John Herschel; expressing myself, it is true, not very accurately, in my anxiety to save space in NATURE at the end of a letter already too long. If Mr. Thompson refers to Sir John's "Meteorology," sections 219 to 224 and still thinks the point requires fuller elucidation, he may possibly supply the deficiency by devising an experiment to prove that the width of the fringes does not vary inversely as the diameter of the drops.

In answer to Mr. Thompson's concluding question, perhaps somebody else will furnish the latest intelligence. I do not know what has happened in the last five years, and I do not know what you call violet; but I believe that in 1867 the extreme rate of vibration for visible rays was about 801 million millions a second. C. J. MONRO

A Curious Phenomenon

A VERY curious phenomenon was witnessed here on Wednesday afternoon last, September 4, about three o'clock, in a westerly direction. A somewhat heavy thunderstorm, originating towards the south, had divided its fury before reaching this immediate neighbourhood, one branch passing N.E. towards the Pennine Hills, the other taking the N.W. course, that to the N.E., however, being more violent. As the storm was passing, a stream—*apparently* of water, and fully six inches in breadth—shot with considerable speed from the vicinity of a dark, fiery cumulus across a rain cloud of a very deep blue, murky tinge. Its passage, as witnessed by my boy from its commencement, was similar to that of a rocket, at first assuming a quivering motion, then darting suddenly forward, for some distance horizontally, afterwards obliquely. Its apparent length would be fully twenty yards, being of a very light slate colour. After I saw it the phenomenon remained about two minutes; but its total duration would be not less than five, vanishing gradually during its whole length.

Whatever the phenomenon itself—or its cause, its upward course was certainly very striking, and to me unprecedented—the impression on some people's minds being that it was water drawn up from Lake Ullswater into the clouds by the lightning!! A terrific storm of thunder and lightning occurred on the previous evening at 9 P.M., when several fatal accidents were reported. T. F.

Blencowe School, Cumberland, Sept. 7

APPEAL FOR SKELETONS OF WILD SPECIMENS OF THE LARGER CARNIVORA FOR OUR MUSEUMS

NEITHER in the Museum of the Royal College of Surgeons nor in that of the University of Oxford is there a skeleton of a wild lion or a wild tiger, and it is probable that there is no such skeleton existing in England. The preparations in our Museums, illustrating the anatomy of the larger carnivora, are almost without exception derived from menagerie specimens.

Lions breed well in confinement, and hence an ordinary menagerie specimen may not only itself have been during its whole life confined in a cage, but its ancestors may have suffered a like fate. At all events it has been trapped whilst still young, and reared in confinement, as is usually the case with the menagerie tiger. Now an animal confined in a narrow space from its youth upwards never has free play for its muscles, and as its food is provided for it, is never called upon to exert them in a violent manner. The result is that the bony framework on which the muscles act never attains in such specimens its full development, and the ridges and inequalities on the bones corresponding to the origin and insertion of the muscles are not well marked. Moreover, menagerie animals, as is well known, very frequently suffer from diseases of the bones, and the marks of these diseases may be seen on many of the skeletons in every anatomical museum. Now, it is of great importance to possess perfect skeletons of adult wild large carnivora, both for general study, and more especially for comparison with the remains of similar carnivora which are to be found in the more modern geological deposits in Great Britain. Considering the number of tigers and lions which are annually killed by English sportsmen, it is surprising that this desideratum has not yet been supplied. The reason probably is that sportsmen generally do not know that it exists, or do not understand how a skeleton should be prepared. The sportsman is usually content with preserving the skin of his tiger or lion; but no doubt there are many who would gladly aid the cause of science by preserving the skeleton as well, if they knew how much the result of their labours would be valued at home. I propose here to give a few simple directions for the rough preparation of skeletons for transmission to England, merely premising that I trust that if any sportsman may be induced by reading these notes to send home a skeleton, that he will send it to the Oxford Museum, in which I am especially interested, and I hope some old University man may help us in this matter. Any packages should be addressed to Prof. Rolleston, Museum, Oxford. Skeletons of other wild animals are, of course, of great value, and will be most gladly received; they also are too frequently only to be got from menageries.

Directions for Preparing Skeletons.—The skin having been removed from the animal, the abdomen should be slit open, and all the viscera extracted. The limbs should then be severed from the body, the scapula or blade bone being left attached to the fore limb, the hind limb being removed at the thigh joints, and care being taken that the articular surfaces are not injured in the process. The flesh should now be removed roughly from each of the limbs with knives; the several bones which go to form each limb should if possible be allowed to remain attached to one another. On no account should the small bones of the hind or fore foot be separated from their attachments. Mr. Flower, indeed, advises that the skin be not removed from the feet at all. The limbs being thus roughly cleaned, they should be placed in water for several hours to allow the blood to soak out, and they should then be placed in the sun till dry. The head should be disjointed from the neck, and the flesh cut off it. It is most convenient to commence with the strong muscles of the jaw. After these have been cut through, the ligaments which hold the lower jaw in place may be divided, and it may be separated from the skull. The tongue may now be removed, and search must be made in its base for several small bones constituting the hyoid apparatus, which should be carefully taken out, and tied at once to the lower jaw for fear of loss. A considerable quantity of the brain may be removed by means of a spoon-shaped stick through the aperture at the back of the skull where it joins the neck. The rest may be removed by means of large shot put in at the hole, and shaken up with water. The neck may be cut off close to the trunk, and the tail close to the rump, and the flesh removed with the knife. The chest cavity should be left entire, the flesh being removed as well as circumstances will permit. The whole of the pieces should be treated with water, and then dried, as in the case of the limbs. The skull, limbs, tail, and neck may be conveniently placed inside the chest cavity for packing, and if it be necessary to get the skeleton into a short packing case the back bone may be divided behind the chest cavity, and the hinder vertebræ and hip bones laid along side of

it. The tail may also be divided into segments. The skeleton should be well packed in dry hay or straw.

Precautions.—The bones should on no account be boiled or placed in hot water. They should not be allowed to remain in the sun after they are once quite dry. In severing the various portions of the skeleton from one another, great care should be taken that the knife passes between the bones through joints, and that the bones are not cut or injured in the process.

H. N. MOSELEY

*NOTICE OF A SUPPOSED NEW MARINE ANIMAL FROM WASHINGTON TERRITORY NORTH-WEST AMERICA**

SOME months ago Capt. D. Herd of the Hudson's Bay Company's service, sent me several specimens which at first sight appeared to resemble long thin peeled white willow wands more than anything else. These objects, of which I exhibit examples, are about a quarter of an inch in diameter at their thickest part near the base, and taper gradually to a slender apex. The base also narrows slightly and presents traces of corrugations. The longest are upwards of six feet in length. Capt. Herd merely stated that they had been brought from North West America, and asked me to find out what they were, promising an account of all he knew about them on a future occasion.

Expecting to see Capt. Herd very shortly, I did not myself make any very accurate examination of these objects, but I convinced myself that they were of animal origin, and was inclined to regard them as possibly bones of one of the gigantic Rays. I gave specimens of them to Prof. Flower, Prof. Milne-Edwards of Paris, and several other naturalists,† who visited the rooms of the Zoological Society, and who all said that the objects were new to them and that they did not know what they were, but were mostly inclined to regard them as the axes of an unknown Pennatulide animal.

Knowing that Prof. Kölliker of Würzburg had recently been engaged on a monograph of the Pennatulidæ, I likewise sent him a specimen, in reference to which he was kind enough to write to me as follows:—

"The object you sent me, found near Vancouver Island, is indeed the axis of an unknown Pennatulide, and agrees with none of those described in my monograph. It differs from all axes of Pennatulidæ investigated by me, in showing no radial fibres, not even the very short ones, described by me in *Funiculina quadrangularis* and *Halipteris* (*Virgularia*) *christii*, and may therefore belong to a new genus. Except in this respect the said axis agrees most with that of *Halipteris christii*, but there is also a difference, as the axis of *Osteocella*, as we may call it, is absolutely *quadrangular* in its lowest part for the length of about 3 centimetres.

"I put the four pieces you sent together and found a total length of 1·769 metres.

"The thickest part is found at the distance of about 0·210m. from the lower end, and measures 6·3mm. in breadth. Both ends are broken; the lower measures 1·8 mm. in breadth, and the upper 0·5mm. In general the axis is cylindrical and smooth but there are granulations and warty excrescences on the lower end for a length of about 0·20m. The axis is calcareous, and shows after the extraction of the earthy matter fine fibrils and lamellæ like the axes of all other Pennatulidæ.

"I may further add, that no Pennatulide of this size is known from the west coast of America."

Shortly after I had received this communication from Prof. Kölliker, I obtained from Capt. Herd the following account of the manner in which these objects had come into his possession.

"These rods are the back bones of a sort of fish found in great abundance at Barraud's Inlet, Washington Territory, North-West America, whence they have been brought by two Captains in our service. These animals are shaped like a Conger eel, but are quite transparent, their bodies being composed of a mass of jelly—they are about 8 inches in diameter. The head is like a shark's head; it is attached to the thick end of the rod—it has two eyes and a mouth placed low down. The back bone is also transparent in the living animal, but becomes hard when dried on the beach by the sun. These fishes swim about in shoals along with the dog-fishes.

The rods were brought by our ships *Prince of Wales* and *Princess Royal*, Capt. Anderson, who has made me the accompanying sketch of the fish itself."

Found at Barraud's Inlet, Washington Territory, amongst the Dog Fish.

A somewhat similar account of the origin of these objects is given in the subjoined extract from a letter of the Hon. Mr. Justice Crease, of Victoria, British Columbia, who has recently sent a specimen of the same object to the Royal Horticultural Society.

"I send you by this post a specimen, which Mr. Claudet (Superintendent of our Government Assay Office) has sent to me, to inquire what it was, of the bone of a fish taken frequently in Barraud Inlet, near New Westminster, Fraser river, by Messrs. Dick and Nelson at their Saw mills. There has been a great discussion here among brother ignoramuses as to whether it is vegetable or animal production. Though it has a singular breakage it answers to the test as lime. Claudet is a clever man, and thinks with me that it is bone. I have broken it in several pieces for convenience of transmission. Can you tell us what it really is? I have seen several like it and from the same place. Dick and Nelson are both respectable men and Claudet of course is beyond suspicion." (May 10, 1872).

Capt. Anderson being absent from England, I have not been able to ascertain whether the information above given was founded on his own observations or on the accounts given to him by the inhabitants of the district of Barraud's Inlet. Supposing the former to be the case, and that these objects are really derived from such an animal as is described and figured above, I can only suggest that they may be the hardened notochords of a low-organised fish, allied either to the Chimæroids or to the Lampreys, in which the notochord is persistent throughout life. It is quite certain I think, that they cannot be any part of the true vertebral column.

But whether this be the case or the Pennatulide view of their origin be the true one, it is certain that the animal that produces these curious rods is quite unknown to us, and it is highly desirable that specimens of it should be obtained. I have already requested Capt. Herd to communicate with Capt. Anderson on this subject, and trust that on his next return from Barraud's Inlet he will bring us the entire body of this wonderful creature preserved in spirits. I hope also that if any student of "NATURE" in Washington territory may chance to read this article he will not fail to exert himself and assist us in solving this somewhat puzzling zoological problem.

P. L. SCLATER

* The substance of this paper was read before Section D at the meeting of the British Association at Brighton, August 20, 1872.

† A specimen given to Dr. Günther was handed by him to Dr. Gray, who to my great surprise without consulting me or even ascertaining correctly where I had obtained it, immediately described it in the "Annal of Natural History" (Fourth series, vol ix. p. 405) as a "new species" of his genus "*Osteocella*," whatever that genus may be, for its author considers it "very doubtful whether it belongs to the Pennatulidæ" and states that "it may be the long conical bone of a form of decapod cephalopod."!

A GIGANTIC "PLEASURING GROUND": THE YELLOWSTONE NATIONAL PARK OF THE UNITED STATES

II.

LEAVING the Yellowstone Basin, and crossing in a westerly direction the range which divides the drainage of the Yellowstone and the Madesin, we come into the great Geyser Basin of the Firehole river, a branch of the Madesin Forth. Travelling in this region is attended with great difficulties on account of the immense quantity of fallen timber. The uplands, as well as the lowlands, are covered with a dense growth of pines, the majority of which have a trunk not over 6 in. to 12 in. in diameter, but run up to a height of 100 ft. to 150 ft., as straight as an arrow. In crossing this shed the source of the east fork

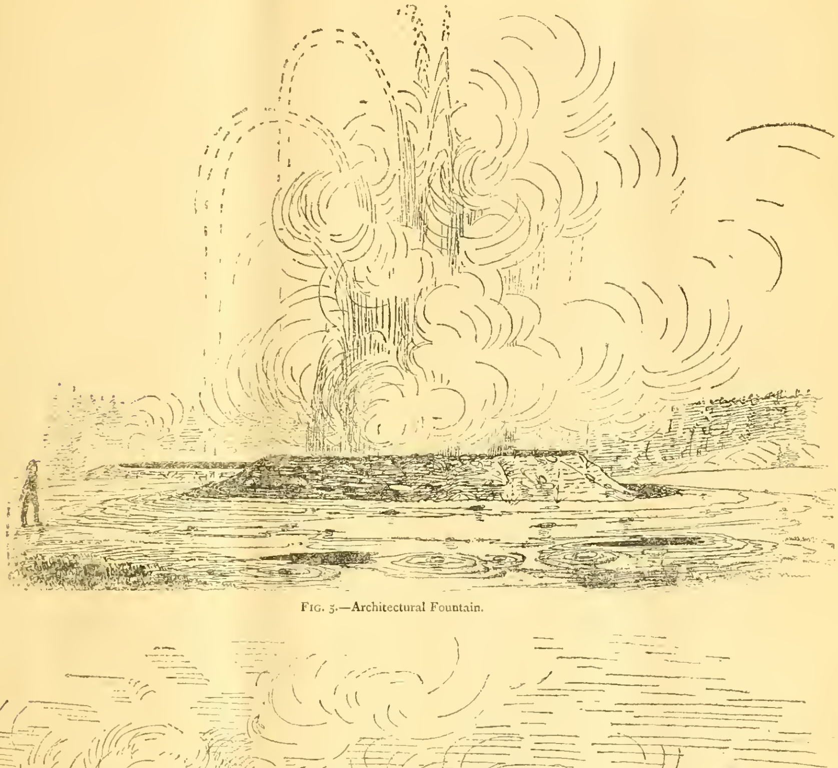

FIG. 5.—Architectural Fountain.

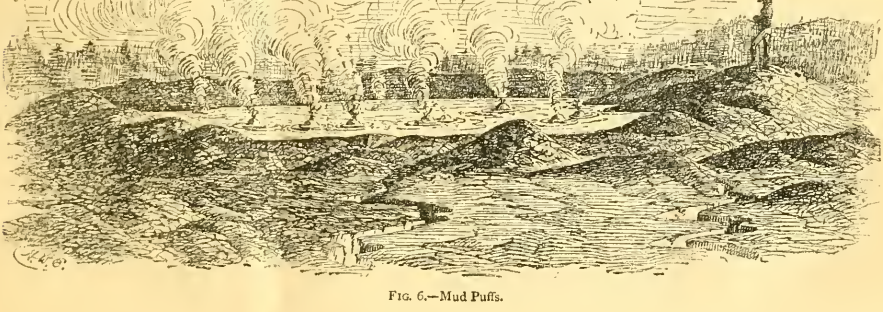

FIG. 6.—Mud Puffs.

of the Madesin is first struck, and every few miles a group of dead or dying springs is met with. In the distant view the appearance of the whole country may be not inaptly compared to a vast limekiln in full operation. The last branch of the Madesin is almost entirely fed by water from the hot-springs, and its temperature is 60° or 80° all the time. The vegetation that grows along the banks, and in the stream itself, is a marvel of luxuriance. The mountains that enclose the valley on either side are composed of basalt and obsidian. As we proceed down the valley, toward the junction of the east fork with the Madesin, the springs grow more abundant, and we soon come to the great basin of the Firehole, in which the most powerful geysers are found.

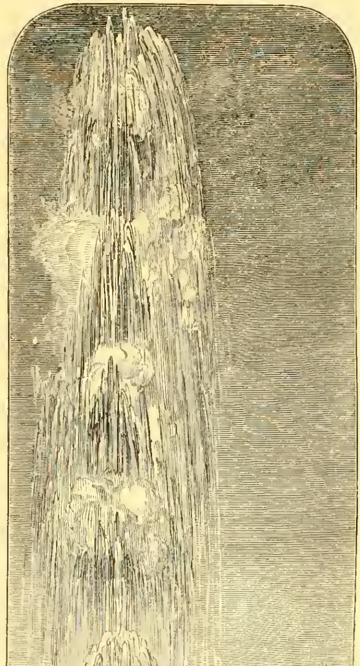

FIG. 7.—Giant Geyser.

The entire valley of the Firehole, averaging about three miles in width, is covered with siliceous crust as white as snow. The elevated mounds and numerous columns of steam reveal where the most important groups of springs and vents are located. In the Lower Geyser Basin, though there are many groups of most interesting springs, none of them can rank as geysers of the first class. Over an area of about three miles there must be at least a thousand active, quiet, dead and dying springs. One of the most remarkable of the springs in this lower basin has built up for itself a cistern, which is so elaborately beautiful that Mr. Hayden calls it the *architectural* fountain (Fig. 5). The whole basin is about 150 ft. in diameter. Near the centre is the rim of the spring, which is about 25 ft. in diameter; the water is in constant agitation, occasionally spouting up a column of water like an artificial fountain, and filling up the reservoir and the sides for a radius of 50 ft. or more. The siliceous accumulation made by this spring descends for several hundred feet in innumerable semicircular steps varying from one-fourth of an inch to two inches in height, and is exquisitely beautiful in all its details. When in active operation, a column of water is thrown 30 ft. to 60 ft. high, the water spreading over a radius of 50 ft., and filling the numerous reservoirs that surround the immense rim of the basin. There are other funnel-shaped basins with elegantly-scalloped rims, covered all over the inner side to the depth of 10 ft. to 20 ft. with bead-like tubercles of silica. Sometimes these siliceous beads are arranged in large numbers like fungi or corals, or like the heads of cauliflowers.

A short distance from this beautiful geyser is a remarkable group of *mud springs*. One of them has a basin 50 ft. in diameter, which is covered over thickly with puffs, like an immense cauldron of thick hasty-pudding (Fig. 6.) The exact symmetry of these puffs, their uniformity of size, and the fineness of the material, render them exceedingly beautiful; and there is among them every shade of colour from a bright scarlet to the most delicate pink or rose, with a base as white as snow. The most fastidious manufacturer of porcelain would go into ecstacies over this magnificent bed of mortar, that has, perhaps, been worked and reworked for many thousands of years.

These springs occur in small groups all over the basin, and are often in close proximity to geysers or to perfectly quiet springs. They are found in every stage, from simply turbid water, through all grades of consistency, to thick stiff mud, through which the gases force themselves with a suppressed thud-like sound. Each of these mud springs probably commenced as a geyser, or at least a boiling spring. The water is at first clear, then becomes turbid, and grows gradually thicker, until the heat dies out.

The Upper Geyser Basin is located very near the source of the Firehole River, and between it and the Lower Geyser Basin there is an interval of about five miles, in which the hills come close to the river on both sides, and the springs occur only in small groups. Near the centre of the upper basin, which is about two miles long and half a mile wide, there is one of the most powerful geysers of the basin (Fig. 7). The preliminary warning is indicated by a tremendous rumbling, which shakes the ground all round with a sound like distant thunder; then an immense mass of steam bursts out of the crater as from an escape-pipe, followed by a column of water 8 ft. in diameter, and rising by steady impulses to the height of 200 ft. Mr. Hayden compares the noise and excitement it produced to that of a battle charge. He says the fountain continued to play for the space of fifteen minutes, when the water gradually subsided, and settled down in the crater about 2 ft., and the temperature slowly diminished to 150°. There are here two separate basins, one of which is in a constant state of violent agitation, while the other plays only at intervals of thirty-two hours; and although, so far as the eye can detect, there is a partition of not more than 2 ft. in thickness between them, neither of them seems to be affected by the operation of the other. The decorations about these springs are beyond

conception beautiful; the most delicate embroidery could not rival them in their wonderful variety and complexity. The surface within and without is covered over with little tubercles of silica, which have a smooth, enamelled appearance like the most delicate pearls; down on the sides of the basin are large rounded masses like corals, formed entirely of silica. There are probably from twenty to fifty geysers of greater or less importance in this valley.

The two kinds of deposits in these regions, the calcareous and siliceous, have been mentioned in the preceding description. According to analysis by Dr. Peale, Chemist of the U. S. Geological Survey, the springs on Gardener's River, known as the White Mountain Springs (Fig. 8), deposit carbonate of lime mostly. There is present also sulphate of magnesia, chloride of calcium, sulphate of soda, and a little silica. In the deposits of the Firehole Basin

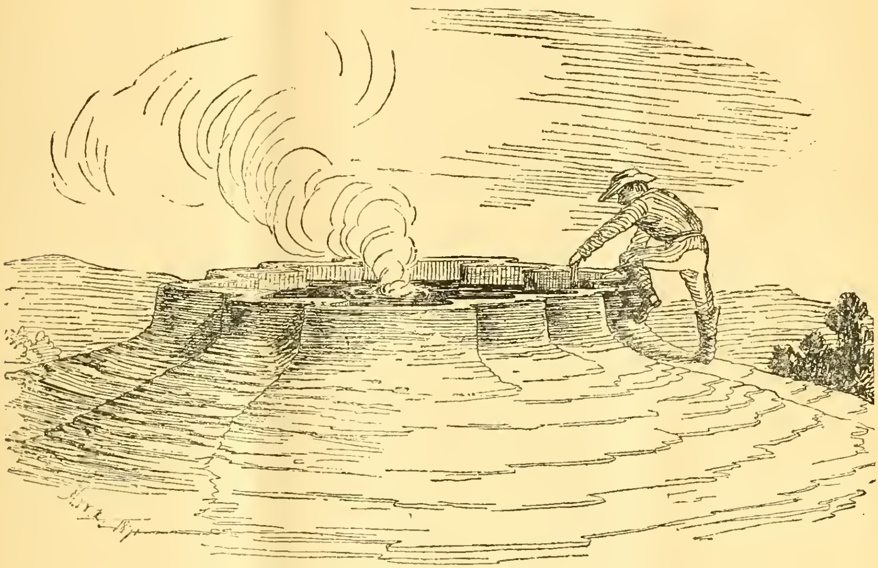

FIG. 8.—White Mountain Springs.

not a trace of lime could be detected, but about 85 per cent. of silica, 11 per cent. of water, and the remainder mostly chloride of magnesium, and only a slight trace of lime has been found in the water. There are, scattered over the great area, a few patches of the sedimentary rocks, and it is most probable that underneath the deposit of this small group of springs there are portions of the carboniferous limestone.

So far as Mr. Hayden and party could ascertain, in all the deposits of the Yellowstone Basin proper, and the Firehole Basin, silica is the dominant constituent. The springs are, with very few exceptions, near the borders of the streams below beds of limestone. It is possible that underneath the vast masses of volcanic material which compose the mountains on every side, the sedimentary rocks exist; but Mr. Hayden is disposed to believe that they occur only in isolated and much restricted patches, if at all.

It may therefore be stated, in general terms, that the great hot-spring region of the Yellowstone and Missouri rivers is covered with rocks of volcanic origin, of comapratively modern date.

NOTES

AT their Statutory Quarterly Meeting on Monday, the Trustees of Anderson's University, Glasgow, elected Mr. George Forbes, B.A., F.R.S.E., of St. Catherine's College, Cambridge, to the vacant professorship of Natural Philosophy. There were originally eleven candidates for the appointment, but one of them died before the day of election arrived. Prof. Forbes is by inheritance, as well as by inclination and education, a man of science. The son of the late Principal, James D. Forbes, F.R.S., of St. Andrews, he received his university training at St. Andrews, Edinburgh, and Cambridge, and has since had the benefit of practical training in physical science at the Royal Observatory under the Astronomer Royal, and on the Continent. In making the appointment, the Andersonian trustees acted on the advice of Sir Wm. Thomson, Sir G. Biddell Airy, K.C.B.; Prof. P. G. Tait, Edinburgh; Prof. Balfour Stewart, Prof. A. S. Herschel, Profs. W. H. Miller and J. C. Adams, Cambridge; Prof. Grant, Glasgow Observatory, and other eminent physicists. It is understood that this professorship is to be established on a more extensive basis than formerly. This would offer to the professor a wider field of useful employment by developing the resources of the professorship, not only through the extension of the system of lecturing, but also by the establishment of a physical laboratory for students, which, it is understood, is in contemplation. Mr. Alexander Lindsay, of Glasgow, has also been elected Professor of Medical Jurisprudence. It was intimated to the meeting that Mr. J. Tennant, of Rollox, has given a donation of 1,000*l*. to the University.

THE following lectures on subjects connected with Physical and Medical Science will be delivered at the University of Cam-

bridge in the Michaelmas Term :—"Heat and Electricity," by the Professor of Experimental Physics (Mr. Maxwell), on Mondays, Wednesdays, and Fridays, at 12 M. ; begin October 23. "Chemistry," by the Professor of Chemistry (Mr. Liveing), on Mondays, Wednesdays, and Fridays, at 12 M. ; begin October 21. "Practical Chemistry," by the Professor of Chemistry, on Mondays, Wednesdays, and Fridays, at 1 P.M. ; begin November 4. "Zoology and Comparative Anatomy," by the Professor of Zoology and Comparative Anatomy (Mr. Newton), on Mondays, Wednesdays, and Fridays, at 1 P.M. ; begin October 21. "Anatomy and Physiology," by the Professor of Anatomy (Dr. Humphry), on Tuesdays, Thursdays, and Saturdays, at 1 P.M. ; begin October 22. "Practicar Anatomy," by the Professor of Anatomy and the Demonstrator of Anatomy (Dr. Wilson), at 9 A.M. daily till October 21 ; after wards on Mondays, Wednesdays, and Fridays ; begin October 7. "Materia Medica and General Therapeutics," by the Downing Professor of Medicine (Dr. Fisher) or his deputy, on Tuesdays, Thursdays, and Saturdays, at 9 A.M. ; begin October 22. "Clinical Medicine," by the Regius Professor of Physics (Dr. Paget), on Mondays, Wednesdays, Thursdays, and Fridays, at 10 A.M. ; begin October 10. "Clinical Surgery," by C. Lestourgeon, M.A., on Tuesdays and Thursdays, at 11 A.M. ; begin October 22. Attendance on the lecture on Botany, Chemistry, Materia Medica, Anatomy, Physiology, and Dissections is recognised by the Royal College of Surgeons, England, as one of the sessional courses required by the regulations of the Council of that College.

WE understand that Mr. Darwin's new work on "Expression in Animals," a subject to which he has devoted great attention, will shortly be published in this country, as well as a German translation by Dr. Carus.

LORD CATHCART, the President of the Royal Agricultural Society, has offered a prize of 100*l.* for the best essay on the causes and remedy for the potato disease.

ON Saturday morning a conference was held in St. Thomas Charterhouse Schools to inaugurate a system of Science Teaching for Elementary School Teachers. The Rev. Evan Daniel, Principal of Battersea Training College, was voted to the chair, and there was a very large attendance of teachers of both sexes. The chairman spoke strongly of the necessity of immediately starting an institution for the efficient teaching of science. On all sides, he said, there was an outcry for it. All provisions hitherto made by the Government for the teaching of science were wholly inadequate. The school is to be known as the St. Thomas Charterhouse School of Science, and its programme for the ensuing session, which commenced on Monday evening last, shows that, in addition to the evening classes, there will be day classes for general students. The subjects include chemistry, geology, mathematics, animal physiology, acoustics, vegetable anatomy and physiology, magnetism and electricity, botany systematic and economic, plane and solid geometry, music, &c. Several professional lectures will be given during the session, and biology students will have opportunities of making microscopical observations. Any communications or inquiries should be addressed to Mr. C. Smith, the organising teacher.

THE Royal Microscopical Society will hold its first meeting for the session on Wednesday, Oct. 2, at King's College, at 8 P.M.

CAPTAIN BURTON, who has been exploring the unknown interior of Iceland, has returned to England. His collections, &c., we believe, are at present left in the care of the Anthropological Institute, London, as he had to leave England at once in order to take up his appointment as Consul at Trieste, to which he was appointed on the death of the late Mr. Charles Lever.

THE Academy of Sciences of Bologna has resolved to give in 1874 a prize of 1,200 francs *(prix Aldini)* for the best scientific experimental essay on Galvanism or Dynamic Electricity. The competition remains open till June 30, 1874 ; the works may be either written or printed, but in the latter case they must not be published before 1874 ; and then they may be written either in Italian, Latin, or French.

THE Academy of Sciences of Vienna instituted in 1869, for the purpose of encouraging astronomers to search for comets, eight special prizes, which it has kept up each year since as part of its programme. Each of these prizes consists of a gold medal of the value of 20 Austrian ducats (between 9*l.* and 10*l.*) They are intended to reward observers who discover a telescopic comet, or a comet visible only by telescope at the time of its discovery. One condition is that the comet has not previously been seen, and that its appearance has not been previously proved with certainty. The discovery should be immediately announced to the Academy by telegraph or otherwise without waiting for further observations, the Academy undertaking to notify at once to the different observatories the fact of the discovery. The place and time of the discovery ought to be indicated, as well as the position of the comet and its orbit as exactly as possible with the first intimation ; the data should be completed at leisure by further observations if it be possible to make them. When the comet has not been seen by other observers, the prize will be presented only when the observations of the discoverer have been sufficient to enable the orbit to be determined. The prizes are decided each year at the general meeting of the Academy held at the end of the month of May. If the first announcement of the discovery reaches the Academy between March 1 and May 31, the prize cannot be decided till the following year.

THE Society of Science and Arts of Utrecht offers prizes for papers on the six following subjects :—1. Experimental Researches upon the Inhibitory Nerves. The author must not restrict himself to a mere critical review of existing opinions on the subjects ; he must elucidate them by new experiments. 2. Researches on the development of one or more species of invertebrate animals whose history is not yet known ; the paper must contain all the illustrations necessary to the understanding of the text. 3. Researches upon the influence which slight variations of external circumstances may exercise upon the evolution of the embryo of one or more species of invertebrate animals. 4. Description of the larva and nymph of the common cockchafer, to complete the monograph on that insect in its perfect state by Strauss-Durckheim. This must be accompanied by the necessary figures. 5. Researches to determine the normal variation of the temperature of at least thirty-five places in the northern regions of Europe. The monthly means of old observations ought to be reduced so as to agree with the time at which the observations are actually made. 6. To investigate and point out how the waters of the rivers which traverse the Netherlands could be purified so as to become drinkable without detriment to the public health ; at the same time to indicate the probable expense of their application on a large scale. Each of the prizes will consist of a medal of the value of about 27*l.* sterling, or its equivalent in money. The papers may be written in French, Dutch, German (Roman letters), English or Latin. They ought to be sent to the Secretary of the Society, M. N. F. Van Nooten, before December 1, 1873, the name and address of the author ought to be attached to each memoir in a sealed envelope.

DEMERARA papers record the death, in the early part of the summer, of Mr. C. F. Appun, an enterprising naturalist who had done much to explore both the physical features and the

natural productions of the colony. He had previously travelled through Venezuela, Brazil, and the Amazons Valley, and had sent considerable collections of plants both to this country and to Germany. His journal has been printed in the *Georgetown Gazette*, and we hope to give extracts from it on a future occasion.

THE Council of the Vienna Exhibition have decided on having a permanent aquarium erected in that city, and the plans of Mr. H. Driver, C.E., who erected the aquarium at the Crystal Palace last year, have been approved.

WE understand that it is not the intention of the Board of Managers of the London Institution to fill up the vacancy occasioned by the decease of Mr. J. C. Brough, F.C.S. until after November.

THE *Newcastle Chronicle* states that some gentlemen connected with the mining interest have for several days been prosecuting their inquiries in the neighbourhood of Waterford with reference to the existence of coals in that portion of county Kilkenny which lies between the Suir and the Barrow, and has a communication with both of these important rivers. The geological maps give no indication of coals in this locality, but the result of inquiries prosecuted with much intelligence has led to the discovery of a coal bed of immense dimensions in this district, about two miles from Waterford, and within easy access to the river Suir. The coal seam to the thickness of 10 ft. lies immediately under the Old Red sandstone, the lower strata being a very fine outcrop of silicate of magnesia. The coal shales come to the surface at the cross road, about half a mile beyond the chapel of Sheverne. The arrangements are in a state of great forwardness for an immediate start, and a number of English miners are daily expected. If the hopes of these parties—and they appear to be well founded—are realised, it will afford a vast amount of employment, and will give the south of Ireland an almost unlimited supply of fuel. We need hardly point out that our Newcastle contemporary must have fallen into an error in speaking of the coal-seam being found *under* the Old Red sandstone.

WE are glad to see that Professor Piazzi Smyth, Astronomer Royal for Scotland, has at last got the reward of his twenty years' persevering and creditable importunity in the shape of a new equatorial telescope for the Royal Observatory on the Calton Hill, Edinburgh, for which Government last year granted 2,300*l*. Hitherto, as the *Scotsman* justly remarks, the Metropolitan Observatory of Scotland has been in the position of the meanest appointed Government astronomical institution in Scotland. To accommodate the new telescope, it is necessary to raise the dome of the Observatory, and Mr. James Fergusson, author of the "History of Architecture," who was consulted on the matter, has decided that the new dome could not be raised more than fourteen inches—that being the largest increase that could be æsthetically allowed in conjunction with the rest of the Observatory, which, viewed as a piece of architecture, is considered to be the very gem of the works of the late William Playfair. In consequence of this the Astronomer Royal has had a difficult task in endeavouring to arrange a form of equatorial instrument which would give a greater amount of power within a smaller line or compass than was ever attained before. The new telescope will have an aperture of two feet upon a focal length of only ten feet—a larger diameter in proportion to focal length than any astronomical telescope yet introduced into any observatory; and it will no doubt be by far the most powerful instrument ever erected under so small a dome. Although the telescope will be much more powerful than any ever before placed in the Observatory, it is still not such as was desired or considered almost necessary in the present state of science. The instrument, which is being built by Mr. Howard Grubb of Dublin, is to be constructed on M. Foucault's comparatively new principle of having the speculum of glass coated with pure silver. The instrument is to be employed both for photography and spectroscopy. Both these classes of research require the seemingly impossible accompaniments—that the telescope must have the utmost amount of firmness, and also have the most accurate possible movement at the same rate at which the stars change their position in the sky. Notable features in the new telescope will therefore be the remarkably perfect clockwork apparatus, the several devices connected with the prisms of the spectroscope, the means by which not merely celestial objects will be kept in view, but those by which the rays of chemical flames will be brought into comparison with the light of the stars. The extremely delicate measuring apparatus to be applied to the respective subjects as they appear on the spectrum will also be noteworthy. December next is the time fixed for the completion of the new instrument, but meanwhile active preparations are being made in the Royal Observatory for its reception. The new dome, it is expected, will be erected in the course of this month, while the weather is yet fine. This dome, which is also being built by Mr. Howard Grubb, will be of iron instead of wood, and that for two reasons: first, because it will afford a greater amount of space in the interior of the instrument room; and second, because it will enable such an arrangement being made for the shutter as will allow of an opening several feet in breadth, whereas the opening in the old dome was only a few inches wide. Although the arrangements of the Observatory are, during operations, necessarily somewhat upset, observations continue to be made by Prof. Piazzi Smyth and his assistants.

IN accordance with the decision of the Scientific Association of France, systematic and simultaneous observations on shooting stars have been made during August in various places in France, Italy, and at Alexandria. The chronometers of the various stations were compared by telegraph, the signals being given from Bordeaux, Lyons, Marseilles, and Paris. The results of the simultaneous observations at the various stations are recorded in the *Bulletin Hebdomadaire*, from which we learn that on the nights of August 9, 10, and 11, observations were made at twenty-two stations; Alexandria and Moncalieri being those from which the greatest number of shooting stars were seen, 2,042 having been noticed during the three nights at the former, and 2,049 at the latter place. It will be remembered that in November last the whole of the shooting stars did not come from Leo, as it was expected they would, and that the observers noticed radiant points in Taurus, Gemini, &c. Somewhat similar eccentricities, though upon a less scale, appear to have occurred during the August shower. At Genoa, about the half of the stars came from various directions; M. Stephan, at Marseilles, intimates that on the third night the radiant point was in Cygnus; and at Paris, M. Tremeschini found that on the third night the majority of the stars did not come from Perseus. MM. Le Verrier and Wolf, who have been charged with the arrangement of the various observations, have presented to the Academy the results of the work done last November, and expect to be able to do the same for that of August, soon after they receive detailed reports from the various observers. For the discussion of the common observations, the astronomers at their meeting at Montpelier decided to employ the method proposed by Colonel Goulier, which however can be applied only when the stars are at least 10° above the horizon; when otherwise, the methods followed by MM. Lespiault and Stephan will be used. M. Goulier has been charged with the construction of the charts of his system; M. Lespiault with the preparation of the method to be followed when the trajectories are at a small elevation above the horizon; and M. Wolf with the final arrangement of the complete results.

BIELA'S COMET

MR. J. R. HIND has addressed the following letter to the *Bulletin* of the *Association Scientifique de France*:—

You will probably think me rather sanguine in supposing for a moment that there is a chance of re-discovering either nucleus of Biela's comet this year, when in the ordinary course of things a perihelion passage would be due. I look at the matter in this light. We know that in February 1846 a very remarkable alternation of brilliancy took place: that the second nucleus, barely discernible at first, so greatly increased its light as to surpass what I will term the parent-nucleus, and continued thus several days, when it gradually faded. Again in September 1852, M. Otto Struve's drawings show the same remarkable interchange of light between the 20th and 25th. Whatever the cause may be, each nucleus appears to have a re-vivifying power, so to term it, and I think it is just possible this may be exercised at one time or other to such an extent as to bring the comet again within our grasp, though its condition in 1865-1866 may have been such as to render it quite invisible from the earth. In this idea of the subject, I have prepared sweeping ephemerides for September and October, part of which (that applying to next absence of moonlight and longer) I now do myself the honour to send you. The mean motion in Dr. Michez's orbit from 1866 would bring the comet into perihelion 1872, October 6·4, and I have calculated places on this supposition, also with variations of ± 8d in perihelion passage. Clausen carried forward the perturbations of both nuclei in 1866, and his elements for that year would indicate (of course, neglecting perturbation 1866-1872) the following times of perihelion passage.

Nucleus I . .	1872 Oct. 4·776	Greenwich
Nucleus II . .	,, Oct. 7·256	,,

and hence these differences of R. A. and N. P. D. between the two nuclei, which, if one is only found, might be useful in bringing to light the other.

	R A (I—II).	N. P. D. (I—II).
	° ′	° ′
Sept. 12 . . .	+ 1·59 . . .	+ 0 55
,, 20 . . .	+ 1·50 . . .	+ 0·57
,, 28 . . .	+ 1·42 . . .	+ 0·55
Oct. 6 . . .	+ 1·34 . . .	+ 0·50
,, 14 . . .	+ 1·26 . . .	+ 0·44
,, 22 . . .	+ 1·18 . . .	+ 0·37

Perhaps there may yet be time to interest some of your many correspondents in a search for Biela during the first ten days of October. Here the weather has been exceedingly unfavourable, and, though I have watched assiduously, there has not been a single opportunity of examining the eastern heavens in the morning during the last period of absence of moonlight.

I remain, etc.

J. R. HIND

Observatory, Twickenham, near London, Sept. 17

SWEEPING EPHEMERIDES FOR BIELA'S COMET

Mr. Hind, in a letter with which he has favoured us, states that M. Stephan, the Director of the Observatory of Marseilles, will employ the large Foucault mirror of that establishment in a search for the comet.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

THE session of this Association opened at Dubuque, Iowa, on August 21. At the end of last year's meeting it was expected that the Association would meet this year at San Francisco, which place it was hoped Prof. Agassiz would have reached in the *Hassler* by the time of the opening, and added an unusual brilliancy to the proceedings by an account of some of his discoveries in the Southern seas. The great naturalist, however, as we know, has not yet reached the Californian coast; and partly on this account, but mainly, we believe, on account of the great expense to most of the members of a journey to San Francisco, that city has not this year been honoured with the presence of the associated *savans* of the United States. Indeed, if we may judge by the somewhat diminished attendance, and the unusually small number of papers read, even Dubuque seems to be too far away from the homes of many of the members. Some of the prominent members of the American Association were absent this year, the many, however, who did attend, met with a very liberal reception from the citizens of Dubuque.

The retiring president of the last year, Prof. Asa Gray, of Cambridge, Mass., made, as is the custom, a valedictory address. He took the opportunity to sketch his recent experience at the West as a botanist, for, strange to say, until the present summer he had not seen the Mississippi nor set foot upon a prairie. Prof. Gray touched lightly upon the history of the Sequoias; that their age must be counted by hundreds of years we cannot doubt; but also we cannot doubt that they did not antedate the glaciers whose icy expanses have left their indisputable evidences everywhere around. The main portion of Prof. Gray's address was devoted to showing the probability that certain trees of the present day, the *Sequoias* of California, the *Taxodium*, or Bald Cypress of the Atlantic, and the *Glyptostrobus*, a Chinese tree, the only ones of their tribe at present existing, were not only closely allied in structure and general characteristics, but were the lineal successors by gradual modification of the fossil trees of geological ages; and that all our existing vegetation was a continuation of that of the Tertiary period. Three hypotheses are open to account for their present existence: either they were created in the detached regions where they are now found; or they are the first members of a new and increasing race; or they are nearly the last representatives of a once powerful and widely-spread tribe. After discussing the first two alternatives, Prof. Gray gives his reasons, which are supported by palæontological evidence, for believing that the "big trees" of California are the last of their race, and that a little further drying up of the climate, which is now in progress, will speedily precipitate their doom. The oldest of the trees now standing he considers to possess an antiquity of about 2,000 years.

A paper was read by Prof. E. S. Morse "On the Oviducts of the Brachiopods." He brought forward for the first time a few facts regarding the development of a species of Brachiopod from the coast of Maine. The various stages in their development, he believed, fully supported the position he maintained, that the Brachiopods were true worms and not molluscs.

Prof. Benjamin Peirce, Superintendent of the United States Coast Survey, gave an exceedingly interesting account of the measures taken by that Bureau with reference to stations for astronomical observations at great heights, such as Sherman, on the Rocky Mountains. Prof Young, of Dartmouth College, has been appointed to examine and give an opinion as to the effect of taking observations from the Rocky Mountains and Sierra Nevadas. Prof. Peirce's opinion was that observatories should be placed on the summits of both, if not permanently at least temporarily, the Rocky Mountains being favourable to some, the Sierra Nevadas more favourable for other observations. In a higher position you get rid of absorption of light by getting rid of half the

atmosphere. Prof. Young reports the whole number of lines in the chromosphere seen from Sherman as 150, which is three times as great a number as have been observed before. This fact alone shows that higher points should be resorted to for astronomical observations. The next element of success depends upon the steadiness of the atmosphere. It can be said in reference to this, that a star has been recognised at these high altitudes as having a companion, or being a double star, not previously known as such. An observer on the Pacific coast reports to Prof. Peirce that he can see the companion of the star Polaris from a high point on the Sierra Nevada. It is well known that this is a test of great nicety, requiring the utmost purity of atmosphere. The best work in astronomy is done in the few best nights at any place, and by these alone the value of the position must be determined.

Prof. Peirce showed that the necessities of the Coast Survey extended its operations to all parts of the United States. To prove the paths by which vessels can best traverse the ocean, to test the best methods by which 2 000,000,000 dollars of values shall be carried from the West to the East, from the East across the Atlantic, or from the shores of China and Japan to the Pacific coast, and thence across the country, was the business of the Coast Survey. All the United States is deeply interested in every part of the subject. Every ship that is lost by imperfectly surveyed harbours is a loss to the whole country. If the coast survey were thorough, and maps were fully representative of ascertained facts, a pilot would scarcely be necessary, but yet never could be entirely dispensed with, especially in bad weather. The pilots discovered that by putting down every rock that they knew of, they made maps that frightened the captains of vessels into employing them. Hence these practical observers have added immensely to the number of facts accumulated by the Coast Survey.

Prof. Peirce explained why he considered it unnecessary to carry out at present so thorough a survey of the Pacific as has been made of the Atlantic coast. The needs of the commerce of the coast is the standard by which the work of the survey is determined. He took occasion to mention that the *Hassler* expedition was at the expense of private individuals, principally of Boston, and was not at the expense of the Government. A general geodetic connection has been effected in these observations, so that the whole United States will benefit by them; and the points will be taken so as eventually to procure a complete survey of the whole continent, passing through each State and the large cities. It is a work that may take a century. It is the hope of Prof. Peirce that this survey will not only be the best in the world, but that its details will be such that before long there will be no necessity for railroad surveys—the facts will be spread everywhere. As to the higher operations of the Coast Survey, their ultimate expression will be an accurate determination of the figure of the earth. Observations in America he thinks are more successful and free from local irregularities than in Asia or Europe. Yet there are some such local irregularities here—notably one near Boston, where there is some strange deviation of density from the surrounding country.

Prof. J. W. Foster, of Chicago, read a paper on what he considers a new species of fossil elephant, called by him *Elephas Mississippiensis*. He presented to the association a fossil tooth found in Indiana, and which he regards as differing specifically from that of any other fossil elephant found in America or on the Continent. The differences are so great that he holds them sufficient to constitute the new species.

Prof. J E. Parry, who had been in a good position for studying the subject, made a few remarks upon the glacial deposits of Northern Ohio. Prof. Foster took exception to several of his positions.

A very interesting paper was read "On the Mounds of Dubuque and vicinity."

A somewhat warm discussion took place on the 23rd between Dr. F. H. Day of Wisconsin and Prof. Morse of Salem, occasioned by the former sending a paper to prove that the trilobite not only resembled the lobster in some respects, but was actually closely related to that crustacean, and must have been in structure and movements almost similar. Prof. Morse stoutly maintained that the congener of the trilobite at the present day was the *Limulus*, not the lobster.

On the same day Prof. F. W. Putnam of Massachusetts, editor of the *Naturalist*, read a brief and well illustrated paper on certain "Stone Carvings of the New England Aborigines."

Prof. E. B. Andrews of Ohio, the State Geologist, presented a paper on Coal, of both scientific and practical interest. The universal law of the accumulation of coal strata seems to be on horizontal lines, determined by water levels. The proof of this is in the marine organic remains found in the coal itself and its associated slates. In addition, there is a distribution through seams of coal of horizontal layers of fine sedimentary matter which constitute the clay partings of the seams. The subsidence which carries down the area of the coal-marsh, if it may be so called, is wide-spread in its character and equable in its movement, having a tendency to a continental rather than a local character. The result of this gives a horizontal parallelism to all the seams of coal at the time of their formation; and this is equally true where one coal-marsh is formed over another, making a series of coal measures. So far as Prof. Andrews's observation goes, a coal seam has never been accumulated on high grounds or ground above water-level; and such formations could not take place, because it would be impracticable to establish the conditions of accumulation on the side of a hill. Hence it is impossible in the nature of things that two distinct seams of coal could ever coalesce, since their subsidences must take place in parallel lines. To suppose otherwise would involve a very unequal subsidence over very limited area, amounting, indeed, to a convulsion of nature, which is almost incredible.

It has hitherto been to some extent conceded that the solidification of coal is an exceedingly slow process; and the popular notion is that there has been a complete accumulation of a series of layers of coal, &c., long before thorough hardening takes place. Prof. Andrews has, however, found instances indicating that the process of solidification, making complete coal, is comparatively rapid. Thus it appears that where a gulley has been torn out of a coal seam by a rapid current of water, the small boulders washed by it over the covering stratum of sand a few feet above, are complete coal, having an angular fracture, some being still sharp on the edges and some being slightly water-worn. These boulders in turn have again been covered by subsequent depositions, and are found at considerable depths, near the base of the coal measures.

There are three leading varieties of bituminous coal; the ordinary resinous or caking coal, the splint, and the cannel coal. These pass into each other by almost imperceptible gradations. The resinous coal seems to be the normal condition which the buried vegetation first assumes, and splint and cannel are modified forms, the cannel coal having lost all trace of structure, and containing no organised forms, except stigmaria, which is very abundant. The ash of coals is the original inorganic matter of vegetation, often increased by sedimentary matter in the marsh during the formation of coal.

Prof. C. A. White, of Iowa City, gave a general sketch of the geology of the State of Iowa, in which he stated that the extent of its coal measures was greater than the entire area of Massachusetts. The occurrence of quartzite in the north-eastern portion of Iowa he regards as of the Potsdam formation. There is a remarkable area of drift in the north-western part of the State, covering an area of at least 20,000 square miles so deeply that no rock crops through. Prof. Swallow thinks that the waters receding from this State went to the Pacific.

In the discussion which took place next day, on Prof. Andrews' paper, several geologists controverted his position that coal seams seldom or never diverged from each other within small areas, adducing instances to prove their statements. Prof. Andrews did not doubt that there were occasional instances of the sort, but in general he did not believe that there were frequent cases where seams separated widely. Seams of coal, as a rule, with rare exceptions, were of parallel levels from uniform subsidences.

On the evening of the 23rd, Prof. Morse delivered to a large and delighted audience a popular lecture on "The Locomotion of Animals," beginning with the lowest forms of animal life, and working his way upwards through all grades to man, illustrating his statements by a series of clever and rapidly-executed illustrations on the black-board.

On the 24th, the Association passed a resolution with regard to what is known in America as "the Chinese Indemnity Fund," the name given to a large sum which China overpaid in settling for damages to United States citizens, and which, when informally tendered to the Chinese Government, was declined, with the intimation that pressure on the subject would be hurtful to Asiatic pride. This fund now amounts to 450,000 dols., and a bill is now pending in Congress which proposes to appropriate this surplus for the education of Americans and Chinese "in the languages, literatures, and sciences of the respective nations; to facilitate commercial, diplomatic and scientific intercourse be-

tween the two peoples; and for the increase and diffusion of knowledge among men." It is apparently intended to accomplish this purpose by establishing an American college in China, and the resolution of the Association "heartily endorses the purpose of the aforesaid Bill."

In expatiating upon the propriety of this resolution, President Smith alluded to the insecurity of the present position of the fund in the hands of the United States Government, since it offered a premium for trumped-up claims, and already 37,000 dols had been thus abstracted from it; that if it remained much longer unappropriated, Japanese as well as Chinese claims would be introduced against it, and it might eventually suffer the fate of the Smithsonian funds, which the Government had to make good after the loss of a considerable portion.

During the course of the same day a scene of intense excitement and disorder took place on the reading of a paper by Prof. B. C. Swallow, the Missouri geologist, entitled "Good Wine a Social and National Blessing,' which was devoted principally to the details of wine making. It was, however, made an opportunity for the discussion of the causes of drunkenness, and the best means for preventing it, which had far more of a social than of a scientific interest.

A very interesting and valuable paper was that of Mr. C. V. Riley of St. Louis, entitled "Insects Shaped by the Needs of Flowers," with especial reference to the fructification of the American Yuccas. Dr. Engleman of St. Louis had this year discovered that these plants must needs rely on some artificial agency for fertilisation. The flowers are peculiarly constructed, so that it is impossible for the pollen to reach the stigma, it being glutinous and expelled from the anthers before the blossoms open. Prof. Riley discovered that there was a small white moth that did the work, and demonstrated on the blackboard how wonderfully well the insect was adapted to the purpose. This little moth, which he calls *Pronuba Yuccasella*, has been unknown to entomologists, and forms the type of a new genus. It is most anomalous from the fact that the female only has the basal joint of the maxillary palpus wonderfully modified into a long prehensile-spined tentacle. With this tentacle she collects the pollen and thrusts it into the stigmatic tube, and after having thus fertilised the flower she consigns a few eggs to the young fruit, the seeds of which her larvæ feed upon. He stated that the Yucca was the only entomophilous plant known which absolutely depended for fertilisation on a single species of insect, and that insect so remarkably modified for the purpose. There was a beautiful adaptation of means to an end, and a mutual interdependence between the plant and animal; and Mr. Riley explained how on Darwinian grounds, even this perfect adaptation was doubtless brought about by slow degrees. He alluded, in closing, to a practical phase of the subject. The plant and its fructifier are inseparable, under natural conditions, and the latter occurs throughout the native home of the former. In the more northern portions of the United States, and in Europe, where our Yuccas have been introduced and are cultivated for their showy blossoms, the insect does not exist, and consequently the Yuccas never produce seed there. The larva of *Pronuba* eats through the Yucca capsule in which it fed, enters the ground and hibernates there in an oval silken cocoon. In this stage the insect may easily be sent by mail from one part of the world to another, and our transatlantic florists may by introducing it soon have the satisfaction of seeing their American Yuccas produce seed without any personal effort on their part.

Among other papers read at subsequent meetings of the Association was one by Dr. J. W. Foster on the "Bird-shaped Skulls found in Indian Mounds," in which he tried to show that the peculiar shape of these skulls was not produced by compression, as in the case with the heads of many modern Indian tribes, but really belonged to a very early and comparatively low type of man intellectually.

Another paper was by Prof. Daniel Kirkwood on "Binary Stars with Extraordinary Orbits," with special reference to Mr. Wilson's communication to the Royal Astronomical Society, as to the orbits of the stars constituting Castor.

Mr. W. W. Wheildon of Concord, Mass., advanced in opposition to what is known as the Gulf Stream theory an atmospheric theory to account for ameliorations of climate and an open sea in Polar regions. He thought that there could be no question that if the whole Arctic region were of open water that fact would not account for all the atmospheric phenomena and warmth of temperature experienced by polar navigators. The theory of Prof. Wheildon is that open water, melting ice, rain after snow, and other phenomena of the sort in Arctic regions, are not caused by winds warmed by an open sea, but by a circulation of air in which warm winds descend from upper atmospheres; being a circulation by which winds heated at the equator reach the poles. The brief discussion which followed this paper did not indicate much difference of opinion on the subject.

Of course, there were the usual numbers of excursions to places of interest, including one to the curious "Picture" or "Calico" Rocks near the town of Macgregor, which are composed of Potsdam sandstone. Far up in a narrow glen, outcropping sandstone rocks, partially denuded, exhibit in narrow stripes and patches, but principally in linear horizontal directions, the greatest variety of colours. Red is predominant, but black, blue, yellow, and intermediate shades are not wanting, each being distinct and not unfrequently contrasting sharply with the adjoining stripe, or with a gray that is almost white. Probably the original sand was white; the colours indicate varying admixtures of iron oxides and carbonates. Another was to the Mississippi, apparently for the purpose of seeing and collecting specimens of the large lily or lotus of that river (the *Nelumbium luteum*), closely allied to the Egyptian lotus. The last excursion was to Sioux City, and was to last for three days.

Altogether this year's meeting seems to have given general satisfaction, and the hospitality of the Iowans was unbounded. Next year's meeting is to take place at Portland, Maine, on the third Wednesday of August, Prof. Joseph Livesing, of Harvard University, being the president-elect.

THE FRENCH ASSOCIATION MEETING AT BORDEAUX

THE first session of the French Association for the Promotion of Science, closely modelled after that at Britain, was held at Bordeaux from the 5th to the 12th of September, and seems in all respects to have been successful and satisfactory. As is usual at similar meetings everywhere, the citizens of Bordeaux lavished their hospitality upon the members, who well deserved this as well as the gratitude of the French generally for inaugurating a movement to spread among that nation a knowledge of and love for science, and thus inform and temper their often misleading enthusiasm; in the words of M. Quatrefages, "to renovate our country by the scientific spirit and scientific studies." The meetings were well attended both by French and foreign *savans*, though the only two English ones whose names we notice were Prof. Odling and Dr. Gladstone. The Society already numbers 800 members, and, as will be seen by M. G. Masson's paper, its finances are in a flourishing condition. The first general meeting was presided over by M. de Quatrefages (the president-elect for next year), in room of M. Claude Bernard, the state of whose health prevented him from attending.

The opening address of M. de Quatrefages, as acting president, was a very stirring and noble one, full of sound sense as to the recent humiliation and present condition of France, enthusiasm towards science, and faith in it as one of the most powerful regenerators of the country. "Science is at present supreme," he said; "she is becoming more and more the sovereign of the world;" and he believes that it is only when all ranks and classes of the people, rulers and ruled, are thoroughly imbued with the scientific spirit, and are guided by scientific knowledge, that France will ever again take and maintain the supreme place in the world which she ought to hold. M. de Quatrefages concluded with a graceful allusion to "our elder sister, the British Association."

After an enthusiastic speech from the Mayor of Bordeaux, M. Cornu gave a brief sketch of the history of the Association. The first idea of the Association, he tells us, originated among a group of French Alsatian students gathered around M. Combes, the late lamented director of the School of Mines of Paris, and it has been nourished by a patriotic desire to contribute to the moral condition of the dejected country. After the death of M.

Combes, M. d'Eichtal came to the assistance of the embryo association, and on January 17 of this year a provisional council was appointed, with M. C. Bernard as president, and on April 22 the French Association was constituted, and already numbers upwards of 700 members. The British Association when it started in 1831 had only 370 members, whereas now it numbers many thousands, and can spend 2,000*l*. yearly for the progress of science. M. Cornu hopes that the French Association may become similarly prosperous, as indeed it seems to bid fair to do, for already, as M. Georges Massen, the treasurer, intimated, it has a capital of 140,000 francs, and can dispose of an annual revenue of 16,000 francs.

M. Laussedat gave an interesting lecture on "The Services which Modern Science can render to the Art of War," in which the starting sentence is that "Germany triumphed over France by numbers, discipline, and science." This was followed by a paper from M. Le Fort, on the Reform of Military Surgery. In the meetings of sections which followed, medical subjects received permanent attention, and called forth many papers of great value.

In the Anthropological Section, M. Lagneau read a careful paper on "The Ethnology of the Populations of the south-west of France, particularly of the basin of the Garonne and its affluents," M. Paul Lopenard one on "Prognathism," in which he gave some new measurements, and described a new method of measuring skulls; M. Parrot gave some details of the Cave of Excideuil (Dordogne), the variety of bones and other remains in which are of the greatest interest to anthropologists. Most of the other papers in this section were on subjects similar to the last, the prehistoric remains of various kinds found in caves, dolmens, &c., a department of Archæology to which much more has been done in France than in this country. M. Cartailhac went the length of saying that two populations belonging to prehistoric times could be distinguished as inhabiting the south of France; one warlike and given to the chase, who knew the beds of flint, and could cut it to perfection, and which was armed with the bow; the other pastoral, seldom feeding on wild animals, ignorant of the arrow and the flint weapon, and which used quartz, ophites, and other stones, but seldom flint for making axes.

But little seems to have been done in the Botanical section, one of the most valuable papers having been that of M. Van Tieghem, expounding the result of his researches into "Germination," which had for their object to determine experimentally the connection existing between the various organs of the embryo, and the degree of dependence of the latter upon the albumen. Another elaborate paper was by M. Baillon, "On the Floral Organisation of the *Amentaceæ*, and especially the Hazel."

Some of the most valuable and interesting papers of the meeting were read in the Section of Physics; the first, and one of the most attractive, was by M. A. Lallemand, President of the Section, "On the Polarisation and Colouration of the Atmosphere." The researches of M. Lallemand have been conducted on the basis of a theory which explains at once the origin of aërial polarisation, the formation of the neutral points indicated by Arago and Babinet, and the blue colour of the atmosphere. According to him, atmospheric illumination is only a particular instance of the phenomena of illumination of transparent bodies by a pencil of non-polarised solar rays. The generation of neutral points is explained simply by the intervention of the dust and atmospheric corpuscles which abound in the lower layers of the atmosphere, in the centre of which the observer finds himself placed. This paper was followed by another by M. Soret, of Geneva, "On the Influence of the Atmosphere upon the Intensity of Solar Radiation." The new experiments of M. Soret have been made by means of two calorimeters made upon the same principle and of analogous construction. The first, which is described under the name of "Actinomètre Transportable," is of small size, and consists simply of a metallic tube open at one end surrounded by a second concentric envelope. The interval between the two is filled with ice. At the bottom of the tube is fixed a thermometer, whose stem crosses the two envelopes, and upon which the sun's rays are allowed to fall. The thermometer, zero at the outset, rises in proportion as the quantity of heat which it receives equals that which it loses by radiation. The temperature which it finally reaches enables us to deduce the intensity of the solar radiation, after a certain number of corrections, the principal of which relate to barometric pressure. The Fixed Actinometer differs from the preceding only in its greater size, which allows of four thermometers being used instead of one: the inclosed interval is maintained at a constant temperature by a current of water. The experiments made by means of these instruments have enabled M. Soret to ascertain, in the first place, that the more moisture there is in the air, the less is the intensity of solar radiation for the same height of the sun and the same atmospheric pressure.

In the same section, M. Cornu presented a detailed sketch of the dark rays in the ultra-violet part of the solar spectrum, following the scale of the wave lengths adopted by M. Angström in his memoir on the normal spectrum of the sun. These sketches have been made from the micrometric measurement to the microscope of photographic plates, forming two series. The first series has been obtained with the assistance of Nobert's network (of 1801 lines), of which the second spectrum was very perfect and very luminous; the proof obtained contained the rays G, H_1, H_2, L, M, N, O, P, and even Q, although the object glasses of Gonionde were of crown and flint glass. M. Cornu has verified the correctness of the measures of M. Mascart; the comparison of the results has always shown four common figures in the numerical expression of the wave-lengths. The second series, intended to furnish details of the rays of the photograph, proceed from a spectrum much dispersed and of great delicacy; more than twenty-five were counted between the two rays H_1 H_2. This spectrum was obtained with a flint prism of 60°; the moist collodion had taken an impression even up to the ray O, in spite of the absorbing power of the two object-glasses. M. Cornu strongly recommends the use of these ordinary achromatic object-glasses for obtaining photographs of the ultra violet region, when it is desired to go no farther than ray O; the inconvenience of the absorbing power is largely compensated for by the ease of setting in position and by the angular size of the region where the lines are clearly distinguished. With regard to the process itself, it differs but little from that of M. Mascart. M. Cornu, however, advises the adoption of a small dark chamber exterior to the telescope, in place of the photographic camera of M. Mascart. The advantage of employing collodionised surfaces sufficiently large to make room for the spots and other defects, arises from the thinness of the plate. M. Cornu further indicates upon his sketches the principal lines of magnesium, lime, manganese, and iron, which, as is known, compose the greater part of the groups, L, M, and N.

M. Saint-Loup followed with a paper on a proposed modification of Holz's machine. Other papers of interest in this department were by M. Potier on "The Elliptical Polarisation produced by Vitreous Reflection;" by M. Petit on a Modification of the Ordinary Telegraphic System, by means of which the telegraph may be made to print directly; M. Descloizeaux a very curious paper on some of the Optical Phenomena of Crystals; and M. Gariel on the Distribution of Magnetism in Magnets.

In the Chemical Section, presided over by M. Balard, M. Berthelot read a paper of considerable practical value "On the State of Bodies held in Solution," in which he brought much discrimination and research to bear upon some of the ordinary problems of Chemistry, especially upon molecular mechanics. Other papers in this section were by M. Jungfleisch "On the Transformation of Tartaric Acid into Racemic Acid," and by M. Filhol "On the Nature of the Sulphuric Composition of the Mineral Waters of the Pyrenees."

In the Section of Zoology, under M. Soubeiran, various interesting papers were read, including one by M. Chatin, "On the Odoriferous Glands of some Mammiferous Animals;" one by M. Jobert, "On the Organs of Touch in Fishes;" one of considerable interest by M. Soubeiran, on the Oyster Culture at Arcachon; and one by M. Pouchet on the Colourisation of Fishes.

The Geological Section was presided over by M. Raulin, Professor at the Faculty of Sciences at Bordeaux, and in the section devoted to Mathematics, Astronomy, Geodesy, and Mechanics a paper was read by Madame Hureau de Villeneuve "On the Mechanism of the Flying Apparatus of Birds." She was preceded by M. Respighi, who read an able paper on the Scintillation of Stars. In accordance with a long series of observations made by him, he showed that the changes in brightness and colour presented by stars near the horizon are caused by momentary and successive deviations of luminous rays of different colours,

by which these rays are carried outside of the object-glass of the telescope or the eye of the observer. These deviations are produced by extraordinary refractions or irregularities in layers of air condensed or rarified, placed at great distance from the observer, and at the precise spot where by atmospheric dispersion the rays of the different colours directed by the object-glass are separated from one another, so as to be only partly contained in the irregularly refracting layers of air. The most important result of M. Respighi's observations is this:—the layers of heterogeneous air are not reached by the luminous rays of different colours by means of the internal movement of atmospheric masses, but by their general movement caused by the rotation of the earth; which shows that the rotation of the earth is one of the principal elements in causing the twinkling of the stars. M. Respighi next described a very ingenious zenith telescope by means of which he can obtain the zenith distance of stars in their passage across the meridian.

In the Section of Geography, Political Economy and Statistics, various papers were read on methods of education.

The first session of the Association lasted eight full days, during which excursions were made to Arcachon, and to the Troglodyte Caves of Eyzies. On the condition and civilisation of the people whose remains they contain, M. Broca gave a very interesting lecture, in which he concluded that these men were savages, but in a state of partial civilisation, having at their disposal abundant food, and consequently leisure, applying themselves to the arts, and already exhibiting the perfectibility of the race. Another excursion was made to the Pointe de Grave, and one, which lasted three days, to the Industrial and Scientific establishment of Landes as far as Bidassoa. The Monday, Wednesday, Thursday, and Friday were devoted to *séances*, the morning for the sections, and the afternoons for general meetings. These public meetings were well attended, especially the evening lectures of MM. Broca and Cornu, who had audiences numbering about 800. Much interest was also manifested in the narratives of MM. Janssen and Respighi, who recounted the results of their researches into the constitution of the sun, and of their visit to India last year.

The reports of the Congress speak in lavish terms of the hospitality and considerateness in all respects of the Bordelais, whose city seems to be one of the foremost in France in respect of educational and scientific institutions. There can be no doubt about the success on the whole of the first meeting of the French Association; and we only hope that by the time it re-assembles at Lyons next year it will have advanced to the same ratio as it has done from its foundation till now, and that ere very long it will have taken as firm root as a recognised and universally beneficial French institution, as the British Association has done among ourselves.

ON PULSE FREQUENCY AND THE FORCES WHICH VARY IT *

THE circulation of the blood is an uniform circulation, the pulsations being neglected, and a uniform circulation is one in which the quantity of fluid flowing through all segments of the circulating system is the same; otherwise there would be a tendency for the fluid to accumulate at certain points, which is contrary to the premises.

To arrive at precise conclusions respecting the circulation there are two points which must be considered—1st., The laws which regulate the flow of fluids through capillary tubes. 2nd., The variations in the capacity of the circulating system under different pressures. These will be considered separately. Poiseuille found that the flow of fluids through capillary tubes varies directly as the pressure and as the fourth power of the diameter of the tubes. The author has verified the former of these results on the vessels of the animal system by a different method. Respecting the capacity of the arteries and ventricles under different blood pressures, it is evident that the capacity of the former must depend on the pressure only, for they are simple elastic tubes, and must be more capacious under high than under low pressures; reasons are given below for a more precise statement of this relation. To maintain a uniform circulation with a pulsating motor, like the heart, it is evident from the above considerations that variations in the resistance at the small arteries must produce variations in pulse-rate; and that unless the capacity of the arteries and heart vary directly as the pressure, variations in blood pressure must be also attended with change in pulse frequency. That the capacity of the ventricles is dependent on the arterial blood pressure can be proved by the varied amount of opening up of the ventricular cavities which follows different fluid pressures in the coronary arteries.

Next, the different forces which vary the pulse-rate must be considered. It can be shown that any change in the resistance to the flow of blood through the capillaries varies the pulse-rate, increased resistance rendering the pulse slower and the reverse. As instances of these effects may be given, the pulse-slowing effects of stripping in a cold air, of a cold bath, and of compression of large arteries; the pulse-quickening effects of a hot bath, whether air or water. Numerous experiments by the author prove that the effect of copious blood-letting is not to modify the pulse-rate at all, thus showing that the law given by Marey respecting pulse frequency is not correctly based. The above points, namely the law of Poiseuille, the dependence of the capacity of the arteries and ventricles on the pressure of the blood, the dependence of the pulse-rate on the peripheral resistance and its non-dependence on the blood pressure, can all be correlated by only one theory, namely, that the heart always re-commences to beat when the tension or pressure in the arteries has fallen at invariable proportions, which also assumes that the capacity of the heart and arteries varies directly as the pressure. The facts that the arteries are generally empty after death, and that the cavity of the heart is sometimes found to be obliterated on *rigor mortis*, show that absence of pressure and capacity go together.

This theory explains the known peculiarities in pulse rate attending change in position, by showing that while standing all the pressure of the body weight is borne by non-compressible rigid tissues and so the circulation is normal, but while lying, the soft parts are compressed and resistance introduced into the circulation, reducing the rapidity of tension-fall, and therefore the frequency of the pulse; an intermediate condition attends the sitting posture. The pulse quickens during inspiration, and becomes slower during expiration; for during the former act the reducing pressure in the chest lowers the aortic blood pressure, and makes the tension-fall more rapid, while in expiration the reverse occurs.

This theory also is the only one which throws light on the cardiograph law published by the author (see *Journal of Anatomy and Physiology*, 1870-73), which may be thus stated —For any given pulse-rate the first part of the heart's revolution has a constant length, but it varies as the square root of the length of the complete pulsation. The pulse-rate not depending on the blood pressure, and the length of the first cardiac interval not varying when the rate is constant, its length also does not depend on the blood pressure. The first cardiac interval may be divided into the systole and the interval between that and the closure of the aortic valve (the diaspasis); these combined not varying as the blood pressure, it is almost certain that separately they do not do so either; so it may be said that neither the length of the systole nor of the diaspasis depends on the blood pressure. But the fall of tension between the pulse beats being but small, and the diaspasis length not depending on the blood pressure, there is no reason why it should vary in length with different pulse-rates; and assuming this in connection with the measured diaspasis length in a particular case (·00183 of a minute), it can be deducted from the above cardiograph law, that the systolic length varies as the square root of the diastolic. From these facts the relation of the nutrition of the heart to the time of heart nutrition (diastole); and to the blood pressure, may be deduced; for the systolic length not varying with the blood pressure when the pulse rate is constant it is evident that the cardiac nutrition must vary directly as the blood pressure in the aorta; and the systole varying as the square root of the diastolic time, shews that the nutrition of the heart varies as the square of the time of nutrition (diastole), for with a quadruple resistance to the peripheral circulation, the heart would be four times

* Paper read before the British Association at Brighton in Section D, Department of Anatomy and Physiology,) by A. H. Garrod.

the time in emptying itself, but it is only double that time, which demonstrates the statement.

A complete logical explanation of the action of the pneumogastric can be given on this theory, by assuming that its function consists in diminishing the calibre of the small arteries of the coronary system, and always keeping them somewhat contracted.

PHENOMENA OF COAGULATION IN FROG'S BLOOD *

I WAS endeavouring in the autumn of last year, at Prof. Sanderson's instigation, to demonstrate upon the frog some of Brücke's fundamental experiments on the coagulation of the blood, which he performed on the tortoise; I was surprised at the apparent failure of some of them. For instance, having tied a glass tube into the animal's aorta and allowed it to fill with blood, I expected that which was in the tube speedily to coagulate, that which remained in the heart to continue liquid for a considerable time. But no such contrast was observable, both portions of blood remained perfectly fluid for an indefinite time. I say apparently, for, in fact, on subsequently turning out the blood, a slight film of coagulated fibrin was observable attached to the walls of the tube. Of course the corpuscles being the heavier gravitate to the bottom, and the blood thus becomes divided into two portions, a clear fluid above and a mass of red corpuscles below, with a thin filmy stratum of white again on the surface of the latter.

To show that the clear fluid is plasma and not merely serum, that is to say, that it fully retains its coagulability, it is sufficient to take a little up into a very fine, almost capillary, glass tube. The extent of surface to which it is thus exposed very quickly determines its coagulation.

Following up the subject still further, I found the same thing to happen when the blood is allowed to drop into a glass vessel, the whole remaining fluid, except that portion in immediate contact with the sides, the corpuscles subsiding as before, and the supernatant liquid being readily coagulable in a capillary tube.

But frog's blood does not always behave in this manner. It is not unfrequently the case, especially at this season of the year, that the blood of these animals behaves to all appearance precisely as we are in the habit of expecting that blood should behave, that is to say, the commencing subsidence of the corpuscles is arrested, the fluid solidifies, seemingly throughout. And, indeed, in rare instances, the coagulation is complete to the centre, and the mass soon separates into clot and serum, which latter, in these cases, never yields a coagulum in a capillary tube. More frequently, however, on breaking the surface with a knife, the interior of the coagulated mass is seen to be occupied by still fluid blood.

In either case, the coagulated fibrin soon begins to contract; and this contraction proceeds to such an extent that not only is the serum of the blood expressed from it, but it comes to pass that there is no longer room in its meshes for the involved corpuscles, which consequently begin to be squeezed out and to fall to the bottom of the glass. This diminution in volume of the clot may proceed so far that in the course of a few hours the blood may present an appearance precisely as if it had not undergone coagulation at all, there being a mass of corpuscles at the bottom of the vessel, and a clear supernatant fluid. The contracted remains of the clot may however be always found, although often obscured by the liberated corpuscles. Now, this disappearance of the clot of frog's blood under certain circumstances was noticed some years ago by v. Recklinghausen, and ascribed by him to a re-liquefaction of the fibrin; and not unnaturally, if we consider the astonishing diminution in bulk which it undergoes, and the fact that the serum in such cases is frequently found to yield a further coagulum.

But in every case of the latter kind, *i.e.* in every case in which the supernatant fluid yields a coagulum in a capillary tube, it will have been found that the primary coagulation was incomplete, *i.e.* that the central parts of the blood remained fluid, whereas on the other hand it is certain that when the primary coagulation has been complete, no further coagulum is *ever* obtainable, although, in this case also, the clot may have contracted to a relatively exceedingly small bulk, in fact, may have almost disappeared.

A further proof, if one were needed, that the diminution of the clot is due merely to contraction and not re-liquefaction of fibrin, is to be found in the examination under the microscope, using an immersion objective, of the process as it occurs in a very thin walled and fine capillary glass tube.

The phenomena here observed are wholly those of contraction; first simply serum, then white corpuscles, and finally red corpuscles being expressed, until a mere thread of fibrin remains, almost obscured by the corpuscles and still including a few.

Throughout the whole process, however, there is no trace of a re-liquefaction of fibrin; this would of course involve the dropping away of the corpuscles from the sides; on the contrary, they are most evidently squeezed out, some of them being actually ruptured in the passage and appearing on the exterior of the clot as small reddish spheroids. The facts then, briefly, are these: that frog's blood, especially if taken during the winter months, exhibits but very little tendency to coagulate, with the exception of the portion in immediate contact with a foreign surface; that, when apparently coagulated throughout, the central portions are very apt to remain fluid, and to impart coagulability to the expressed serum; that the clot when formed frequently tends to attain a relatively very small bulk; and, finally, that this diminution in bulk is due to contraction merely, not reliquefaction of the fibrin.

PHYSICS

Acoustic Experiments on the Seine during the Siege of Paris

IN the experiments made by Colladon and Sturm on the Lake of Geneva, in 1827, to determine the velocity of sound in water, the source of sound was a bell, weighing sixty-five kilogrammes, fixed to a boat immersed in the water near Rolle. Another boat, moored near Thonon, carried the observers, who employed a long acoustic tube made of metal, one extremity of which, widened and closed with a membrane, was thrust into the water. The distance from Rolle to Thonon is about 13,500 metres, so that the range of the sound was considerable. The water in that part of the lake is of great depth.

During the siege of Paris, the idea arose of establishing an acoustic telegraph by means of the Seine, between the invested city and provinces that had not been invaded. The Geneva experiments appeared to favour the proposal.

M. Lucas was charged by the Minister of Public Works to make some experiments on the subject, which he accordingly did in November, 1870. He gives an account of these to the Paris Academy.

In the first series, a bell weighing forty kilogrammes was lowered by a windlass from the bow of a barge, to a position twenty or thirty centimetres from the bottom. It contained a clapper, which was moved by means of wires carried up to the barge. Two workmen were charged to ring the bell at certain fixed intervals, while the observers, in another boat, marked the effect at different distances, being carried along by the current. The acoustic tube employed was 1·50m. long, and the membrane of its orifice, immersed in the water, was turned towards the bell. At the distance of a few metres, a dull sound was heard (like that of a drum beat with a drum-stick), at each stroke given to the bell. The intensity diminished with the distance, and the sound ceased to be perceptible at about 1,800 metres. The result was constant for experiments repeated at different parts of the river.

In a second series of experiments, a bronze bell, weighing 354 kilogrammes, was used. This was hung in a wooden frame weighing 446 kilogrammes, constructed in the form of a quadrangular pyramid. The hammer of the bell weighed sixteen kilogrammes, and was moved by wires, as in the other case. The frame and bell were suspended by chains from the four corners, between two barges, and then lowered into the water. The mode of observation was the same as in the former case.

A few metres from the barge a slight metallic sound was heard, doubtless from the acoustic tube vibrating with the membrane. The sound soon became dull, its intensity decreased rapidly with the distance; at 1,400 or 1,500 metres there was no perception of it.

Comparing these experiments with those of the first series, we have the unexpected result that the very intense sound of a bell weighing 354 kilogrammes has a less range than the weaker sound from a bell of forty kilogrammes.

In a third series, a small bell, twelve centimetres diameter, was sounded in the water alternately with the bell of forty kilo-

grammes; the range of the latter extended, as before, to 1,600 or 1,800 metres; that of the little bell was small, it exceeded one kilometre, however. M. Lucas concludes from the experiments that the range of sound in a river, even in the direction of motion of the water, is much less than that of sound in a lake; and that by increasing considerably both the intensity and the gravity of the sound, the range is but little increased, and may even be diminished. It further appears that, with equal intensity, the range of sound in a river will increase with its acuteness. If so, a considerable range ought to be obtained, he thinks, with a blast of compressed air for the sonorous source. A. B. M.

SCIENTIFIC SERIALS

THE *Geological Magazines*, Nos. 97—99 (July to September 1872).—One of the most important contributions contained in these three numbers is a translation of Prof. Nordenskiöld's account of his expedition to Greenland, which runs through the whole of them, and is not yet completed. With a good deal of general matter, this paper includes a vast amount of interesting geological information, and it must be welcome to English geologists, few of whom could make much out of it in its original Swedish dress. This translation is illustrated with the original plates, maps, and woodcuts.—Another highly important memoir, which appears in two parts in the July and August numbers, is Dr. H. B. Holl's essay on those most puzzling objects, the fossil sponges.—In the August number Prof. Allman gives us a note on a fossil *Hydractinia* from the Coralline Crag, the *Cellepora echinata* of Michelin.—Mr. S. V. Wood, jun., has some further remarks on Mr. Geikie's correlation of the glacial deposits; and Mr. J. Lucas a paper on the Permian Beds in Yorkshire, one portion of which calls forth a note by Mr. J. Clifton Ward, on rock-staining, in the September number.—The latter further contains a notice of the occurrence of the genus *Cupressocrinus* in the English Devonian, near King's Teignton, the first part of a paper, by Mr. Alfred Tylor, on the formation of Deltas, and some other papers, among which we may mention especially Mr. Woodward's description of a new species of Phalangiiform Arachnide (*Architarbus subovalis*) from the Lancashire Coal Measures, which is especially interesting from its generic identity with a North American form.

THE *Memoirs of the Natural History Society of Bremen* for 1872 (Abhandlungen herausgegeben vom naturwissenschaftlichen Vereine zu Bremen, Band iii. Heft 1) contain some exceedingly valuable papers for the study of zoological and botanical geology. In the former department we have Dr. O. Finsch's contribution to the ornithology of North-western America, from which inhospitable region the author records about 120 species of birds, many of them possessing a very wide geographical range. Singularly enough the author does not describe a single new species, but of some variable forms detailed descriptions are given, and with regard to many others we find valuable synonymic and descriptive remarks.—The flora of high northern latitudes receives a contribution in the shape of a list of the vascular plants of Spitzbergen and Bear Island, by Dr. T. M. Fries.—The student of the geographical distribution of European plants will find most valuable information in M. C. Nöldeke's Flora of the East Frisian Islands (including Wangeroog) which treats of the vascular plants in a most exhaustive fashion, and is supplemented by a short notice of the mosses of the islands, by M. C. E. Eiben.—From Drs. Buchenau and Focke we have an important paper on the *Salicorniæ* of the Baltic coasts of Germany, which includes a discussion of the views of previous authors on the species of that genus.—Dr. Buchenau has also a paper on the variation of the curious bracts of the lime tree.

SOCIETIES AND ACADEMIES

SAN FRANCISCO

Academy of Sciences, May 20.—Dr. Blake, on presenting some stone implements that had been found in stratified rock, at an elevation of 1,700 feet, observed there can be no doubt that up to the present time the earliest traces of man's existence on the earth have been found in this country. The skull found in the Pliocene deposits in Table Mountain is certainly the oldest human skull that has yet been discovered. Many stone mortars have also been taken out from the same deposits. I have examined the spot where one of these mortars was taken out ten feet beneath the surface of the Pliocene gravels on the Sierras, and as this was some six hundred feet above the valley and near the top of a rolling hill, there was no possibility of the strata having been disturbed. The objects I now have to present to the Academy furnish important evidence on this point. They are two implements cut in serpentine, and evidently fashioned by the hand of man, or of some animal capable of using its anterior extremities so as to fashion objects to meet its wants, and apparently possessed of sufficient intelligence to use lines or nets for catching fish, as it would seem that these instruments must have been used as sinkers. They are cut in serpentine, the surface of which is slightly weathered to the depth of about $\frac{1}{20}$ of an inch. One is pear-shaped, $\frac{3}{4}$ in. long, and $5\frac{1}{2}$ in. in circumference at its largest part; near the smaller end is a hole passing through it, and immediately above this is a notch passing across the end. The other instrument is cylindrical, thicker in the middle than at the ends; it is $5\frac{1}{2}$ in. long, and $3\frac{1}{2}$ in. in circumference at its thickest part. There is a hole through it at about an inch from one end, and above the hole is a notch passing across the end. The spot where they were found is on a rolling hill within a few feet of the summit of the coast range, and at an elevation of about 1,700 feet. They were met with in digging away the side of the hill, at about eight feet from the surface, four feet being alluvium, and four feet argillaceous shales, in which they were found embedded. These, and four other instruments of the same form, were found in a space of about two square feet. A great deal of alluvial soil had been removed whilst levelling the ground for a house, but no instruments had been found until the shales were dug into. In company with Prof. Whitney I visited the spot, and we have not the slightest doubt but that they were taken out at the place indicated. As to the geological age of the rock in which they were embedded, this is to a certain extent undetermined. It certainly cannot be later than the Pliocene, and Prof. Whitney is of opinion that it is still older. Dr. Blake then made some remarks as to the absence of anything like a rim to the Great Basin, north of the Puebla Mountains. In going north from the valley of the Humboldt near Mill City to the Puebla Valley, the highest elevation crossed between the Rattlesnake and Vicksburg ranges did not exceed three hundred feet, whilst the country to the east of this, between the Rattlesnake and Umsham ranges, is at a still lower level. North of the Puebla Buttes nothing but some low ranges are found until we reach the head waters of the Owhyee, a tributary of the Columbia, so that there can be no doubt but that the larger part of the waters of the Great Basin must have escaped through the valley of the Columbia. The quantity that was left for evaporation did not probably exceed from 100 to 150 feet, as he had not found concretionary deposits at a greater height than 100 feet above the present level of the Humboldt.

THURSDAY, OCTOBER 3, 1872

BOTANICAL MUSEUMS

THE question of the future relations of the national herbarium at the British Museum to that at Kew is at present engaging the attention of the Royal Commission on Science. The minute of 24th July last shows that it will presently be dealt with by the Treasury. On the motion of Messrs. Bentham and Ball, at the recent meeting of the British Association at Brighton, the Committee of the Biological Section secured an instruction to the Council of the Association to take action in connection with this question in the interests of botanical science; and the question has been submitted to the readers of NATURE in an anonymous article on "Botanical Museums," published on the 23rd March last year.

The authorship of this article was unknown to me until I was summoned to give evidence before the Royal Commission on Science. At the request of the President of the Commission, the proof of Mr. Bentham's evidence was placed before me; I then saw that the article alluded to was incorporated in it, and in the statement with which Mr. Bentham introduced it I read his history of its preparation and publication.

In dealing with this part of Mr. Bentham's evidence, I informed the Commissioners (Q. 7,739-40) that the opinions and arguments stated in it had been, two years before, submitted by Dr. Hooker, through the Board of Works, to the trustees of the British Museum, and had been answered by my predecessor, Mr. Bennett, to the satisfaction, as I then understood, not only of the trustees, but of the authorities at the Board of Works, and that the article on "Botanical Museums" was merely a reproduction of this official paper, without any reference to its answer.

After supplying the date of this official document, my examination, under the guidance of the Commissioner who was then dealing with me, took another direction. On subsequent reflection I therefore felt it necessary to ask leave to present a detailed reply to the Commissioner, which was granted. This reply is printed with the other evidence in the recently printed Blue Book (p. 44).

That the readers of NATURE who have already perused Mr. Bentham's article may have the opportunity of considering my answer, I submit it to them, earnestly desiring that this question now raised should be fully and exhaustively considered, and that no hasty or one-sided judgment should be arrived at; being thoroughly convinced that the action to be taken by the Treasury, whatever it may be, will seriously influence the whole future of the science of botany in England.

I desire to submit to the Commissioners my views:—(I.) On the statements contained in Mr. Bentham's paper, and (II.) on the matters naturally flowing out of these statements.

I. *The statements contained in the paper*

1. The views expressed by Mr. Bentham regarding the main purposes of a botanical museum and herbarium, and the requirements of a collection for such a close study of plants as would supply a "sound foundation upon which the science of botany can be usefully established," arise from his estimating the science of botany as limited to that particular department of it to which he has devoted his life, and in which he has done important service. The profound study of plants is, in his view, "their accurate determination and practical classification," and he states that he requires for its prosecution nothing more than an exhaustive herbarium of the fragments of plants supplying the diagnostic characters at present employed for distinguishing genera and species, with a complete library and staff of officers. This is, in my opinion, a very defective estimate of the science of botany, and of the materials required for its advancement.

Robert Brown took a very different view of the profound study of plants, and in the Botanical Department of the British Museum he tried to develope that masterly grasp of the science which is to be found in his works, by illustrating, as far as possible, the structure of all plants from the lowest to the highest, both existing and extinct. Accordingly, the National Herbarium, large as it is, forms but a part of the botanical collections. The specimens placed in the outer rooms, which exhibit chiefly the form and structure of the stems and roots of plants, are as necessary a part of the purely scientific collection as the dried foliage and flowers in the herbarium. While such specimens "excite the interest," and "gratify the curiosity" (and, what is more important, instruct the minds) "of the general public," these are very far from being their principal, still further from being their only purpose in a botanical museum, as Mr. Bentham appears to imply. The scientific investigator whose notion of systematic botany is somewhat larger than ascertaining the technical name and order of a plant, consults these specimens as he does the herbarium. It is, therefore, a mistake to suppose that they, "when once placed, require no further handling."

The purely scientific collection of the British Museum consists of:—I. The herbarium, comprising (*a*) the general herbarium, (*b*) the British herbarium, (*c*) various separate small and complete herbaria of historical interest. II. The structural series, comprising (*a*) the fruit collection, (*b*) the collection of gums, resins, and other natural products, (*c*) the general collection, exhibiting the form and structure of plants, and consisting of the larger specimens chiefly exhibited to the public; and (*d*) the microscopical preparations, illustrating the minute structure of recent and fossil plants.

2. The limitation of the science of botany to the plants now existing on the earth is another grave defect. No subject has recently received more attention from biologists than the relation between existing and extinct plants and animals. Every philosophic estimate, or systematic classification of the one kingdom or the other must include the fossil as well as the recent. This is fully acknowledged and acted upon by zoologists, and no better illustration can be adduced than Prof. Huxley's "Introduction to the Classification of Animals" (1869). In botany also, in the standard and only complete *Genera Plantarum*, by Endlicher, the fossils are ranged in their systematic position with the recent plants. It is true that the *Genera Plantarum* now in progress, of which Mr. Bentham is one of the authors, ignores all extinct plants. This retrograde step is in entire accordance with the views expressed by Mr. Bentham in NATURE. A systematic account of the *Lycopodiaceæ* which took no notice of the arborescent forms of palæozoic age, or of the *Cycadeæ* which ignored the numerous forms and remarkable variations of this order in the secondary rocks, would be obviously very incomplete and unsatisfactory. In forming a collection to supply a sound foundation for the science of botany, it would be as reasonable to exclude the plants of any existing botanical province—say Australia—as to omit those which have existed at any particular period of the earth's history—say that of the Wealden.

3. The distinction which Mr. Bentham draws between a herbarium "for the close study of plants" and one for their "rapid determination without dissection" is most

undesirable, and, in my opinion, practically impossible. No botanist has so extensive an acquaintance with the vegetable kingdom as to be able to make "a close study," in his necessary work, of every group of plants he may be naming or arranging; he must in many groups make a "rapid determination without dissection." If Mr. Bentham's distinction were in force, and the two herbaria he proposes existed, he would himself, when rapidly naming some of the important collections which have passed through his hands, have often been driven from the great scientific collection to work in his single specimen herbarium with the "general naturalist," "the palæontologist," and "the mere amateur." Every systematic botanist is at first, and more or less all along, a "comparer" of plants. The man who begins as a mere comparer naturally becomes a close student under the influence of the collection he is consulting, and the workers he encounters in that consultation.

4. Mr. Bentham's single specimen herbarium is chiefly intended for the palæontologist, and in addition he proposes to provide him with "separate collections of leaves and fruits, . . so arranged as to enable them to be rapidly glanced over," and these, it is added, "would be most useful." No better testimony to the utter worthlessness of such materials for the purpose proposed can be adduced than the criticisms of Mr. Bentham himself, on the evidence for the existence of the natural order *Proteaceæ* in Europe, from leaves found in Tertiary strata. Mr. Bentham was specially fitted to deal critically with the hundred fossil species referred to this order, as he had just made the analysis and detailed descriptions of between five and six hundred *Proteaceæ*. The Order is also the best fitted to test the value of the leaf characters on which the fossils had been referred to it, because, as he testifies, it "is one of the most distinct and most clearly defined amongst phanerogams," and is without "a single plant intermediate in structure between that and the nearest allied orders." With regard, then, to the leaves of this order, Mr. Bentham says, "I must admit that there is a certain general *facies* in the foliage of this order that enables us in most, but not in all cases, to refer to it with tolerable accuracy —leafy specimens known to have come from a proteaceous country, even without flowers or fruit—but as to detached leaves, I do not know of a single one which, in outline or venation, is exclusively characteristic of the order, or of any one of its genera." I cannot reconcile this declaration by Mr. Bentham to the Fellows of the Linnean Society as their President in May 1870, with the statement published by him within a year thereafter, that such a collection of detached leaves not for a limited and exceptionally defined order, but for the whole vegetable kingdom, "would be most useful."

I must further observe that Mr. Bentham has overlooked the fact that a large proportion of fossil plants have been determined from their internal structure, that is, on evidence which no mere herbarium, however extensive, can supply, far less one for rapidly determining plants without dissection, or a collection of detached leaves. The palæontologist requires the most extensive collections possible for his work, and he must be a working zoologist or botanist. All such work done by mere "geologists" and on such data as Mr. Bentham proposes to supply would always deserve strong condemnation.

II. *The matters flowing out of these statements*

In considering the matters naturally flowing out of Mr. Bentham's paper, and the views I have now expressed, I venture, *firstly*, to submit the reasons which make it desirable in my opinion to retain the two herbaria as separate and independent institutions.

1. The two herbaria already exist, and are to a considerable extent parallel collections. Mr. Bentham, whose extensive private herbarium formed the foundation of the public herbarium at Kew, declared, in 1858, "that a great portion of the additions to the Banksian herbarium since Sir Joseph's death are duplicates of those already at Kew." As the Banksian plants form less than a quarter of those now existing in the British Museum herbarium, the duplicates would be, according to Mr. Bentham, about three-fourths of the whole. Sir William Hooker, also, whose large collections form the great bulk of the Kew herbarium, testified, in 1858, that "the Museum specimens are to a great extent duplicates of those at Kew." And the present Director of Kew Gardens corroborated this statement at that time. In 1860 Sir William Hooker further said, in reference to the transfer of the National Herbarium to Kew as affecting the herbarium there, "To Dr. Hooker and myself it literally and truly can be a matter of no consequence."

2. The two herbaria have been under different management, and to some extent express different results of "the close study of plants." The important bearing of this consideration on botanical science in Britain can scarcely be overestimated. One practical illustration may be adduced. The most varied views are entertained by botanists as to the limits of a species, and consequently as to what constitutes a duplicate. Thus, in the case of the indigenous flowering plants of Britain, Mr. Bentham considers them to form 1,274 species; Dr. Hooker, in his recent Flora, makes 1,473 species; Prof. Babington increases the number to 1,648 species; while a botanist adopting the views which Jordan and some continental authors have applied to local floras, would make them three or four times more numerous than even the last estimate. It is quite obvious that these different botanists have each very different notions as to "duplicates," and that a distribution undertaken by Mr. Bentham would certainly result in the loss to the herbarium of plants which Dr. Hooker would consider good species, and the "duplicates" distributed by Mr. Bentham or Dr. Hooker would include numerous plants which would be of the utmost value in M. Jordan's eyes. The two herbaria, existing, as they do, under different directors, to a considerable extent counteract these and other analogous evils.

3. The objects of the two herbaria are fundamentally different, and in as far as they fulfil these objects, they are employed for totally different purposes. The National Herbarium at the British Museum was founded in 1827 for the use of the scientific botanist; while that at Kew was, as Dr. Hooker says, "originally maintained expressly for the use of the gardens." This was the primary object for which Sir W. J. Hooker accepted the private herbarium of Mr. Bentham in 1855. Before that year the gardens had been fulfilling their proper functions without a scientific herbarium attached to them. The two editions of the "Hortus Kewensis" are the best testimony to the efficiency of the gardens, and to the value of the collections brought together there under the Aitons. No herbarium of any kind, I believe, existed at the gardens during their time. The Banksian Herbarium was often and for a long time systematically used for naming the Kew plants; and the strictly scientific portion of the "Hortus Kewensis" was the work of Solander, Dryander, and Brown, the successive curators of the Banksian Herbarium. Even Sir W. J. Hooker, the successor of the younger Aiton, who raised the gardens to their present eminence, had no public herbarium from the time of his appointment in 1841 to 1855. It is, therefore, evident that a great scientific herbarium is not a necessity to the efficiency of the gardens at Kew.

It is, however, certain that such a herbarium as Sir W. J. Hooker and Dr. Hooker desired, that is, one sufficient to enable the officials to name the plants in the gardens, would be a most useful adjunct at Kew, as it would save the great waste of time which would be incurred in consulting a herbarium at a distance. Inasmuch as growing plants are, to the extent that they are developed, perfect, and permit thorough examination, it is obvious that the

single specimen herbarium proposed in NATURE would meet all the requirements at Kew, and this could be kept up as suggested by Mr. Bentham from the duplicates not required in the great National Herbarium, all being accurately named before being sent.

4. The practical difficulties in the administration of two separate, and to some extent independent, herbaria would be numerous and serious, and in the course of time a condition of things similar to what at present exists would result. It is needless to speak of a London herbarium, consisting of single specimens of each species, because such a herbarium, if practicable, would, as I have already shown, be utterly worthless for the purposes to which it is proposed to be applied. If the London herbarium were to contain only specimens sent by the keeper of a herbarium, whose notion of the science of botany was confined to the "accurate determination and practical classification" of herbarium specimens, it is obvious that the palæontologist would not find there the materials for prosecuting his work. If, on the other hand, the London herbarium were constituted to be of real use to the palæontologist, the keeper must have the power of acquiring as opportunity offered the suitable materials, and he would necessarily secure collections which a future agitator might demand to be transferred to Kew, with as pertinent reasons as those Mr. Bentham now employs.

5. It is not an unimportant consideration that the continued separate existence of these two great herbaria is a great security against their destruction by fire.

6. The expense of the two herbaria is very small. I am unacquainted with the amount granted for Kew herbarium, but it cannot greatly differ from that required by the National Herbarium, which amounted for the financial year lately completed to 1,767*l*. I know of no way in which the country can at once advance the interests of science and encourage its students, at a smaller cost and with more important results than by maintaining in their full efficiency the two botanical collections at present existing.

But, *secondly*, it must be admitted that the formation of a single great national botanical establishment, comprising the two public herbaria now existing within a comparatively small distance from each other, is a very attractive scheme, and should the Commissioners think that its realisation is desirable, I submit the following considerations as in my opinion essential :—

1. It must form part of the National Museum of Natural History. Such a museum, as far as it is an exhibition of biological science, will consist of animals and plants, both existing and extinct. It is absolutely necessary in the study of geology that the plant remains should not be separated from the animal remains ; and further, it is as necessary for the satisfactory interpretation of the fossil plants, as well as for forming a true estimate of the vegetable kingdom that the recent plants should not be separated from the fossil. The separation of any one department would be a serious injury to all.

2. It must represent the whole science of botany, and not consist of only dried foliage and flowers, which constitute a herbarium properly so called ; and consequently it must be formed on the principle adopted by Robert Brown, and exhibited in the Botanical Department of the British Museum, and not on the imperfect plan advocated by Mr. Bentham.

3. It must be placed in the position in which it will be most serviceable to the public and most accessible to botanists, and that place is beyond all question London. The statistics which I submitted on the occasion of my former examination establish this, by showing the extent to which the botanical collections at the British Museum are made use of. Further, it is universally acknowledged that a herbarium for scientific use must exist in London. The long experience of Mr. Brown and Mr. Bennett in the National Herbarium made them entertain and express very decided views as to this necessity. My shorter experience has been long enough to convince me that its removal to Kew would be practically placing it out of the reach of the busy men who frequently use it to the advantage of science. Of course the working botanist who devotes himself exclusively to the science would follow the collections wherever they went ; but the active professional man, and the man of business, who devote their spare hours to botany, would be deprived of the assistance necessary to their work which they now obtain at the British Museum. That such men do a large proportion of the scientific work of the country may be shown in many ways, as for instance, by the fact that out of the nineteen botanical memoirs contained in the last two volumes of the Linnean Transactions, four are produced by professional botanists, and fifteen by others.

The late Prof. Henfrey, as representing the botanical teachers of London, Sir Charles Lyell, for the palæontologists, and Dr. Falconer, Mr. Bentham, and Dr. Hooker, have recorded it as their decided opinion that the interests of science require that a public herbarium should exist in London. Such a herbarium, even if used only by palæontologists, must be, as I have shown, as extensive as possible ; otherwise, it will tend to mislead, like all other imperfect sources of information.

I would further add in favour of London being the proper site for the national botanical collections, that important collections of plants, both recent and fossil, accessible to students, but not to the general public, now exist and must still remain in London. These are : (1) the Linnean herbarium, containing the plants described by Linnæus ; (2) the great Wallichian herbarium ; (3) the Smithian herbarium of British plants ; all belonging to the Linnean Society ; (4) the collection of fossil plants belonging to the Geological Society ; and (5) the extensive public collection of fossil plants in the Museum of Practical Geology. The removal of the National Botanical Collection from London would so separate them from these collections as seriously to injure their value to scientific investigators.

4. The accommodation provided for the Botanical Department in the New Museum of Natural History, the plans of which have been accepted by the trustees of the British Museum, will be in every way superior to any that exist in the world, and will be amply sufficient to accommodate the proposed single national herbarium, as well as fully to display the structural, histological, and palæontological departments of the science. All the requisites specified by Mr. Bentham for the close study of plants, excepting the connection with a garden, exist to a greater or less degree at the British Museum, and some of them in a greater degree than at Kew. That living plants are a requisite adjunct to a herbarium is in opposition to the testimony of Mr. Brown and Dr. Falconer, to the effect that there is no necessary connection between a herbarium and a garden ; and is opposed moreover to the testimony of Mr. Bentham himself, as well as to his declaration that his extensive systematic labours have all been based on herbarium specimens, although they have been carried on in close proximity to the finest scientific garden in existence.

In the event then of its being resolved to maintain only one great national botanical collection, I would submit that it should not be cut off from the allied biological collections, but be placed with them in the same building in London. And that for this end the collections presented by Mr. Bentham to the public, and all that have been added to them by purchase or presentation, be removed to London and incorporated with the national herbarium ; and further, that the extensive botanical library formed at the national expense at Kew be made, with the Banksian library, the foundation of that national natural history library which will be required for the National Museum of Natural History.

It is necessary, in dealing with Mr. Bentham's printed

and publicly expressed views on this matter, to bear in mind that he cannot be considered an unprejudiced witness. I have frequently referred to his relations to the herbarium attached to the Royal Gardens at Kew. He has thus stated the reasons by which he was influenced in presenting his herbarium and library to the public in 1855:—"I thought that at that time there was no herbarium and library in London sufficiently open for the use of botanists, and I presented them on condition that they should form the nucleus of a national herbarium and botanical library, to be kept at the expense of Government, and open to the free use of botanists." I can assert in opposition to Mr. Bentham's belief—and a similar opinion has been, I understand, recently expressed—that at that time the National Herbarium and the national library, as far as it is an adjunct to the herbarium, were fully and freely accessible to botanists, and were largely used by botanists; and this I am able to maintain from the contemporary records of this department, as well as from the testimony of botanists who were then in the habit of consulting the collections. Under the influence of this erroneous supposition, Mr. Bentham made his own herbarium a national institution, and a rival to the Banksian herbarium, and under the influence of this same spirit of rivalry, he now believes that there exists "a state of continual competition" between the two herbaria. I am sure that Dr. Hooker and the authorities at Kew will as strongly repudiate this statement as I do now, if it is meant to imply a competition in any way to the injury of science or the public. It is only in keeping with the motives which actuated him at the first that Mr. Bentham now agitates for the incorporation of the Banksian herbarium with that of which his own forms the nucleus.

WILLIAM CARRUTHERS

FRESENIUS'S QUALITATIVE ANALYSIS

Qualitative Chemical Analysis. By Dr. C. Remigius Fresenius. Eighth edition. Translated from the 13th German edition, by A. Vacher. (London: J. and A. Churchill)

THE present edition of Fresenius is one which will be looked at by chemists with interest. In the last so-called edition of Fresenius's Chemical Analysis, published in 1869, the text had been so altered and curtailed that the volume could scarcely be recognised as Fresenius of old, it having been reduced to about one half of its original size. It appears, however, that this condensation did not coincide with the author's views, and in this edition we have simply a translation of the original text. The editor in his preface confesses that he then, in the last edition, took too broad a view of his duty. It certainly seemed strange that a work which had passed through twelve German editions with a gradual and steady enlargement, could be condensed to about one-half without losing a considerable amount of its clearness and usefulness. We confess that we heard with pleasure of the appearance of the eighth English edition of this work, but, unfortunately, our pleasant anticipation has been to some extent marred.

In criticising this book, it will be necessary to consider it from two points of view; in the first place, to consider the work of the translator; and in the second, the author's responsibilities, and the book itself. To commence with the translator's work: it appears, on the whole, to be very well executed, although by far the greater part of the book is identical with the sixth edition, published in 1864 and edited by J. Lloyd Bullock; in fact, at first sight, there does not appear to be very much difference between the two editions; but on a closer acquaintance with the present edition, there is found a considerable amount of new matter, and some little alteration in the old. As is almost certain in a book of the size, we have found some sentences which would have been better for a little more attention; to quote one instance, p. 51, "Solution of ammonia, although formed by conducting ammoniacal gas ($N H_3$) into water, and letting that gas escape on exposure to the air, and much quicker when heated, may also be regarded as a solution of oxide of ammonium ($N H_4 O$) in water, the first acceding equivalent of water ($H O$) being assumed to form $N H_4O$ with $N H_3$." This sentence cannot certainly claim precision and clearness as its chief characteristics, and we have much doubt whether a young student would understand its meaning. Taking the translation, however, as a whole, it is clear and well expressed.

It will be seen from the above quotation that there are some points about this edition which will not recommend themselves to the generality of English teachers; we refer of course to the nomenclature and notation, which have not been altered since the edition of 1864. Of course Mr. Vacher is not responsible for this; if Dr. Fresenius said the work was to be literally translated, there was no help for it, the old notation must be used, but still we must consider that it is a great mistake. Generally speaking, at the present day for a book to be published in the old notation is sufficient to limit its use to a very small number of students. It certainly seems a great pity that this, which until lately has been looked up to as the best and most reliable text-book on qualitative analysis, should not have progressed side by side with modern chemistry; for English chemists, almost without exception, have adopted the new system of atomic weights, and the new and more systematic nomenclature now in use. The adoption of the old notation in the present volume will add a considerable amount of trouble to the teacher's work, and in many cases may probably lead to the adoption of another text-book. Looking at the very general, in fact almost universal, use of the new notation both in England and on the Continent, it certainly appears that this book is about five years behind the times. On the other hand, the present edition will, perhaps, on this account prove more useful to our manufacturing chemists, who seem very loth to adopt the new notation.

Although we do not feel satisfied, and, in fact, are disappointed, with the book in this respect, we cannot help feeling pleased with the substance matter itself. As might be expected from the numerous editions of his manual which the author has already published, he continues to keep the information contained in the work quite up to the progress of the science. Many parts of the work show alterations, though the very fact of the accuracy of the author's work precludes any very great change. It is in the parts on the rare metals, and on the alkaloids, that there appears to be the greatest amount of new matter. Thus the sections on berylla, thoria, zirconia, tellurium, vanadium, iridium, and didymium, show a considerable increase in our knowledge of these substances; whilst indium, which is not to be found in the edition of 1864, has here received a very good notice. Again, in the edition of 1864, only one

method is given for the separation of lanthanum and didymium, but in the present there are no less than four distinct methods given. On the subject of the alkaloids, we notice three new articles on digitaline, picrotoxine, and atropia, which in the previous edition are not noticed. In the portion which treats of the acids, and in Part II. "On the Course of Analysis," there does not appear to be much alteration; but we must not omit to mention that the index to this edition is far more complete, and in every way better than in the previous editions. The general plan of the work is too well known to need any detailed account, and the number of editions through which it has passed is a sufficient guarantee of its usefulness and trustworthiness. A few new illustrations have been introduced, and a new table of spectra, but in the general style and plan of the book there has been no alteration. For our own part, although we have a great admiration for Fresenius's book, more especially as a work of reference, we scarcely think that his system is perfect for educational purposes, and perhaps not so good as those of some others, such as Valentin's or Galloway's; no doubt a student working conscientiously through the work under review will be able to make good and correct analyses, but we doubt whether he will learn much beyond the mere analytical details, for in this book there seems little room for the student to use his powers of originality, and nothing to stimulate him to reason, from his accumulation of facts, to general principles. There appears about the book almost too much of the system of telling this and showing that, for the book to be perfect as an educational agent, and we fancy that better results in this direction may be obtained from works which give more opportunity and encouragement for original and individual reasoning; and this we believe is the case in the two other works we have mentioned, as they tend to exercise and strengthen the student's originality, and will at the same time give him as full and complete a knowledge of qualitative analysis as he would obtain from Fresenius's book.

OUR BOOK SHELF

Verhandlungen des naturhistorischen Vereines der preussischen Rheinlande und Westphalens. 28er Jahrgang. 1te u. 2te Hälfte. (Bonn, 1871.)

THE volume of these Transactions for 1871 opens with biographical memoirs of Wirtgen and Haidinger. S. Simonowitsch contributes a paper on the Bryozoa of the Greensand of Essen, illustrated by four lithographic plates, which is introduced by a critical account of the anatomy and systematic position of the Bryozoa. From Prof. Förster we have a Review of the Genera and Species of the Family of Plectiscoideæ. F. G. Herrenkohl follows with a list of the Phanerogams and Vascular Cryptogams of Cleve and the neighbourhood. R. Bluhme gives a series of analyses of the water of different wells in the vicinity of Bonn, compared with that of the Rhine. In addition to these papers printed at length, a large number of other subjects connected with medical and natural science are treated in the Reports of the Proceedings of the Lower Rhine Society for Natural History and Medicine. Among these we may refer especially to a valuable paper by Dr. Brandis on the climatic conditions which principally affect the growth of forests in the British East Indies. The Indian climate is characterised by its long period of uninterrupted drought; and where the rainy season falls in spring or autumn, the summer heat is excessive. Where, however, the rainy season falls in the summer, as is the case in Burmah, Bengal, and a portion of Central India, the climate presents the peculiarity that the hottest period is in the spring, from March till May and the commencement of the monsoon, and again in the autumn, Calcutta having again a comparatively cold winter. The great obstacle to the growth of forests is the prevalence of fires towards the close of the dry season, which do incalculable damage every year; but of late years something has been done to limit their ravages. The growth of tree vegetation is extraordinarily rapid in India when young, but the forests do not eventually attain such luxuriance as in Ceylon, Brazil, and some extra-tropical countries.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Oceanic Circulation

THE letters of Prof. Everett and Mr. Wallace (NATURE, Aug. 22) establish one point which must go a good way towards the settlement of the disputed question of the cause of oceanic circulation, viz., that in order to maintain the bare mechanical possibility of the gravitation theory, it is necessary to assume that water is so nearly quite devoid of molecular resistance to motion that, were it not for the impediments offered by continents, water flowing from a low to a comparatively high latitude would be revolving eastwards with the velocity of an arrow. In the southern hemisphere, where continents are "few and far between," and where a comparatively open channel exists through which the waters may circulate round the globe at any velocity without much impediment, this rapid general eastward motion of the ocean ought to be developed to a large extent. But the fact remains that no such motion has ever been observed. Dr. Carpenter says:—"It is well known to navigators that there is a perceptible 'set' of warm surface water in all the southern oceans towards the Antarctic Pole; this 'set' being so decided in one part of the Southern Indian Ocean as to be compared by Capt. Maury to the Gulf Stream of the North Atlantic" (NATURE, March 24, 1870). This general motion of the water in the southern hemisphere Dr. Carpenter adduces as strong evidence in favour of his theory. But why is not the "set" as much to the east as to the south? If the presence of the Antarctic continent does not hinder the motion of the water polewards, why should the presence of the continents of Australia or the southern portion of South America hinder the motion of the water eastward, seeing that rotation performs about 1,500 times more work in deflecting the water eastward than the difference of specific gravity performs in impelling the water southward? The very fact that the water does not turn to the east but moves straight towards the Antarctic continent, shows that the waters must be impelled by a force immensely greater than that derived from difference of specific gravity, because it must be greater than that derived from rotation, or else the "set" would be as much to the east as to the south. There are, it is true, a few currents in the southern hemisphere with an eastern motion, but these the advocates of the gravitation theory would call "mere surface drifts produced by the winds." Besides the majority of the currents in that hemisphere move in wrong directions to be explained either by difference of specific gravity or by rotation.

That the explanation given by Prof. Everett and Mr. Wallace does not even touch the difficulty which besets the gravitation theory, far less removes it, will, I trust, be further evident from the following considerations, viz., a current in mid-ocean a thousand miles from land, flowing from a low to a higher latitude, has its eastward motion due to rotation as effectually checked and diminished as though it abutted against a continent. This retardation cannot be attributed to the presence of continents, for it occurs equally the same whether the land be one thousand, two thousand, or five thousand miles to the east. It is the resistance of the molecules of the water through which the current moves that destroys the eastward motion. No matter how slow the current may flow polewards, by the time the water reaches, say latitude 60°, each pound has lost at least 9,000 of the

eastward velocity which it possessed when it left the equatorial regions. It is a matter of indifference in what way this energy is consumed by the molecules of the water, whether it be in friction in rotation, or whether it becomes potential in the raised water through which the current flows; for in either case it is the resistance offered by the stationary molecules which causes the moving molecules to lose their velocity. The resistance being molecular, that which holds true of eastward holds equally true of westward motion. This is proved also by the fact that a current flowing from a higher to a lower latitude has its westerly motion due to rotation as effectually checked and diminished as a current flowing from a lower to a higher latitude has of easterly. And what holds true of motion to the east or to the west, holds equally true of motion to the south or north, for there is no reason why the resistance should be less in one direction than in another.

It therefore follows that it is impossible that 6 foot-pounds could impel a pound of water from the Equator to latitude 60° against the molecular resistances to its motion, when during the passage of the pound of water it requires 9,000 foot-pounds to overcome the resistance to the easterly deflections which take place. Or if the molecular resistance of water be so infinitesimal that 6 foot-pounds is sufficient, then it is impossible that molecular resistance could consume 9,000 foot-pounds during the easterly deflection which takes place.

I respectfully submit that this is a clear and obvious demonstration of the mechanical impossibility of the gravitation theory of oceanic circulation.

Prof. Everett says that Mr. Ferrel's argument from the tides is quite conclusive in showing that the forces arising from difference of temperature are of sufficient magnitude to keep up an oceanic circulation. If. Prof. Everett, like Mr. Ferrel, really supposes that a slope produced by the moon is the same as one produced by difference of density, and that the process by which the water tends to regain its level is the same in both cases, I am not surprised he should consider Mr. Ferrel's argument conclusive.

I beg to refer Mr. Wallace to the *Philosophical Magazine* for October 1871, p. 244, for an explanation of the fallacy of Dr. Carpenter's famous experiment to which he alludes.

Had the present state of my health permitted, I should have entered somewhat more fully into some of the above points, but in the meantime I must withdraw from any further discussion.

Edinburgh, August 27 JAMES CROLL

The Aurora of Feb. 4

THE Hon. Rawson Rawson, Governor of Barbadoes, has favoured us with the following note:—

"Memo. for his Excellency the Governor-in-Chief.

"The aurora of the 4th of February last, to which you allude, and notices of which you kindly sent me in NATURE, was seen here, and caused much concern.

"I was not myself an eye-witness, but I have descriptions of it from trustworthy persons. I was first informed of it by a servant of mine, who has the overlook of Mont Grace.* He was returning to his home near the Fort after 7 P.M., when, about a mile away from Mont Grace, his attention was arrested by what he imagined was a 'great fire'—the trees at Mont Grace and all about the yard were lighted up and clearly seen. My brother, who leased a sugar plantation in the neighbourhood of Government House, and Mr. Gordon, who owns one in that immediate neighbourhood, happened to be both in Scarborongh at the time, and, seeing the 'great glare,' were both seized with the notion that their respective properties were on fire, and hastened out to them to find that the supposed fire was farther away.

"Mr. Taylor, master of the barque *Tobago*, was riding at anchor at Courland Bay,† and was a witness of this aurora. He described it to me as of 'a dark-red colour, extending half way up to the zenith, and very brilliant, its situation being about N.W. by W.' The labourers exclaimed that St. Vincent was on fire.

"This aurora lasted till half-past nine. Such a phenomenon, if not altogether unknown in this latitnde, is at any rate very rare.

"Tobago." "DUGALD YEATES"

* Mr. Yeates' property, three miles from Scarborough, Island of Tobago. (Tobago is in 11° 9′ N. lat., and 60° 12′ W. long.)

† On the opposite side of the island, *i.e.*, the northern side.

The Solar Spectrum

I HAVE lately obtained and read "Schellen's Spectrum Analysis," translated by the Misses Lassell, and edited by Mr. Huggins, and feel at length constrained to dissent from a statement which I there find—in this the present standard work on the subject—distinctly and repeatedly made, as I have seen it made elsewhere before, a statement belief in which has tended and must always tend to deter many from prosecuting independently a most interesting study. I refer to the passage beginning "The Possibility of Observing" (p. 382) to end of paragraph, italicising the words "ordinary" in l. 7 of p. 383 ' by increasing the number of prisms" three lines below, "highly dispersive power" in line 22.] The italics are mine, and are intended to indicate that to which I object, not that the particular passages in which they occur are explicitly incorrect, but that they implicitly convey the incorrect notion, that the "highly dispersive power" is essential to the primary success of the observation "of the lines of the prominences in bright sunshine."

The reason of my objection will be found in the following extract from an unpublished letter dated May 3, 1869:—

"I think it will surprise you to hear that I have just seen Mr. Lockyer's three bright solar lines at several parts of the sun's circumference with the Royal Society's telescope and spectroscope *without any appliances or devices whatsoever (sic)*, and that with the greatest ease and certainty. Had I merely *looked* for them, or for anything of the kind, a twelvemonth ago, I do not see how I could have failed to see them!

"When the slit is placed parallel to the limb, the red line is vivid across a bright solar spectrum, and the line near D (there is no doubt about its position when seen in connection with the solar spectrum) which is less prominent, as also the line at or near F, are easily seen."

Also in another letter of the same date:—"Before I went into camp last December (while still rumours only of Janssen's observations were current) I resolved to try with coloured glasses. They were not received till too late; the instrument was packed up, and I was away. By the time I returned the question had passed on; but I still wished to carry out original intentions, and prepared accordingly, and was proceeding to direct the telescope this morning when I saw the red line in the undefended part of the slit, where I was focussing on the sun's limb. Of course, I saw at once that I could do without my coloured glass, which, practically, limited my field of view, and accordingly removed it, and examined various parts of the limb with no screen at all. At nearly all I could see the same three lines. At one place the red was so bright that an outsider looking in at the spectrum would certainly have carried away the impression of a coloured ribbon with a bright line of red near the end." As a matter of fact my wife had no difficulty in seeing at any rate the red line.

Now, the application of this is to be found in the fact that the spectroscope in question contained a single equilateral prism and no more.

Were there any merit in a fortuitous discovery of the kind, it would suffice for me to declare that I was in complete ignorance of the methods and appliances by which MM. Janssen and Lockyer had succeeded in doing long before that which I now found so obvious. What I do insist upon is that the visibility not of the prominence *lines* only (see also Proc. R.S., No. 113, 1869, in this connection), but of the prominences themselves does *not* require a high dispersion. I have a fair acquaintance with prominence forms; but it has been derived almost entirely from a study of them with *an open slit*, the use of which I had learnt long before, and a *single prism* spectroscope.

Of course, I do not contest that the power of extended examination depends directly upon increase of dispersive power, only that the *lower* limit is fully attained by a single 60° prism.

That high telescopic power is not essential either is proved by the fact that I have examined prominences by applying a $1\frac{3}{4}$ in. object glass to the end of the sliding tube of the spectroscope at solar-focal distance, and using the instrument on its "soirée" stand on a table—by way of experiment—with an amount of success which, in 1868, would have made some sensation.

It is obvious to remark in reply that probably the explanation of the ready visibility asserted is to be found in more favourable climatic conditions. I cannot admit it. By night, it is true, there is often a remarkable translucency; but the dusty, agitated state of the atmosphere (in May) under a tropical sun, and at an inland station, can certainly not be considered favourable for observations of this particular character. And even were such

an explanation in some measure correct, clear skies are not so unknown in Europe and America (nor indeed in England) that the illumination of the atmosphere can be broadly said to "completely overpower" that which "in an ordinary instrument" is by no means overpowered in India in ordinary states of the sky.

The erroneous notion to which I refer has been promulgated again and again. It is unnecessary that I should specify the various passages—in lectures and elsewhere—and ultimately in Mr. Proctor's work on the Sun* : but having now found it so distinctly enunciated in the above cited passage, and elsewhere, in "Schellen," the time seemed to have come when it ought no longer to pass unnoticed; the more so as I have never been able to understand the real reason why the momentous discovery was not made earlier. It has been said that *knowing where to look*, the main difficulty was overcome. But two days after my first experience of these three known lines, I recognised the presence of three more hitherto unknown ones—and subsequently of a seventh. From that time to this however I have not seen any others, with the same dispersive power.

If asked how it was that, with the very same power at command, I had not myself seen them before; I need only reply that I had small leisure by day, and was under the impression that the experiment had been fruitless in more experienced hands—the identical reason which P. Secchi has given for a like remissness, in this very matter.

Bangalore, Aug. 25 J. HERSCHEL

* See particularly p. 286, footnote.

Botanical Terminology

I VENTURE, as no one else has done so, to make a few remarks on Mr. Kitchener's letter.

I suppose the necessity will not be denied of employing some technical terms in studying subjects which do not fall under ordinary observation, and for the discussion of which ordinary language is consequently insufficient. When these technical terms are first devised, it is natural, indeed unavoidable, that they should reflect the scientific ideas current at the time. But inasmuch as knowledge progresses, we find ourselves, sooner or later in every branch of science, in the predicament of having to give effect to new views in terms which are an inheritance from old ones. We are able to do this because things themselves remain the same though our ideas about them change, and the names they once received with an intelligible meaning have now become purely arbitrary. No man bearing the name of, say, Baker, would probably change his name because he did not make bread. Nor do chemists discard the term oxygen because there are acids of which it is not a constituent. In the same way the morphological analogy implied in the use of the term "ovule," in the case of plants, is undoubtedly incorrect, but any one must have a singularly tender conscience who would object to it on that ground.

To save, therefore, confusion, and preserve uniformity in scientific literature, there is a tacit convention to treat in a great many cases as arbitrary terms words which once implied acquiescence in a theory. That a word in common use belongs to "a pre-Adamite stage of botanical knowledge," as Mr. Kitchener calls it, is not, I take it, sufficient ground for replacing it with another if there is no ambiguity in its application.

Next I would remark that Mr. Kitchener appears to me to have an exaggerated notion of the copiousness of botanical terminology. The number of terms really indispensable is not large. For example, he speaks of the troop of words ending in "tropous." Was this particular noun of multitude suggested by the termination? because as a matter of fact the troop consists of three. Prof. Henslow found no difficulty in teaching the terms contained in Prof. Oliver's Lessons in Elementary Botany to girls in a village school. Surely the Rugby boys cannot be less apt.

That Professor Henslow succeeded seems to dispose of the objection that a knowledge of Greek is "a necessary *open sesame* to the correct remembering and spelling of botanical terms." To teach these terms as "unintelligible gibberish" is only what in any case must be done with whole hosts of words not very different in form. Why should it be insuperably difficult for a boy, even if ignorant of Greek, to remember spell and apply the term hypogonous when he cannot possibly evade sometime or other having to face hypothesis, hypochondria, and hypocrisy, to say nothing of hydrostatics, hydraulics, hydrogen, and hydrocephalus?

I can see no reason why, as Prof. Henslow was in the habit of doing, technical terms carefully reduced to the smallest number absolutely required (and text-books bristle with unnecessary ones) should not be taught to boys as mere arbitrary names. Syngenesious, as a mere matter of taste, seems to me preferable to "united by dust-pouches."

If this be done, Mr. Kitchener's further difficulty as to "gamogenetic analogy" disappears.

The teacher, of course, may himself reasonably exercise some liberty. Thus no one would, I suppose, object to quincuncial being expressed by $\frac{2}{5}$, though quincunx is to be found in any dictionary, and is a word for which botanists are not responsible. Again, the suggestion to express by a fraction the depth of leaf-incision is really commendable, even to technical descriptive botanists.

October 1 W. T. THISELTON DYER

The Hassler Expedition

UNDER this heading in your number for August 29, p. 354, is this sentence, "One lesson I must confess to having learned at Indefatigable Island (Galapagos). I saw there indisputable proof that the surf of the sea is capable of rounding angular fragments of lava into pebbles somewhat resembling in shape (but not at all in polish and grooving) glacial boulders. I had always from boyhood doubted the power of the sea to make angular fragments round. I had supposed that the action of the surf upon such fragments would be simply to pack them into a sort of McAdam's roadway. And even now, having had the proof that under peculiar circumstances the sea can make a tolerable imitation of drift, I am not a whit more ready to believe that the sea made the drift itself. You may prove to me experimentally that flour can be made from wheat with a pestle and mortar, but that will not convince me that the flour markets of the world are thus supplied."

If the countless myriads of tons of beach on the shores of this globe could be passed through the hands of this writer, he would not detect a single "angular fragment" (McAdamised) among them. On the shore each lump of rock is successively worn into a boulder, each boulder into a pebble, and finally each pebble into sand. This is the main source of the sand which lies between the beach and the ooze-bed of the ocean.

But the sea-shore factory of boulders and drift is not the only factory, or even the largest factory of boulders and drift. The rocky gullet is the main boulder factory. Lyell (Principles), speaking of Etna, attributes "the enormous rounded boulders of felspar, porphyry, and basalt, a line of which can be traced from the sea from near Giardini, by Mascali and Zapharana to the Val del Bove" to one flood of melted snow. The valleys of the low part of Teneriffe, away from the Peak and near Santa Cruz, are almost all dry except in rain. The beds of the upper parts of these valleys are sheer rock, the middle parts wear the appearance of torrents of boulders, the lower parts are *alluvial plains* of boulders, and opposite the mouths of these valleys are very commonly deltas and bars of boulders. Behind these bars, after each rain, large deposits of earth and sand are formed which the people collect diligently. Where permanent streams exist, they are usually lost at a considerable distance above the mouths of the valleys. That is, except in rains, they percolate to the sea beneath the plains deltas and bars of boulders.

From the sides, hundreds or thousands of torrents of boulders fall into these rivers of boulders. Sometimes these lateral shoots have formed barriers of boulders across the main valley behind which large beds of boulders and earth have accumulated, again to be cleared out and thrust down to the sea-shore by heavy longitudinal rain floods.

So, in Madeira, who does not know the sea-shore boulders of the Praya-Formosa? and for fresh water boulders, the stream at Funchal brings down such a crop at every flood as to choke the channel through its delta of boulders, and unless the channel is kept clear of them artificially, the lower town is subject to the most disastrous inundations.

I mention Teneriffe and Madeira because, like the Galapagos, they are deep-sea volcanic islands. Their surfaces have been ejected when they were already above the sea, and they have been coated and re-coated thousands of times by floods of melted rock when they had long been *sub dio*. So that I conclude that even Agassiz would not attribute the moulding of their surface to the "Glacial epoch." But leave volcanic islands or volcanic mountains out of the question, there is not a mountain stream or

streamlet in the wide wide world which is not at this moment a boulder-factory. Take Europe; in Scotland, Switzerland, and Norway you may see the whole of the hill-side streaked with streams of boulders. They are hurled into Romsdal now by every cascading river and rivulet or dry gullet which scores its magnificent mountain sides when flooded by rain or its equivalent melted snow. Every cascade of water above forms a cascade of boulders below ending in a somewhat vertical triangle or delta of boulder talus. That is, these triangles or deltas of boulders are horizontal where there is room, while they approach the vertical directly as the narrowness of the valley and the consequent steepness of its sides.

Distinct from the clays resulting from atmospheric disintegration, this inland grinding of rock into boulders and pebbles is the main source of the sand which is found mingled with boulders in the parallel terraces into which raised *marine* alluvial plains are cut, and of the *inland* parallel terraces on the opposite sides of each soft valley above each hard gorge. It is the source of the sand of the Scottish Kames and of the Irish Eskers. The so-called northern drift and glacial drift are the combined result of atmospheric decomposition and marine and inland grinding of rock, sized and sorted by water.

This is all going on now, as it ever has gone on *qualis ab incepto* and according to the *fortuna locorum*. That is according to the circumstances of the *place*, not the *period*. And nothing can be more absurd than the expression a "drift period" or a "boulder period" or a "pluvial period" or a "diluvial period" or a "gravel period" or a "period of invertebrates" or an "age of reptiles," or other mistakes between place and period.

GEORGE GREENWOOD

Brookwood Park, Alresford, Sept. 14, 1872

P.S.—Since this was written, I have had the honour to receive from the Smithsonian Institution the Report of the Survey of Wyoming, by Mr. Hayden, United States Geologist.

As far as I have read, he appears to attribute the moulding of the earth's surface, after upheaval, not to glacial but to atmospheric agency and the erosion of rivers. With regard to the inland grinding of rock into boulders, pebbles, and sand, he describes, page 14, the "worn masses of iron ore" "in the bed of the Chugwater," and ends thus: "thousands of tons have been washed down to the valley of the Chug and distributed among the superficial drift. As we leave the ore beds themselves, these strong masses are larger and more angular, and as we pass down the Chug they dwindle to minute pebbles and disappear."

An Entomological Query

I FIND the subjoined note in the recently-published "3e Livraison of Fauvel's Faune Gallo-rhénane; Coléoptères, p. 11. Will some entomologist kindly say whether Fauvel's observation has been since verified or not? If correct, it is one of the most curious of the many curious phenomena connected with beetle-life in formicaries.

"J'ai remarqué ailleurs (Bull. Soc. Linn. Norm. 1861, v. 252), que, sur un assez grand nombre d'individus capturés dans les fourmillières, il ne se trouvait pas un seul ♂. J'engage les entomologistes à vérifier ce fait, si l'occasion s'en présente. Il peut avoir de l'importance au point de vue des mœurs peu connues de nos espèces myrmécophiles."

The note has special reference to *Microcephus staphylinoides*.

W. W. SPICER

Itchen Abbas, Alresford, September 28

Cats' Teeth

DOUBTLESS the case mentioned by Mr. Lydekker is somewhat unusual; but the mere fact of an animal possessing an extra tooth can hardly upset Prof. Owen's theory. It is by no means an uncommon thing to meet with examples of supernumerary teeth in man, and these rarely disturb the arrangement of the others, (mostly occurring on the palatal or lingual sides of normal teeth), I do not therefore see why (judging from analogy) it should be very unusual for the lower animals to possess like peculiarities, although they are not often met with on account of the limited number of skulls examined. Mr. L. does not tell us whether the extra tooth occurs in the superior or inferior maxilla.

4, Finsbury Square W. G. RANGER

PHOSPHORESCENCE IN FISH

WHILE off the Land's End, Cornwall, or between the "Wolf Rock" and "Longships" Lighthouses, in the screw steam-ship *Cumbrae* (*ex* Plymouth for Belfast and Glasgow), on the night of Thursday, August 27, my attention was directed to one of the most beautiful marine phenomena that could well be imagined. At some distance ahead of the vessel the sea appeared quite luminous over large portions of its surface. This luminosity, observed at intervals, on a nearer approach proved to be nothing more nor less than the phosphorescence of immense shoals of fish—mackerel or pilchards, probably both—which could be distinctly seen near the surface; they of course appeared somewhat large, owing to the light which they emitted.

It was a dark, rough night, a strong breeze blowing off the Atlantic at the time; and as a consequence, the vessel, as may be supposed from her description, was lurching and pitching considerably—in fact more so than I had ever experienced in any other vessel, or on any previous occasion.

Having taken up a position on the forecastle, and secured myself by a tight hold on the stanchions immediately over the bow, I watched these fish with intense interest—so much so that at times I could scarcely restrain myself from a loud burst of laughter, so exceedingly interesting were their movements. As the vessel rolled and dipped, these fish, evidently startled by her movements, could be seen near the surface, ahead and on the starboard and port bow, darting forward in quantities as close as I should think it was possible they could well swim together. It was a sight long to be remembered.

I may add, that as the sea broke over the fore part of the vessel, the spray rested on me in drops or globules of, as it were, fatty matter, and much resembled in its luminosity, which lasted for some time, the appearance of so many glow-worms; doubtless this was given off by the fish themselves.

Some interesting particulars of the nature of phosphorescence in fish appeared in NATURE (Notes) vol. iv. p. 287 (Aug. 10, 1871), as presented in a memoir to the Association of Naturalists and Physicians at Turin, by Sig. Panceri of Naples, from which I extract the following:—

"The phosphorescent substance in fishes, in whatever part of the body it may be situated, is always fat" (this bears out my former remarks) "and the phenomenon is due to its slow oxidation in contact with air."

Further particulars appeared in NATURE, vol. v. p. 132 (Notes), December 14, 1871, as derived from the same author, of which the following is also an extract:—

"In all cases the phosphorescence is due to matter cast off by the animal—it is a property of dead separated matter, not of the living tissues.

"He" (Sig. Panceri) "also finds that this matter is secreted by *glands*, possibly special for this purpose, but more probably the phosphorescence is a secondary property of the secretion. Further, the secretion contains epithelial cells in a state of fatty degeneration, and it is these fatty cells and the fat which they give rise to which are phosphorescent. It is due to the formation in decomposition of a phosphoric hydro-carbon, or possibly of phosphuretted hydrogen itself."

Are there any special conditions of weather, or season, during which this phenomenon of phosphorescence is more readily observed than at others? Although by no means a stranger to the sea, I have never, on any occasion, seen anything approaching to it.

I made a trip from Plymouth to the Eddystone Lighthouse and back on the previous night, and although nets were out (as known by their floats) at some distance from land for the purpose of securing the fish that I have mentioned, no phosphorescence of the kind was to be seen; the sea on this occasion was comparatively smooth.

JOHN JAMES HALL

ON THE RETENTION AND COLOURING OF EGGS, AND THE PROTECTIVE MIMICRY OF SOUNDS

1. IS it known for how long a time a bird possesses the power of retaining its egg?

Last summer, from the number of nests in this neighbourhood, the writer was able to study the habits of kingfishers (*Halcyon vagans*) with more facility than usual. The movements of one pair excited much interest. On the 19th October this pair were observed to be busily engaged in excavating a home in the back of the turf chimney of an empty cottage. After many days spent in hard labour, this was abandoned; subsequently several tunnels were commenced, in some of them considerable progress was made; then they were in like manner deserted. The seventh resting-place, begun November 26 (there must still be a witchery about number seven even at your Antipodes), was finished, occupied, and therein, on December 24, a brood was hatched. Can there be reason to doubt that the eggs in the ovary of the female must have been in a forward state in the third week in October? At the close of that month the first egg to be laid must have been ready for extrusion. From personal observation we know that our kingfisher lays nearly every morning till the clutch of eggs is completed; the number of eggs to a clutch varying from five to seven. Here we have a bird engaged in laborious, almost incessant exertion, for quite six weeks, physically in a condition analogous to that of a pregnant animal. Three of the homes excavated and abandoned were so far finished that the chamber was hollowed out, so that a deposit of eggs must have been imminent on three occasions during that period of six weeks. It is well known that the domestic fowl, on a change of quarters, will, in its strange home, sometimes retain the egg for hours beyond the usual time of laying, often depositing what is called a double-yoked egg, but we have to do with the freedom of wild nature. It is easy to suggest that our kingfisher relieved itself by dropping its egg; obviously that would be opposed to the marked instinct of so persevering and painstaking a nest-builder; besides, would that mode of acquiring ease be twice repeated by a bird that endured such toil to make a hiding-place for its progeny—toil only to be appreciated by those who have watched its daily work?

2. Can a bird influence the colour of its eggs protectively?

A proposition that few physiologists would answer in the affirmative, yet naturalists have held, perhaps still do maintain, diverse opinions as to the cause of abnormally coloured eggs. The following facts are laid before your readers for information:—Rather late in last summer a female bittern (*B. poicilopterus*) was slightly wounded and secured. It was kept within a *grassy* enclosure. While thus confined it laid an egg of a pale bluish green colour, precisely like that of a heron. The egg of our bittern is about the same size; its normal colour of a similar olivaceous buff as that of your *B. stellaris*. This buffy olivaceous tint harmonises well with the half-faded leaves of aquatic plants of which the nest is often built, such as those of *Typha angustifolia*, *Carex virgata*, &c.; in fact, a bittern's nest is by no means an offensively obtrusive object.

Having had eggs from several nests under observation, I have noticed that bittern's eggs do now and then vary in tint from buffy brown to pale olivaceous; but in no case approximately to that blue green of the heron's egg.

In the instance cited, was the peculiar colouring used as a means of securing for the egg the protection of the *verdure of the grass* in which it was deposited? or was it merely the effects of a brief confinement and a slight local wound? The conditions under which this egg was laid may be considered as somewhat analogous to those under which the cuckoo laid No. 26 specimen in the famous series of eggs formed by Herr Baldamus (see vol. f.p. 508); nor is the occurrence of this peculiar-looking bittern's egg without its use in estimating the value to be accorded to certain abnormally coloured eggs as illustrating and supporting a theory not adverse to the proposition—Can a bird influence the colour of its eggs protectively?

3. Are the eggs of the cuckoo ever approximately coloured like those of its dupe for protective purposes?

In vol. v. p. 501, may be found a brief note, stating that the eggs of our whistler, or small cuckoo, were not coloured approximately to those of its dupe, nor, indeed, would such precaution appear necessary, when the form of the nest of its victim was considered. Last season one of the writer's children brought in a nest of the blight bird (*Zosterops lateralis*) containing four eggs, one of which was a puzzle indeed; it was found on comparison, that although a shade darker in colour, it resembled the rest of the eggs in the nest, pale green-blue, spotless and unstained as those of the homely russet-clad hedge-sparrow. In size and shape it was like that of the small cuckoo. Hundreds of eggs of the *Zosterops* (a new colonist, yet already one of our commonest birds) have passed under the notice of the writer, but none have resembled the specimen alluded to. That it might possibly have been laid by a whistler seemed at length the only solution of the problem, how an egg of that size and shape came into that nest. The *Zosterops* does not belong to the purely indigenous genera of New Zealand; like the *Chrysococcyx* and its usual dupe, the *Gerygone*, it is to be found in other colonies far beyond the bounds of ferny Maori-land. It builds a suspended nest, another indication of its foreign origin. It is quite likely that in warmer climes the small cuckoo may readily avail itself of the advantages presented by this mode of construction, as ensuring a greater degree of safety from reptilian egg-robbers. The open cup-shape of the *Zosterops'* nest would disclose to its owner the marked contrast between its own clear blue-green eggs and the large, greenish-dun egg of the parasite; hence the effort at protective mimicry. This would be unnecessary, as before pointed out, in the dimness of the domed structure of the *Gerygone*. If the egg described is that of the small cuckoo, it is the first instance known to the writer of the *Zosterops* being used as a dupe. It should be noticed that last season the small cuckoo appeared in greater numbers than usual in this neighbourhood, where the nests of the blight bird, in the aggregate, now outnumber those of every other species of bird.

These facts are communicated under the impression that they may be of interest to ornithologists, and in fairness should not be withheld, the rather as the writer does not yet give in his adhesion to the theories of Herr Baldamus.

4. On the Mimicry of Sounds.

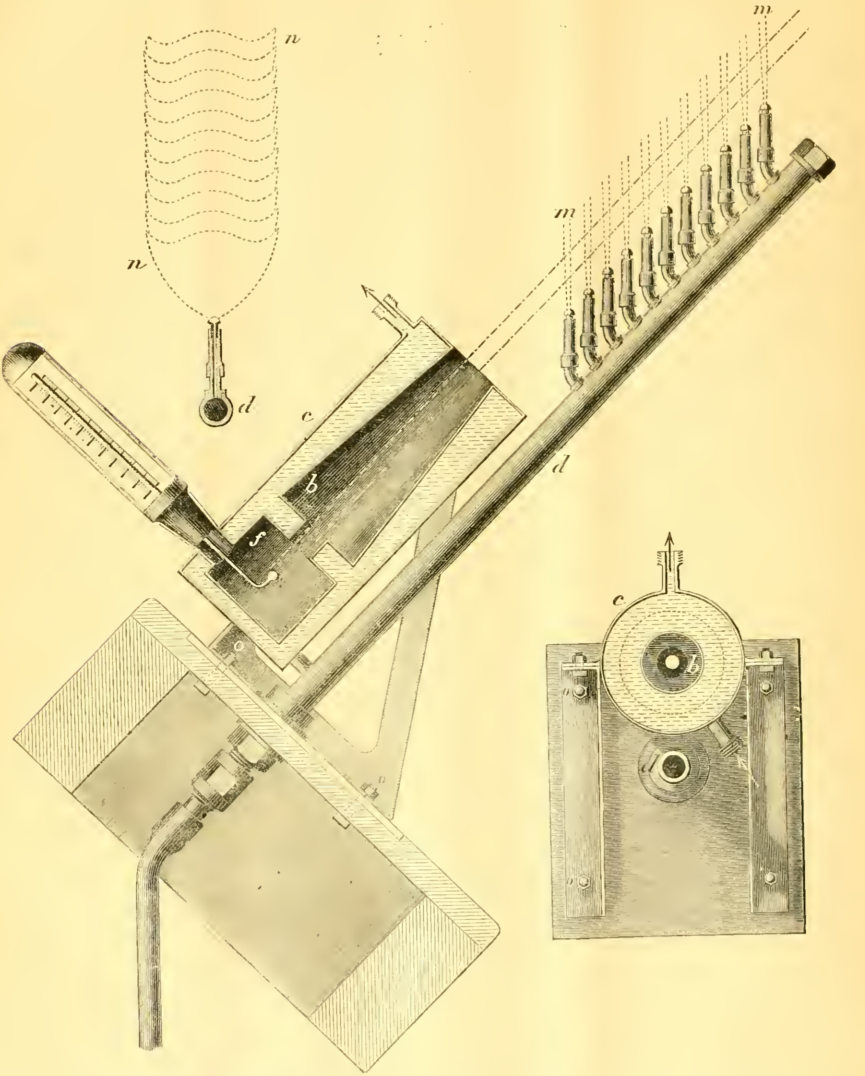
When camping for some days on a river-bed, where many species of birds abounded, the writer and one of his sons (well acquainted with bird voices) frequently heard what they took to be one of the notes of the *Hæmatopus*, but that wader was nowhere to be seen; at length we traced the call to the Piopio (*Keropia crassirostris*) a bird with feeble powers of flight, yet one that delights in the open glades of river-beds. The mimic cry was always given when near to a stream, just where the red-bill (*Hæmatopus*) would be likely to be found. A pair of red-bills can drive away a hawk; now a hawk, "from his place on high," perceiving something near the water, might forego its swoop on hearing the mimicked note of the wary, yet bold red-bill. We have observed our grey warbler give an exact imitation of the cry of our common tern (*S. antarctica*) one of the boldest birds in defence of its young.

THOMAS H. POTTS

Ohinitahi, June 29

THE SUN'S RADIANT HEAT

THE readers of the *Comptes Rendus* are aware that Père Secchi addressed a letter to the Academy of Sciences at Paris, some time ago (Comp. Rend. tome lxxiv. pp. 26–30), containing a review of my communications to NATURE, published July 13, October 5, and November 16, 1871, in which he questions the correctness of the reports which I have published containing tabulated statements of the temperature produced by solar radiation. His reason for questioning the reliability of my



tables, appears to rest on the supposition that my instruments do not furnish correct indications. "It is astonishing," he says, "that Mr. Ericsson should find with his instrument a higher stationary temperature in winter than in summer. This (even bearing in mind the greater proximity of the sun in winter) makes me think that there must be something very singular in his apparatus, possibly making all its indications deceptive. Even under the beautiful sky of Madrid, M. Rico y Sinobas found, in

December, for the solar radiation, 12^{div}, by his actinometer, and, in June 25^{div}, 56"." It is not my purpose to prove the fallacy of M. y Sinobas' actinometric observations; but I think "that, there must be something very singular in his apparatus," since in North America in lat. 40° 42′ (the latitude of Madrid is 40° 24′), solar intensity at noon during the latter part of June is 64°·5; while when the sky is clear at noon during the latter part of December, the temperature under similar atmospheric conditions, reaches 58°·7. But observations made in the morning or evening during the month of June at the hour when the sun's altitude is the same as at *noon* in December, show that the intensity of the radiant heat in June is only 53°·08 against 58°·7 in December. Actual observations have thus established the fact that for *corresponding zenith distance*, the temperature produced by the radiant heat when the earth has nearly reached perihelion, is 58·7—53·8 = 4°·9 *higher* than at midsummer. Referring to the table published in NATURE, vol. v. p. 47, it will be seen that, owing to the greater proximity of the sun, the increase of absolute intensity of solar radiation is 5°·88 Fah. during the winter solstice. Père Secchi will do well to examine the subject more carefully, and make himself better acquainted with the character of the investigations which had led to an exact determination of the temperature produced by solar radiation.

The readers of the *Comptes Rendus* who have examined the review referred to, ignorant of the contents of the articles in NATURE, will be surprised to learn that I have not, as the reviewer asserts, questioned the power of vapour to diminish solar intensity. Having stated the result of numerous observations of the sun's radiant power at corresponding zenith distance, and proved that the temperature during midwinter is higher than at midsummer, I made the following remark in NATURE, Nov. 16, 1871: "In the face of such facts it is idle to contend that the temperature produced by solar radiation under corresponding zenith distance and a *clear sky* varies from any other cause than the varying distance between the sun and the earth." It is absurd to suppose that a person having devoted many years to the investigation of solar radiation should deny the retarding influence of vapour, since not one observation in a hundred indicates maximum solar intensity, owing to the presence of vapour in the atmosphere.

The following brief description of the actinometer will show that there is not, as Père Secchi supposes, anything very singular in this apparatus tending to render its indications deceptive. The principal part of the instrument consists of an air-tight cylindrical vessel, the axis of which is directed towards the sun, the upper end being provided with a thin lens covering an aperture of 3in. diameter. The bulb and part of the stem of a mercurial thermometer is inserted through the upper side, at right angles to the axis; a small air pump being employed for exhausting the air from the cylindrical vessel. The latter is surrounded by a casing through which water is circulated by means of an ordinary force pump and flexible tubes, connected with a capacious cistern containing water kept at a constant temperature of 60° Fah. The bulb of the thermometer is cylindrical, 3 ins. long, its contents bearing a very small proportion to its convex area. The upper half is coated with lamp black, while the lower half of the bulb is effectually protected against loss of heat from undue radiation. The diminution of energy attending the passage of the sun's rays through the lens is made good by the concentration effected by its curvature; hence the entire energy of the radiant heat will be transmitted to the cylindrical bulb. The inclination of the latter, it should be observed, promotes a rapid upward current of the mercury on the top side, and a corresponding downward current on the lower side, thereby rendering the indication prompt and trustworthy. The water in the surrounding casing being maintained at a constant temperature of 60° Fah., it will be evident that the *zero* of the thermometric scale of the actinometer must correspond with the line which marks sixty degrees on the Fahrenheit scale. It scarcely needs explanation that the height reached by the mercurial column after turning the instrument towards the sun, will be due wholly to solar energy, since the radiation of the exhausted vessel towards the bulb of the thermometer is only capable of raising the column to the actinometric zero (60° Fah.)

The readers of NATURE will remember that one of the articles reviewed by Père Secchi, the one published in vol. v. pp. 449-452, contained a demonstration accompanied by several diagrams, proving that the radiant heat emitted by the chromosphere and outward strata of the solar envelope is inappreciable at the surface of the earth. It will be remembered also that the mode adopted in deciding the question whether the solar atmosphere is capable of emitting heat rays of appreciable energy, was that of shutting out the rays from the photosphere, and collecting those from the chromosphere and envelope in the focus of a parabolic reflector. Scarcely any heat being produced notwithstanding the great concentration by the reflector, we proved the fallacy of Père Secchi's remarkable assumption that the high temperature at the surface of the photosphere is caused by *radiation* "received from all the transparent strata of the solar envelope." It is surprising that notwithstanding the completeness and positive nature of the demonstration referred to, no allusion whatever is made to the same in the review put forth as a careful examination of the contents of the article under consideration. Ignoring the evidence furnished by actual trial, in proof of the extreme feebleness of the radiating power, the reviewer proceeds to state "that the outward strata might be less hot, and that the effect which we measure is the aggregate of the quantities of heat which are added, emanating from the various transparent strata." How the outward colder strata cause an elevation of temperature by their radiation towards the solar surface, is not explained; but reference is made to the result of an experiment with three small flames, in support of the assertion that the high temperature of 10,000,000° C., assigned to the surface of the sun, is owing to radiation received from all the transparent strata surrounding the photosphere. The reviewer states: "a very simple experiment, made at my request by P. Provenzali, has shown that, if a heating of 2°·5 can be obtained with one flame, with two flames placed one before the other 4°·5 are obtained, with three flames 5°·4; a result, which of course could be easily foreseen, for everybody knows that flames are transparent."

My practical demonstration establishing the feebleness of the radiating power of the matter composing the solar envelope having received no consideration, while the reviewer, in support of his singular theory of solar temperature, points to the result of the rude experiment conducted by Père Provenzali, I have deemed it necessary to show that transparency of flames is too imperfect to warrant the inferences drawn.

The accompanying illustration represents an apparatus by means of which the exact degree of transparency of a series of flames has been ascertained.

Description: *b* conical vessel open at the top, the bottom communicating with a cylindrical chamber, *f*, by an intervening narrow passage, the whole being enclosed in an exterior vessel *e* charged with water kept at a constant temperature, precisely as in the actinometer. A thermometer is applied near the bottom of the cylindrical chamber, the centre of the bulb coinciding with the prolongation of the axis of the conical vessel. A gas pipe, *d*, provided with a series of vertical burners, is firmly secured to a table, in a position parallel to the axis of the conical vessel. The burners are provided with caps in order to admit of any desirable number of jets being ignited at one time. When gas of ordinary pressure is admitted into the pipe *d*, the side view of the flames will be as indicated by the dotted lines at *m*, *m*, the thickness of each flame being nearly 0·20 ins, while the width, shown by the dotted lines *n*, *n*, somewhat exceeds 3 inches from point to point. It will be observed that the prolongation of the axis of the conical vessel upwards passes through the central portion of the flames at the point of maximum thickness and intensity. Supposing that the instrument (attached to a table turning on declination axis within a revolving observatory) is directed towards the sun, it will be evident that all the rays of a beam the section of which corresponds with that of the bulb of the thermometer, will pass through the flames before reaching the said bulb. Now the temperature of the flames at the point pierced by the solar rays, is fully 2000° Fah., while the intensity of the rays does not exceed 60°. The illustrated device enables us to ascertain whether the rays thus entering at a temperature 1,940° lower than that of the incandescent gas, have their intensity augmented or diminished during the passage through the heated medium. But before we can determine this question, it will be necessary to ascertain what temperature is communicated to the thermometer by the radiant energy of the flames, independent of solar heat. Accordingly, a series of experiments have been made, the result of which is recorded in the annexed table. The nature of the investigation will be readily understood from the following explanation. The instrument being turned away from the sun and the upper flame *m* ignited, while the external casing *e* is kept at a constant temperature of 60°, the column of the thermometer at *f* slowly rises to 61°·76. The radiant heat, therefore, of a single flame produces a differential temperature of 61·76 − 60 = 1°·76. The

second flame being ignited, the temperature rises to 62°·88, thus increasing the differential temperature to 2°·88. The ignition of the third flame augments the differential temperature to 3°·80. The remaining flames being ignited in regular order downwards, their combined radiant energy elevates the temperature to 67°·90. Deducting the temperature of the enclosure *c* (60°), the trial shows that although the single flame at the maximum distance from the bulb, is capable of producing a differential temperature of 1°·76, the energy of the *ten* flames together produces only 7°·90. This fact furnishes conclusive evidence of the imperfect transparency of the flames. Assuming that the heat rays are capable of passing freely through the incandescent medium, it will be perceived that the entire series of flames should produce a differential temperatue of $1{\cdot}76 \times 10 = 17°{\cdot}60$, showing a retardation of $17{\cdot}6 - 7{\cdot}9 = 9°{\cdot}7$. And if we take into account the diminished distance of the lower flames from the bulb of the thermometer, it will be found that the actual retardation greatly exceeds this computation. We have thus demonstrated that flames are most transparent, as supposed by Père Secchi. Consequently, the inferences drawn from the experiment to which the distinguished *savan* refers in his letter to the French Academy of Sciences are wholly unwarrantable.

Having disposed of the question of transparency, and ascertained the degree of temperature communicated to the thermometer by the radiant energy of the flames alone, let us now suppose that the instrument has been turned towards the sun. The temperature produced by the combined energy of solar radiation, and the radiation of the flames, after directing the instrument towards the luminary, will be found recorded in the fifth column of the table. Our space not admitting of a detailed statement, we must dispense with an examination of the energy transmitted for each flame separately, and at once consider the effect produced by passing the sun's rays through the entire series. It has already been stated that the radiation of all the flames combined imparts a differential temperature of 7°·90 to the thermometer. By reference to the table it will be seen that, the temperature produced by the sun's rays is 21°·69 when the flames are extinguished.* Consequently the temperature, after lighting the whole series, ought to be $21{\cdot}69 + 7{\cdot}90 = 29°{\cdot}59$, since solar heat, under analogous conditions, is capable of increasing definitely the temperature of substances whatever be their previous intensity.† Referring again to the table, it will be found that the maximum increase of temperature attending the passage of the comparatively cold solar rays through the incandescent gas, is 2°·31, while the radiant energy of the flames produces a differential temperature of 7°·90. This extraordinary discrepancy points to an increase of molecular energy within the incandescent gas, notwithstanding its temperature being fully 1,900° higher than that produced by the sun's radiant heat.

J. ERICSSON

* Notwithstanding the low temperature indicated by the thermometer of the experimental apparatus, 21°·69, the actual solar intensity during the investigation, ascertained by the actinometer, has at no time been less than 50°, a very instructive fact proving the futility of attempting to measure solar intensity by thermometers the bulbs of which are exposed to the refrigerative action of surrounding air. For the purpose in view, however, that of measuring the comparative radiant power of flames and solar heat, the unavoidable exposure of the bulb to atmospheric influence, is unimportant, provided the enclosure be kept at a constant temperature during the experiments.

† Père Secchi reminds us, in "Le Soleil," that Mr Waterston found by his solar intensity apparatus, that, when the thermometer was enclosed in a heated vessel imparting upwards of 400° Fah. to the bulb, the same degree of differential temperature was reached by exposure to the sun, as when a cold enclosure was employed which reduced the indication of the enclosed thermometer to that of ordinary atmospheric temperature.

NOTES

MR. DARWIN's forthcoming work on "Expression in Man and Animals" bids fair to be of a more popular character than any of his other publications. It will commence with a statement of the general principle of Expression;—that serviceable actions become habitual in association with certain states of the mind, and are performed, whether or not of service, in each particular case. This will be illustrated in the case of expression of the various emotions in man and the lower animals. The means of expression in animals will then be discussed, and the special expressions of animals and man, such as the depression of the corners of the mouth in grief, frowning, the firm closure of the mouth to express determination, gestures of contempt, the dilatation of the pupils from terror, the causes of blushing, &c. In conclusion, the bearing of the subject will be spoken of on the specific unity of the races of man, the part will be discussed which the will and intention have played in the acquirement of various expressions, and the question of their acquisition by the progenitors of man will be referred to. Seven heliotype plates reproduced from photographs will illustrate the work.

HISTORY is said to repeat itself. It is singular to find that six months ago the colony of Victoria was involved in a similar controversy to that which has recently agitated the scientific world at home. Baron Friedrich von Mueller is the Dr. Hooker of Australia. The Botanic Gardens at Melbourne have become under his management as truly scientific an institution as those at Kew, and their Director has performed similar eminent services both to the colony and to the mother country in spreading a knowledge of the value of the indigenous vegetable products of Australia. After twenty years' service, however, it is discovered that von Mueller is "not a landscape gardener," and an agitation is set on foot—we do not, however, hear that it originates in the Board of Works, if there is such a department in Victoria, nor do we know who is the Ayrton of the Antipodes—to deprive him virtually of the control of the Botanic Gardens. Next to the removal of Dr. Hooker from Kew, botanical science all over the world could receive no severer blow than the deposition of von Mueller from the position he occupies at Melbourne.

WE believe that, in addition to the 4,000*l.* which we recently noted, another 8,000*l.* will be voted in the next French Budget, to be devoted to the preparations necessary for the observation of the forthcoming Transit of Venus.

THE Californian Academy of Sciences experienced a genuine sensation at its meeting on September 9, in welcoming Prof. Agassiz returning from the *Hassler* Expedition, on his first arrival on United States' territory, where he was received by Prof. Davidson, the president of the Academy; Prof. Gillman, the principal of the University of California, Prof. Torrey, of Columbia, the Nestor of American Botanists, and others. In his address on the occasion, Agassiz alluded in the following terms to the growth beneath his eyes of the great Cambridge Museum:—"I went single-handed to Cambridge, to teach natural history, twenty-five years ago. When I delivered my first lecture there was not in the University a single specimen which I could use to illustrate what I had to say. And yet a little band of students, feeling an interest in what they could learn

in the lecture-room, and others, thought such a pursuit was worth encouraging, and by-and-by the idea arose that a museum would be of use, and the means were gradually forthcoming, at first sparingly in small contributions, but gradually more liberally in larger sums, until at this moment, after fourteen years only, the museum at Cambridge stands in my estimation without parallel in the world." This he followed up by a statement of what could be done in a new country like California for the advancement of science:—"What would you think of the man who would raise himself his food when he is engaged in the law business or in the medical profession? You would think he was wasting his time. Now I say the scientific man is wasting his time or is obliged to waste his time when he is not provided with the appliances with which he can work, and which he is capable of producing. And I hold that it is one of the duties of those who have the means to help those who have only their head, and who go to work with an empty pocket. So I think that one of your duties, besides fostering and nursing the interest you individually feel for science, is to arouse that general interest in the community, which will make every true patriot, every lover of his State, every philanthropist, every man who has the heart to leave a good repute and an honourable memory, desirous of contributing to your progress." We know there are men in California who both can and will respond to this generous appeal.

PROF. TYNDALL left England on Saturday last by the *Russia* from Liverpool, on a visit to the United States.

THE Council of the Bedford (Ladies') College, Bedford Square, have decided on attempting to introduce some branch of Natural Science into the regular programme of the college studies, and will make a commencement with a class of Vegetable Physiology Mr. A. W. Bennett, who will conduct the class, will also give the Introductory Lecture of the session on Wednesday, October 9th, on "The Place of Natural Science in a Liberal Education."

A VACANCY has occurred in the staff of the Royal Observatory, Greenwich, by the resignation of Mr. James Carpenter, whose services have been transformed to a private engineering firm.

FROM the second report of the Cambridge Natural Science Club we learn that seven meetings have been held during the long vacation, at which the following papers have been read:—"On Turacin," by Mr. R. M. Lewis, B.A., Downing College; "On the old Glaciers of Wales," by Mr. G. E. Paget, Caius College; "On Colour," by Mr. C. T. Whitmell, B.A., B.Sc., Trinity College; "On Sponges," by Mr. A. F. Buxton, Trinity College; "On Thermo-Magnetism," by Mr. J. E. H. Gordon, Caius College; "On *Peronospora infestans*," by Mr. H. M. Martin, M.B., D.Sc., Christ's College; "On Absorption Spectra," by Mr. R. M. Lewis, B.A., Downing College. The club consists of twelve members, of whom seven or eight were in residence during the Long. The attendance at the meetings was good, averaging six or seven members, and two or three visitors. The rule, requesting that members shall give "such practical illustration as the subject admits of," has been very well observed, as almost all the papers have been illustrated by experiments or specimens.

THE opening (public) lecture of the Literary and Scientific Society attached to the Whitechapel Foundation School, was given on Tuesday evening last. Among the lectures to be delivered during the session, will be one on the "Early History of Man," by E. Clodd, F.R.A.S., and on one of the "Divisions of Light," by W. Spottiswoode, F.R.S.

MR. R. PRATT, late Master of the Queen's School of Art, and gold medalist of the Department of Science and Art, has been elected Art-master in the Hartley Institute, Southampton; and Mr. J. R. Brittle, Associate of King's College, London, and late Whitworth Scholar, has been appointed Lecturer on Engineering at the same institution.

THE following classes in connection with the Manchester Mechanics' Institution have been commenced for the season, under the management of Mr. Robert Routledge, B.Sc.:—Applied Mechanics, Steam and the Steam Engine, Acoustics, Light and Heat, Magnetism and Electricity, Organic Chemistry, Inorganic Chemistry, and Practical Chemistry.

THE management of the Islington Youths' Institute has just issued the programme for the winter session. Amongst the various subjects taught at this Institution, those in connection with the Science and Art Department form a conspicuous feature, and six classes in Art and eight in Science are announced. Among these we may mention Drawing (Freehand, Model, and Geometrical), Building Construction, Machine Construction, Geometry (Plane, Practical, and Solid), Electricity and Magnetism, Physical Geography, Physiology, Acoustics, Light and Heat, and Inorganic Chemistry. At the examinations held in May last, out of 129 who competed for the Government prizes, only 13 failed to pass.

THE Council of the Institution of Civil Engineers have awarded the following premiums and prizes for work done during the session 1871-2:—A Telford medal and a Telford premium in books to each of the following gentlemen: Bradford Leslie, for his "Account of the Bridge over the Gorai River, on the Goalundo Extension of the Eastern Bengal Railway;" Carl Siemens, for paper on "Pneumatic Despatch Tubes: the Circuit System;" W. Bell, for paper on "The Stresses of Rigid Arches, Continuous Beams, and Curved Structures;" J. H. Latham, for description of "The Soonkésala Canal of the Madras Irrigation and Canal Company;" G. Gordon, for paper on "The Value of Water, and its Storage and Distribution in Southern India;" A Telford premium in books to F. A. Abel, F.R.S., for paper on "Explosive Agents applied to Industrial Purposes;" and the same to Bashley Britten, for paper on "The Construction of Heavy Artillery, with reference to Economy of the Mechanical Forces Engaged." The Manby premium in books to C. Andrews, for paper on "The Somerset Dock at Malta." A Miller prize each to Oswald Brown, for paper on "Sewage Utilisation;" A. T. Atchison, for paper on "Railway Bridges of Great Span;" J. Addy, for paper on "The most suitable Materials for, and the best mode of Formation of, the Surfaces of the Streets of Large Towns;" A. E. Preston, for paper on "Wood-Working Machinery;" W. P. Orchard, for paper on "The Education of a Civil Engineer."

WE are informed of the early publication of the first number of the *Telegraphic Journal*, a Monthly Illustrated Review of Electrical Science. It will be edited by the Rev. William Higgs, M.A., sometime assistant to Sir Charles Wheatstone.

THE present autumn has been remarkable for the appearance in scattered localities all over the country of one of our rarest and most beautiful butterflies, the Camberwell Beauty, *Vanessa Antiopa*, very few British specimens of which exist in our cabinets. The *Entomologist* records the capture of upwards of 200 specimens in all parts of the country, from the Channel Islands to Aberdeen. It is very remarkable that they nearly all differ in colouring to a perceptible extent from the Continental variety, the border being creamy white instead of buff-coloured. If they are genuine natives their spasmodic appearance in this manner is very singular, and worthy of careful observation. Several other rare butterflies, especially *Argynnis Lathonia*, *Pieris Daplidice*, and *Colias Hyale*, have also been unusually abundant this season.

A PLAGUE of butterflies is a rare occurrence. A short time ago, however, the town of Florence was invaded by a prodigious quantity of these insects. All the distance of the Long'arno between the Piazza Manin and the Barriera and in all the adjacent streets the passage was almost obstructed by an extraordinary quantity of butterflies that had swarmed in such thick clouds round the gaslights that the streets were comparatively dark. Fires were immediately lighted by order of the Municipality and by private citizens, in which the butterflies burnt their wings, so that half an hour afterwards one walked upon a layer formed by the bodies of the butterflies an inch thick ! ! ! They were of a whitish colour, and some of the streets appeared as if covered with snow, at least so say the Italian papers.

DR. PATERSON, of Bridge of Allan, writing to the *Scotsman* of September 9, says that on Saturday last he captured in his garden on the flowers of *Lilium auratum* a fine specimen of the Striped Hawk Moth (*Deilephila Livornica*). Dr. Paterson believes this insect has been captured only once before in Scotland.

THE REV. M. J. BERKELEY describes in the *Gardener's Chronicle* a very remarkable instance of luminosity in fungi. It occurred in the mycelium of an unknown species growing on a trunk of spruce or larch, and was so powerful as to make a perfect blaze of white light in the track where the trunk had been dragged, and vividly illuminating everything in contact with it. It gave almost light enough to read the time on the face of a watch, and continued for three days.

THE Brighton Aquarium has lately received two pair of beautiful specimens of the Paradise or Peacock fish. This fish came first from China, and has been acclimatised by M. Carbonnier, the great pisciculturist of Paris; they are very lovely little creatures. Some of their habits are singular; thus M. Carbonnier states that "as the eggs are laid the male carries them away in his mouth, and deposits them in a nest which he builds for them. He will not allow the female to come anywhere near the nest, and if she ventures to approach he swings himself round, and drives her away."

THE Secretary of the U.S. Navy has recently received, by way of Copenhagen, a letter from Captain C. F. Hall, of the *Polaris*, written on the 24th of August, 1871, at Tossak, North Greenland, latitude 73° 21', longitude 56° 5' west. Although this is but a few days later than the despatch brought home by the frigate *Congress* nearly a year ago, it renews the assurance of the harmony existing on board the vessel between the members of the expedition, and the perfect satisfaction of all with the equipment and preparations for the coming winter. It is well known that no efforts were spared by the Navy department to render this expedition the most perfect and complete in its equipment of any ever sent to the North; and the success of these endeavours must, therefore, be a source of great gratification to it. Governor Elberg, of the Upernavik district, accompanied the *Polaris* as far as Disco, and brought back the despatches, which have thus been a year in their journey to Washington. Through his help Captain Hall obtained sixty strong, healthy young Esquimaux dogs, and a large supply of reindeer furs, seal-skins, &c. At Upernavik Hans Christian, well known to the readers of Kane's narrative, joined them as hunter and dog-driver, and was accompanied by his wife and three children, who with Joe, and Hannah, and their child, Captain Hall's faithful companions in previous years, made up quite a party. It will be remembered that Captain Hall met the returning Swedish expedition at Holsteinbourg, and that its commander supplied him with charts and copies of such of his notes as promised to be of service to him. Partly in consequence of the suggestions of the commander, Baron Von Otter, and of other scientific men whom he met in Greenland, Captain Hall concluded to abandon the Jones Sound route, and intended to cross Melville Bay to Cape Dudley Digges, and thence to steam directly to Smith Sound, with a view of finding a passage on the west side of the sound from Cape Isabella to Kennedy Channel. Captain Hall speaks very favourably of the steaming qualities of the *Polaris*, her passage having been perfectly satisfactory from port to port. The entire steaming time from New York to Disco was twenty-seven days, seven hours, and thirty minutes.

MR. HULL, of the Irish Geological Survey, has published a letter in the *Dublin Morning Mail* in reference to the quantity of coal available for use in the Irish coal-fields, in which it is stated that the net tonnage available in Ireland is 182,280,000 tons—in Ballycastle, County Antrim, 16,000,000; in Tyrone, 32,900,000; in Queen's County, Kilkenny, and Carlow, 77,580,000; in Tipperary, 25,000,000; in Clare, Limerick, and Cork, 20,000,000; and in Connaught (Arigua district) 10,800,000 tons.

WE are glad to observe from the eighth Report on the Melbourne Observatory that the southern half of the heavens is being observed to good purpose, though both the Board of Visitors and Mr. Ellery think that several improvements in details are much needed in order that the work may be done with anything like sactisfactoriness. The great telescope continues to give increased satisfaction, though there seem to be serious defects in the Magnet House, and a great want of clerical assistance in reducing the great number of stars observed. The number of stars observed up to the period of the report was 48,672, the number reduced being only 36,917. It appears that a large number of drawings of nebulæ and other celestial objects observed with the Great Melbourne Telescope has accumulated, and we earnestly hope that the Board's request to Parliament to supply the funds necessary to publish these may meet with a favourable reply. Naturally the Board and the Government Astronomer express regret that the Eclipse Expedition should have turned out a failure from the unfavourable weather. Still the colony deserves the greatest commendation for the gallant endeavour it made. We are glad to see that vol. iv. of the "Melbourne Astronomical Observations" is now in the press, that a General Catalogue for 1870, containing the results of all the transit work at the observatory, is in preparation, and that in January last the publication of a series of monthly meteorological observations was commenced. Moreover, photographic pictures of the moon are being taken, and promise, we are told, to be both excellent in themselves as works of art, as well as useful in aiding the scientific observations now taking place in Europe. Altogether the Report reflects the greatest credit on Mr. Ellery, the Government Astronomer, and his too limited staff.

THREE slight shocks of earthquake were felt on the evening of July 27 at Valparaiso and at Caracas.

A SLIGHT shock of earthquake was felt at Chopea in Khandeish on the evening of Friday, July 12, at about seven o'clock. The shock lasted about a minute, and appears to have been felt at the same time at Amainer, Dhurrangaon, Dhulia, and Julgaon. Its course was from west to east.

ON the 15th of April a very violent volcanic eruption took place from the volcano Merapi in Java, which had been quiet since 1863. Great destruction of lives and property occurred, many villages being totally destroyed. The outburst was entirely unexpected, and the showers of stones and ashes and the streams of lava were very destructive. At Solo and other places the showers of ashes lasted for three days, and it became so dark that the lamps had to be lit. By the last accounts some 200 dead bodies had been found on one side of the volcano.

THE BIRTH OF CHEMISTRY

I.

Introduction—Ancient Science—Origin of Chemistry—Derivation of the Name—Definitions of Chemical Science—Early Ideas relative to the Formation of the World.

THE history of a natural science resembles in many respects the history of a nation. In each instance the object is first to obtain a knowledge of causes, then to frame laws. The first are those causes which most promote the well-being of the nation, the second those causes which produce the phenomena of the Universe. In each instance we start with an absence of all law, and we may observe the slow efforts of the human mind to trace each effect to its proper cause, to group together causes, and finally to connect them by one bond. The main difference is this, that in the case of the nation man has to deal with laws which must be founded upon a just study and close observance of every phase of that particular community, influenced as it is by numberless external causes, such as race, climate, religion, habit of thought, tradition; while in the case of the science he has to evolve pre-existent laws, also by the close observance of facts, which are hidden from him by the complex mechanism of nature. M. Taine would tell us that the laws which influence the development of peoples are just as absolute, definite, and pre-existent, as those which govern the affairs of nature; but we are quite disinclined to admit this, even in regard to one particular race, in one particular locality. In both histories we have similar forms of government, similar assemblies of lawgivers; we have our aristocracies, oligarchies, democracies, republics: we have at some period or other Conservatives and Liberals of every shade. We know not what Conservative rule can compare with the dominance of the science of Aristotle for twenty centuries, and we cannot be too ready to welcome the Liberal-conservative era of Copernicus and Giordano Bruno, the Liberal era commenced by Galileo and Francis Bacon, which by easy stages is passing, if it has not passed, into the right Radical era of modern scientific thought. The "Republic of Learning" is no empty phrase.

No one would venture to deny the value of a knowledge of the history of nations, and we are inclined to believe that the history of the natural sciences is not without its uses. It is neglected because during the last century new discoveries have quickly succeeded each other, old sciences have augmented, while new sciences have arisen; in fact, the progress of science has been so extraordinarily rapid that we have scarcely time to turn aside and look at its past history; the present is sufficient for us, and if we once get out of the main current of thought we have difficulty in regaining lost ground. Yet we may no more forget that we owe our present wise laws and great constitutional system to the labours of ten centuries of men, than that our science of to-day represents the accumulation of the scientific thought of twice ten centuries. Intellectual revolutions have not been less frequent than social revolutions, nor battles of the pen than battles of the sword; the crash of a fallen philosophy has often been louder than that of a fallen throne; the wail of the last Phlogistians rent the heavens; the Aristotelian physics died with groanings and gaspings and a discoloured visage.

In tracing the history of a science, we are first led to inquire whether the Ancients possessed any knowledge of it, and whether it originated among them. Now the Ancients made but little progress in any of the natural sciences. They divided all human knowledge into three parts: Logic, or mental philosophy; Physics, or natural philosophy; Ethics, or moral philosophy. Some placed logic first, some ethics, but no one physics. Philosophy was compared to an egg—logic the shell, physics the white, ethics the yolk; or, again, it was compared to a living creature—logic the bones, physics the flesh, ethics the soul. Plato separates logic as the knowledge of the immutable, from physics the knowledge of the mutable. The Cynics sought a complete freedom from any object or aim in life, and renounced all science. Sokrates aimed at logical definition, and affirmed that the true nature of external objects can be discovered by thought without observation. The knowledge of one's self (γνῶθι σεαυτόν) is the true object and aim of all philosophy. Knowledge obtained from external sources is worthless; there is nothing to be learned from fields and trees. A certain philosopher is said on this principle to have put his eyes out, in order that his mind might not be influenced by external objects, and might be left to pure contemplation. (How curiously this contrasts with the plaint of Galileo just before his death, "*Proh dolor!* the sight of my right eye, that eye whose labours, I dare say it, have had such glorious results, is for ever lost. That of the left, which was and is imperfect, is rendered null by a continual weeping.") Others of the ancients allowed that geometry might be employed for the measurement of land, and astronomy cultivated so far as it might be of use to sailors, but on no account as serious subjects of mental occupation.

Thus it happened that natural science made but little progress among the ancients; thus it happens that a schoolboy of twelve knows more about earth, and fire, and water, than was dreamt of in the philosophies of the greatest thinkers of antiquity. Let us, however, give them their due; let us confess that Plato possessed the "finest of human intellects, exercising boundless dominion over the finest of human languages;" that Aristotle was the greatest genius the world has ever seen; that as pure intellectual evolutions they have handed down to us a mass of grand philosophy; ten thousand noble efforts of the human spirit. Everything favoured the exercise of the unaided intellect, while it is hard to estimate the difficulties which presented themselves in the investigation of nature. At one period it was considered impious to attempt to explain the manifestations of the gods. There was an outcry in Athens, a popular demonstration, when the thunderbolts of Zeus were referred to common fire produced by the collision of clouds. The feeling was of the same nature as that conveyed by Campbell's stanza:—

> When Science from Creation's face
> Enchantment's veil withdraws,
> What lovely visions yield their place
> To cold material laws!

only the feeling existed in an intensified form, for here the first of the gods was derided—the Olympian Zeus, Lord of the Air, he who rides upon the storm, and hurls the thunderbolt. For a length of time, therefore, any investigation of nature was impossible for religious reasons. Men were to worship nature, to be filled with awe and wonder—δεισιδαιμονία—in presence of great natural phenomena, but not to inquire too closely into their causes. Twenty centuries later the Doctors of Salamanca who interrogated Columbus, the Inquisitors of the Sacred College who examined Galileo, upheld the same old doctrines, albeit the old gods had passed away. But the investigation of nature was impossible among the Greeks; their capabilities were very limited, they had no instruments for observations or experiments of any kind, neither had they the faculty of observation; their minds were untutored in that particular direction. Then they had to contend against their own particular habit of thought, the extreme tendency to concretion, to hasty generalisation from purely mental premisses; or if an observation had been made, a broad general law was deduced from it without further observation. So also the Chaldæans and Parsis had to contend against the mysticism, the astrology, and magic, which originated among them; and the ancient Hindu was so given to extreme abstraction, and to the evolution of all manner of strange metaphysical dogmas, that we could scarcely look for much science from an Eastern source. Egyptian learning was monopolised by the priests, and they so wove together the real and the unreal, and were so secret withal in their actions, that although much of the Greek learning came direct from Egypt, we cannot trace it to its direct source, or point to one Egyptian writer on philosophy. The Greeks, too, received much from the Phœnicians; but here also we find no record. We will presently inquire more fully into the exact amount of science possessed by the ancients.

We have chosen for our historical survey one of the oldest of the natural sciences, for obvious reasons, the chief being that it will enable us to observe more minutely the early thoughts of ancient peoples in regard to certain phenomena of nature. The science of chemistry does not owe its existence to any one people, or to any sudden process of development. The basis of the edifice is sunk deep in Eastern soil; the time when the foundation stone was laid is too remote to be even suggested; the walls were slowly and laboriously raised during the Middle Ages, and were completed by Lavoisier, Black, and Priestley; the men of our day are working at the roof. We neither hold with M. Goguet that Moses possessed considerable knowledge of chemistry, because he dissolved the golden calf, nor with M. Wurtz, when he says "La chimie est une science Française. Elle fut instituée par Lavoisier d'immortelle mémoire." Chemistry was not a science until long after the time of Moses; it was a science long before the time of Lavoisier. We wonder what Dr. Hermann Boerhaave of Leyden (whose large quarto "Elementa Chemiæ" was published in 1732, nine years before the birth of Lavoisier), would say to the proposition of M. Wurtz. Short of

this, it would be difficult to overrate the services which Lavoisier rendered to chemistry. But the science has grown up by a gradual process of evolution; upon its surface we find the impress of many and diverse phases of thought and of action; the science of to-day is the summation of many intellectual efforts produced by the constant struggle of the human mind for truth. How often that truth has been hidden by a mass of sophistries; how often it has been absorbed by some false philosophy to appear again untarnished in due time; how often the attempt has been made to crush it under foot; and how it has ever risen to the surface at last, all who read the history of faiths, nations, ideas, must know. It will be our object to show this is the study of the particular science which now engages our attention.

The word χημεία first occurs in the Lexicon of Suidas, a Greek writer of the eleventh century; he defines it as "the preparation of gold and silver." In the "Lexicon Græco-Latinum" of Robertus Constantinus, published in 1592, the same definition is given, and Suidas is quoted as the authority. According to Olaus Borrichius, however, there were Greek writers on alchemy before this date; there is said to be a Greek MS. of the fifth century on alchemy in the King's Library in Paris, and others of a somewhat later date in the libraries of Munich, Milan, Venice, Hamburg, and Madrid; but we are inclined to doubt whether any of these were written before the ninth or tenth century. They are probably the work of monks living at Alexandria and Constantinople; indeed, one of them is entitled, "Cosma the Monk, his Interpretation of the Art of making Gold." The titles of some of the others will prove to us that we can place but little faith on any date which may be assigned to them:—

"Heliodorus on the Art of making Gold" (περί χρυσοποιήσιος).

"John the High Priest, in the Holy City, concerning the Holy Art."

"Isis the Prophetess to her son Orus."

"Moses the Prophet on Chemical Composition" (περί χημευτικῆς συντάξιος).

"Cleopatra on the Art of making Gold."

"Democritus the Abderite, the Natural Philosopher, on the Tincture of Gold and Silver, and on Precious Stones and Purple."

Equally worthless, we believe, are the Greek derivations of the word chemistry. Many (among others M. Hoefer) derive the word from χέω, to fuse or melt, because the majority of old chemical operations were effected by fire—witness calcination, ignition, distillation, sublimation, desiccation, reverberation. The earliest chemical arts, such as the smelting of metals and the production of glass, were also operations of fire. Indeed, the science has been called *Pyrotechnia* (πῦρ τέχνη, the art of fire), because, says Lemery, in his "Cours de Chimie," "we in effect produce all chemical operations by means of fire." Others derive chemistry from χῦμα—that which is poured out, a liquid, in allusion to the various liquids used in chemical operations; but this derivation is not worth a moment's notice. We must rather look to an Egyptian source. Plutarch tells us that Egypt was called *Chemia*, on account of the black colour of the soil, and that the same term was applied to the black of the eye, which symbolises that which is obscure and hidden. This word is related to the Coptic *khems* or *chems*, which also signifies obscure, occult, and is connected with the Arabic *chema*, to hide. It is probable that we have here the true derivation of the word chemistry. The first treatise on the science, the date of which is known with any certainty, was written by the Arabian Yeber or Geber, and at that time (the eighth century), Arabic learning had considerable influence on European culture. The science was called the *occult*, or *hidden*, because it related principally to the secret art of the transmutation of metals, as the definition of Suidas, given above, and the earlier works on the science prove. The term *black art* has been applied both to alchemy and to the magical arts so often associated with it, and clearly agrees with the above derivation. The *al* in alchemy is the Arabic particle *the*, so that alchemy signifies "the hidden science" *par excellence*; we notice the same prefix in *al*koran, *al*cohol (the burning liquid), *al*kali (the acrid substance), *al*gebra, *al*embic (the cup-shaped vessel), and in the names of many stars, as Aldebaran, Algenib, Alpheratz,—all words of Arabic origin.

Whatever difficulties there may be in determining the precise derivation of the word chemistry, there can be none in defining the science as distinctly and definitely the science which treats of the *changes* which matter undergoes; while physics proper treats of the action of various forces—heat, light, electricity, magnetism—upon matter, in all cases unaccompanied by any change of composition. If we heat a piece of iron to redness, or cause it to convey an electric current, or place it in contact with a magnet, it has been submitted to various actions, but when they are removed it returns to its original condition. On the contrary, if we fuse it with sulphur a chemical change takes place, a new substance is formed, and the iron does not return to its original condition. This idea of change is the fundamental chemical conception. The first man who made glass, or extracted a metal from its ore, effected a chemical change; the idea became most sovereign and dominant in alchemy, the attempt to change base metals into gold; it reigned throughout the period of phlogistic chemistry, for was not phlogiston a subtle entity which effected changes in matter according as it was assimilated by matter or rejected from it? It is equally the character of the chemistry of Lavoisier and Cavendish, of Davy and Dalton, of Bertholet and Cannizzaro. The "philosopher's stone" (of which much more anon) was a substance supposed to *change* all things into gold; the "elixir vitæ" was a substance which was to *change* old men into youths; the "universal solvent" was to *change* everything to a liquid form. Let us look at some of the definitions of chemistry. Boerhaave says, "Chemistry is an art which teaches the manner of performing certain physical operations, whereby bodies cognizable to the senses, or capable of being rendered cognizable, and of being contained in vessels, are so changed by means of proper instruments, as to produce certain determined effects, and at the same time discover the causes thereof, for the service of various arts." Sir Humphrey Davy writes as follows:—"Most of the substances belonging to our globe are constantly undergoing alterations in sensible quantities, and one variety of matter becomes, as it were, transmuted into another. Such changes, whether natural or artificial, whether slowly or rapidly performed, are called chemical; thus the gradual and almost imperceptible decay of the leaves and branches of a fallen tree exposed to the atmosphere, and the rapid combustion of wood in our fires, are both chemical operations. The object of chemical philosophy is to ascertain the causes of all phenomena of this kind, and to discover the laws by which they are governed." Quite recently Dr. Miller defined chemistry as "the science which teaches us the composition of bodies," and such knowledge we can only obtain by pulling matter to pieces (analysis), or by building it up (synthesis). Dr. Hofmann of Berlin has defined the vast body of so-called organic chemistry as "the history of the migrations of carbon," and is not migration change of place?

Chemistry, then, is the science which treats of the various kinds of matter, whether simple or compound, of which the world is composed, their properties, and the laws which govern their combination with, and separation from, each other. We shall first discuss any ideas of the ancients which bear upon changed matter in any form or condition: thus their early cosmogonies; the knowledge they possessed of metals and compound bodies; and their various technical operations, such as glass-making and smelting, alike demand our attention.

If we compare all the earliest ideas as to the formation of the world, we find them resolve themselves into the belief that the ether and chaos, mind and matter, were the original principles of things. The ether, a subtle vivifying principle, "passing as a mighty breath over the chaos; the chaos a boundless watery expanse without form." It was thus according to Sanchoniathon in the belief of the Phœnicians, and the twenty-five principles of the Hindu philosophy of San'chya are finally reduced to these—matter and spirit, nature and soul. The Egyptian deity was called Num as the spirit moving over the face of the waters, Pthah as the principle of production. The Hindu deity Brahme typified the productive force of nature. Among more western nations Gaia, the personification of earth, was held to be the first that sprung from Chaos, and the wife of Ouranos. Okeanos was their son, and according to Homer was the source of all the gods. The worship of the elements, and of the sun and moon, was among the very earliest forms of worship; thus we have in India, Agni the god of fire, Indra the god of the firmament; the sun was sometimes worshipped as a symbol of the deity, sometimes as a deity; fire was worshipped by the ancient Persians as a symbol of the deity; in the Homeric religion we find the Olympian Zeus, lord of the air, who possesses absolute and Universal power. We must notice, too, Aidoneus, the brother of Zeus, and lord of the Underworld, said by some of the Greek philosophers to designate earth, and undoubtedly an old nature

power. Again, "Hephaistos," says Mr. Gladstone, "bears in Homer the double stamp of a nature power representing the element of fire, and of an anthropomorphic deity who is the god of art at a period when the only fine art known was in works of metal produced by the aid of fire." He is also one of the seven star-deities of Chaldæa, the signs and names of which were given at an early date to the seven metals.

G. F. RODWELL

THE AMERICAN EXPLORING EXPEDITIONS *

THE various Government exploring expeditions, the departure of which to the fields of operation for the season we have already announced, are busily engaged in carrying on the important work entrusted to them; and it will be safe to expect as the result a larger addition to our stock of detailed information respecting the western regions of America than has ever been brought together during a single year. The most important of these parties are the northwest boundary survey, the geological explorations of Mr. Clarence King along the fortieth parallel, and the surveys of Lieutenant Wheeler in Nevada and Arizona, under the War Department; that of Prof. Hayden, in two divisions, under the Interior Department; and that of Major Powell in Colorado, under the Smithsonian Institution.

Perhaps the most thoroughly equipped and elaborate exploration is that of Lieutenant Wheeler, which is now fairly in the field, and engaged in carrying on its work. This has for its object a thorough investigation of the region west of the hundredth meridian, for the purpose of determining its geographical positions, thoroughly working out its topography, and investigating its geology, natural history, and climatology.

As the basis of this work, it is proposed by Lieutenant Wheeler to divide the region referred to into eighty-five rectangles of equal size, and to mark their corners with great precision, then, taking each one in detail, to determine its astronomical, physical, and natural history features. This, of course, will require considerable time for its completion; and it is hoped that Congress will grant the necessary authority, so that the work may be accomplished as speedily as possible. As each rectangle is elaborated, it will, of course, join on to those previously investigated; and an index map is to be carried along simultaneously for the more ready understanding of the details. Eight rectangles have been completed by Lieutenant Wheeler in his previous expeditions, and it is expected that thirteen will be finished by the end of the season.

To carry out this programme certain points are to be determined astronomically with great precision, and these as nearly as possible along a continuous parallel. Those already selected are, according to the *New York Herald*, a point near Beaunois, near north-western Kansas; the crossing of the Union Pacific and the western boundary of Nebraska; Cheyenne; the eastern limit of the survey of the fortieth parallel by Clarence King; Sherman, the highest point on the Union Pacific; Fort Steele; Laramie City; the crossing of the Union Pacific and the western boundary of Wyoming; the crossing of the Central Pacific and the 120th meridian; and a point on the western boundary of Nevada.

Telegraphic determination of the longitude will be used very freely, and for this purpose Brigham Young has kindly permitted the employment of his well-equipped observatory in Great Salt Lake City. It is proposed to establish a principal station at or near Sherman, the position of which will be determined with the utmost accuracy, and to use this as a point of reference for the other stations referred to. The work of the present season will be carried on almost simultaneously in Utah, Arizona, and Nevada, several divisions of the main party having already been organised and set to work. The southern and south-western portions of the Salt Lake basin are to be explored; also the mining regions on the Virgin and in Eastern Nevada. It is proposed to establish astronomical points, by means of which to determine with greater accuracy the location of the mineral veins. The Wasatch Mountains will constitute the eastern limit of operations during the year.

The expedition, as organised, embraces the following among the more important of the *personnel*:—Lieut. George M. Wheeler, United States Engineers in command; Lieuts. R. L. Hoxie and W. L. Marshall, U. S. Engineers; Dr. H. C. Yarrow, surgeon and naturalist; T. V. Brown, hospital steward and meteorologist; G. K. Gilbert and E. E. Howell, geologists; J. H. Clark and E. P. Austin, astronomical observers; Louis Nell and John E. Weyss, chief topographers; H. W. Henshaw, assistant naturalist; M. S. Severance, ethnologist; and William Bell, photographer.

At the latest advices the latitude and longitude of Beaver, in Utah, were being determined by Mr. Clark, Mr. Austin being stationed at the Salt Lake City Observatory. Pioche, in Nevada, will be the next point to be occupied. One branch of the expedition, under Lieut. Hoxie, and accompanied by Dr. Yarrow as naturalist, is exploring the regions west of Great Salt Lake City; while the other, under Lieutenant Wheeler, is surveying the Wasatch and the Sevier River regions east of it. From these main divisions parties are sent out to examine the water-courses and mountain regions of the country traversed. They will all concentrate at Beaver, Utah, about October 1, and proceed together toward the south.

* Communicated by the scientific Editor of *Harper's Weekly*.

ITALIAN SPECTROSCOPY *

PROF. TACCHINI presented the matter for the fourth issue of the *Giornale degli Spettroscopisti*, consisting of two memoirs, one by Prof. Blaserna, on the displacement of the lines of the spectrum according to the heat of the prism; the other, by Prof. Donati, on observations of the spectra of solar spots made at Florence with a new spectroscope.

The new spectroscope of Prof. Donati contains twenty-five prisms. They are so arranged that the eye receives only Fraunhofer's line C, and a small portion of the red to the right and left of that line. With this spectroscope Donati has succeeded in seeing clearly the line C reversed on the nucleus of the spots. It does not appear that any of the Italian observers have yet seen the prominences on the disc, a result announced by Lockyer in 1869.

Prof. Tacchini further directed the attention of the Society to his last spectroscopic observations of the sun. For the last few days the number of the protuberances had been rather small, but the chromosphere had been greatly developed, and the vapours of magnesium mixed with it had occupied regions of vast extent. He exhibited a drawing of the spectroscopic image of the Sun's edge, taken on the morning of the 6th of May, 1872, showing the continuous presence of magnesium over an arc of 168°, extending from the north pole to distances of 50° and 118°. This was the first time that he had observed a magnesium region of such vast extent in the sun. And taking account also of isolated tracts, there results a total of 222°, that is to to say, nearly two-thirds of the entire edge, occupied by magnesium vapours more or less intense. The drawing likewise shows the usual correspondence between the faculæ, the magnesium regions, and the portions of the edge at which flames arise to the height of 14 to 28 seconds.

Lastly, Prof. Tacchini gave an account of some spectroscopic observations maae at Geneva by Prof. E. Gautier, and exhibited the drawings of a protuberance observed by Gautier on the 15th of April of this year, which serve to confirm the observations made at Palermo on the solar rains, that is to say, masses of luminous hydrogen suspended in the sun's atmosphere, which gradually separate, and ultimately unite at the edge of the disc, and then present all the appearance of eruption, whereas their formation actually takes place by a directly opposite process.

Prof. Blaserna said that he had heard with much interest of Donati's attempt to observe the reversal of the lines on the solar spots. He had also, in accordance with the admirable conferences of Prof. Tacchini in January last, occupied himself with the problem of observing the protuberances on the full solar disc. He then wrote to Prof. Tacchini a detailed letter, proposing two different methods of arriving, if possible, at the solution of this important problem.

The first of these methods, already applied by Janssen and Lockyer to the protuberances on the solar edge, and now adopted by all spectroscopists, consists in using spectroscopes of continually greater power. Prof. Donati has also pursued this method, and has now arrived at the construction of a spectroscope of twenty-five prisms. Theoretically, it is highly probable that in this manner the protuberances might ultimately be seen in full sunshine. But for this it would be necessary to go much further with the number of prisms, increasing them to 50, 73, or perhaps even to 100. This, however, involves a great practical difficulty, and, moreover, it is doubtful whether so powerful a

* Societa di Scienze Naturali ed Economiche di Palermo, May 18, 1872.

dispersion would not weaken the phenomenon to such an extent as perhaps to render it impossible to see anything at all.

The second method, to which he is inclined to give the preference, consists in attaching to the eye-piece of a good telescope a spectroscope which shall form a real spectrum, well defined and sufficiently extended. A diaphragm is provided with a fine moveable slit, adjusted so as to permit the passage only of the Fraunhofer line C and the line D_3. This slit acts like the slit of a second spectroscope of high dispersive power.

The advantage of this construction consists in intercepting all the solar rays excepting those which correspond to the lines which it is desired to study, or those in their immediate vicinity. The extraneous solar light is thereby arrested, and by dispersing this isolated beam by means of a second powerful spectroscope, Prof. Blaserna believes that we must ultimately succeed in seeing the protuberances on the full solar disc.

The importance of such a fact for spectroscopy induced him to associate himself with Professors Cacciatore and Tacchini, for the purpose of putting it to the test; but the means at their disposal were too slender, and neither did nor could yield any result. For this reason he believes that it will be useful to explain the method, in the hope that some other spectrocopist, and perhaps Donati himself, may follow it out with better means and greater success.

SCIENTIFIC SERIALS

Journal of Anatomy and Physiology, vol. vi., part 2, May. A large portion of this number of the Journal is occupied by a series of papers on Myology, by Prof. Humphry; among them by far the most important is one in which the writer indicates a general plan on which the muscles of vertebrate animals are arranged. Prof. Humphry's scheme is simply this:—The locomotory system of a vertebrate animal consists fundamentally of a successional series of alternating skeletal and muscular planes, having generally a transverse direction between the axial line and the circumference. The skeletal planes, "sclerotomes," are represented in the high vertebrate classes by the vertebral processes, ribs, limb and hyoid girdles, tendons of the dorsal muscles, Poupart's ligament, tendinous inscriptions on the rectus abdominis, &c. The muscular planes, "myotomes," are made up of muscular fibres, the general arrangement of which is in an antero-posterior direction. The muscles of the trunk may be grouped under two heads, the dorsal muscles and the ventral muscles, the latter being disposed in three layers. The muscles of the limbs are derivatives from the middle stratum of the ventral muscle with a funnel-shaped investment derived from the external stratum. Prof. Humphry's other papers are on the arrangement of the muscles of the Lepidosiren, the Ceratodus, the smooth dog-fish, and the glass-snake.—Prof. Turner furnishes a description of this sternum of the sperm whale. Hitherto in the specimens of the cetacean that have been examined the sternum was incompletely ossified, so that the present communication fills up a gap in our knowledge.—Dr. Hollis, in a paper entitled "Tissue Metabolism, or the artificial induction of Structural Changes in Living Animals," describes some experiments made with mechanical and chemical irritants on the now nervous, now vascular tissues of Actinia. The results point to nothing beyond what has been before observed, a swelling and softening of the tissues, with a proliferation of the nuclear elements. Dr. Hollis also furnishes a short paper "On the Homology of a Mandibular Palp in certain Insects," and a note "On the Growth of the Masticatory Organs of Isopod Crustaceans."—Dr. Garrod, in a paper "On Sphygmography," points out the objections to the ordinary "knife-edge" sphygmograph, and describes a new instrument by Bregnet, in which these defects are remedied by a rack-work plan of construction. He further points out most clearly and forcibly the direction in which this apparatus is most useful as a means of observation, both to the physiologist and physician.—Dr. Braxton Hicks brings forward some most valuable evidence against the idea of a placental sinus system into which the fœtal silli protrude, and almost proves that normally no blood exists among the silli.—Prof. Traquair describes the caudal fin of the tailless trout of Islay.—Mr. Stirling notes Trichiniasis in a rat caught in the neighbourhood of a dissecting-room. Several anatomical anomalies occurring in the human subject are recorded in this journal. Mr. Bradley provides some notes on myological peculiarities.—Mr. Champneys describes a communication between the external Ilian and Portal veins.—Dr. Watson mentions a case of the termination of the thoracic duct at the junction of the *Right* subclavian and internal jugular veins; and Mr. Galton reports from Vienna the case of a man possessing two supernumerary teeth behind the upper median incisors. The number concludes with the usual review of books and the reports on the progress of anatomy by Prof. Turner, and on physiology by Drs. Rutherford, Brunton, and Ferrier.

Journal of the Chemical Society, May.—This number opens with the proceeding at the anniversary meeting of the Chemical Society, and also the address of the president on that occasion. Dr. Frankland in his address reviewed the present condition of chemical research in this country, as exemplified by the number of original papers received and read before the society, pointing out that during the past year only 22 papers have been received from the members, the number of whom has reached 656, 32 of these being foreign members; whilst, on the other hand, the German Chemical Society, which numbers 528 native members, has received during the same period the results of no less than 238 original researches. Dr. Frankland mentioned one fact which he believed to be one of the principal causes of this comparative lethargy on the part of English chemists. It is that our Universities and examining bodies do not recognise original research, but are content to accept book knowledge to a great extent; and that, on the other hand, in Germany a candidate for a scientific degree has to submit a memoir or dissertation on some original investigation before he is admitted to examination. The only original communication in this number of the journal is by Dr. Debus, on "The action of sodium amalgam on alcoholic solution of ethylic oxalate." In the year 1864 Friedlander, experimenting on this subject, obtained a substance which he named glycolinic acid, to which he assigned the formula $C_2H_4O_4$, that is isomeric with glyoxylic acid. Dr. Debus has now carefully repeated Friedlander's experiments, but has not succeeded in obtaining this body, but instead of this the sodium salt of glycolic acid. Several attempts were made under varying conditions, but all failed to produce the first-named body, sodium glycollate being obtained. As one of the by-products of the reaction in question, Dr. Debus has isolated tartaric acid. It is probably formed by the action of a molecule of hydrogen on one of oxalic ether, which would yield ethylic glyoxalate and alcohol; and it will then be seen that one molecule of hydrogen, combining directly with two molecules of ethylic glyoxalate, would yield ethylic tartrate. The abstracts of foreign papers contain many of great value, several of which have already been noticed in these pages.

Verhandlungen der k. k. geologischen Reichsanstalt, No. 9, 1872. There is not much of special interest for English geologists in this number of the Proceedings. Amongst the papers are the following:—"On the movements which the sedimentary formations of France have undergone," by M. Delesse; in which the author's studies lead him to the conclusion that the sedimentary strata that are buried in the earth's crust, are always in a more or less soft condition; and "A Contribution to Richthofen's theory of the Loess," by D. Stur. The literary notices and reviews which complete the number are unusually full.

Prof. E. D. Cope contributes to the *American Naturalist* for July an exceedingly interesting account of the Wyandotte Cave and its Fauna, to which we shall probably take an opportunity of again referring. Another important article in the same number is by Dr. H. Hagen on Mimicry in the Colours of Insects. Dr. Hagen distinguishes three different kinds of colours as present in insects—viz., colours produced by interference of light, colours of the epidermis, and colours of the hypodermis. The colours produced by the interference of light are only optical phenomena. The epidermal colours belong to the pigment deposited in the cells of the chitinised external skin or epidermis, and are mostly metallic blue, green, bronze, golden, silver, black, brown, and rarely red; they are persistent and never change, either during life or after death.

SOCIETIES AND ACADEMIES

Philadelphia

American Philosophical Society, December 15, 1871.—A sum of money was appropriated for the planting and preservation of a grove of oaks in Fairmount Park, to be called the Michaux Grove, in accordance with the will of the botanist Michaux.—Prof. E. D. Cope read a paper "On the Pythonomorpha of the Cretaceous Strata of Kansas." This embraced a synopsis of the

species of the order known from all parts of the world, by which it appeared that America was its home, only four species having been described from Europe. He said that the *Danubiosaurus* of Bunzel had no relationship to the group. The American species were forty-two, distributed as follows: viz., New Jersey Greensand, 15; Rotten Limestone of Alabama, 7; Chalk of Kansas, 17; other localities, 3. The Kansas species were referred to *Clidastes* 3 sp., *Edestosaurus* 4 sp., *Holcodus* 4 sp., *Liodon* 6 sp. Of these *Edestosaurus tortor* and *E. stenops: Holcodus coryphaeus* and *H. tectulus*; and *Liodon curtirostris, L. latispinus, L. glamiferus, and L. crassartus* were described as new.

January 5.—Hon. Eli K. Price read a paper "On some Phases of Modern Philosophy," in which he combated the views of the heterogenists and of the evolutionists. In the latter part of the subject he opposed the views of Darwin, asserting that the variations seen among domesticated animals had no parallel among those in a state of nature, and the fact of their ready hybridisation is an indication of their specific unity. He quoted Prof. Wyville Thomson to the effect that no transition from species to species had ever been observed in palæontological history; and asserted that the variations observed among animals on which the developmentalists relied in evidence of their theory were few and abnormal, and utterly insufficient for the use made of them; that the origin of man from apes was not supported by evidence; lastly, that the theories of evolution are highly injurious to faith and morals, and thus to Christian civilisation.

Janaury 19.—Mr. Benj. Smith Lyman read a paper on "The Oil-bearing Region of the Punjaub," accompanied by a topographical map. He pointed out the tertiary age of the oil-bearing strata.—Prof. Cope read a paper on a new Dinosaurian from the cretaceous strata of Kansas, which was named *Cynocercus incisus*. The vertebral articular faces were deeply excavated above and below, so as to give them a transverse character.—Prof. H. Hartshorne read a paper on "Organic Physics." It explained that the expression "organic physics" is as well justified as "organic chemistry" and "animal mechanics," for vital force is clearly correlated with other physical forces, as heat, light, &c., but the correlation is not identity. Advocates of the continuity theory have endeavoured to make it appear to be identity, but they will not succeed; because the effects of heat, light, electricity, magnetism, and gravitation are known, and they always tend (in the absence of life) to an opposite kind of change to that which occurs under life force; namely, they form of C, H, N, S, P, &c., compounds of few equivalents and stable equilibrium; while under life force the same elements are made to produce compounds of many atoms or equivalents, and of unstable equilibrium. The first are mainly crystalloids, the second always colloids. The directness of this opposition is especially demonstrated by the result of death (arrest of life force), which is attended by the resolution of the complex, unstable, colloidal, organic substances into more simple, stable crystalloids and gases. Eliminating all the functions of living beings otherwise explicable, we must restrict the term "vital action," or "action of life force" to the conversion of inorganic into organic material, with type-formation or organic construction as its result. It is supposable, at least, though not proven, that the assumption of particular forms under given circumstances is (analogous to crystallisation) the property of the bioplasm; *i.e.*, given the matter, the form results as its property or attribute. But chemists have never succeeded in making organisable matter by synthesis; nor is it likely that they ever will. All complex organic substances made in the laboratory (as urea, by Wöhler; fatty acids, &c., by Berthelot; and even, if made, crystallisable neurin) are post-organic (a term first used by the auth[illegible] salts of the downward or retrograde metamorphosis; produced, not by life force, as such, but by the composition or balance between life force and the other forces. They are not germinal or formative, but formed and effete materials (Beale's terms). The question of the possibility of abiogenesis is not yet finally decided. Crosse gave it momentum with his galvanised acarus; Pouchet and Pasteur have long debated it; Owen, Bennett, Clark, and a few others have of late years reasserted it; Bastian (NATURE 1870) makes an elaborate experimental defence of it. We note concerning it as follows:—(*a*) The manipulation (to avoid introducing minute visible forms) requires an almost or quite impracticable delicacy throughout. (*b*) When heat is used, we have always the alternative, to conclude that certain minute organisms, germs or spores, can resist a higher temperature than was supposed, or to conclude that, taking for granted that the heat employed must have killed all germs, new life afterwards sprang up, without parentage. All experience makes the former much more probable. George Pouchet's experiments with rotifers tend this way. Jeffries Wyman found that, although four hours' boiling would not, five hours would put an end to all manifestations of life. Franklin's experiments (and Calvert's) gave similar results against abiogenesis. Supposing (although Huxley does not) that Bastian could not have mistaken "Brownian" molecular movements for evidence of life, we yet observe that if life sprang up in Bastian's apparatus, it was such life as can exist without air or oxygen; altogether unlike, therefore, ordinary world-life. The assertion of Pasteur is justified, that the *onus probandi* lies with abiogenesists, since there is no experience of any living form more than $\frac{1}{1000}$ of an inch in diameter springing into life out of inorganic matter; it is therefore vastly improbable (needing most cogent evidence to prove), that any form less than $\frac{1}{1000}$ of an inch in size can be made to spring into life from inorganic matter. While abiogenesis is unproved, we hold to the conclusion that vital force is not the mere outcome or resultant of any or all of the other cosmic forces. How does it differ? Of the organic cell, or "physiological unit," the most constant determinable acts or changes are incretion and excretion; atomic or molecular motion, definite in results, is an essential of life. Must not the motion itself be peculiar? More definitely, we find that while in the condensation of matter in the (nebular theoretical) formation of the sun and planets there was integration of matter with dissipation of force, such as heat (H. Spencer), life action involves integration of matter with accumulation of force (stored up physical force in the plant, of Barker; "bottled sunshine," of some one else). This is a striking contrast. Sexual union is closely analogous to chemical union; instead of combustion, it makes construction by detaining products. Again, we notice the analogy between the spiral phyllotaxis of plants (opposite leaves a double spiral), (whorls two or more, and bilateral symmetry of vertebrates and articulates and some molluscs, and radial symmetry of radiates and cœlenterates corresponding) and the spiral helix of the electro-magnet. As the opposite chemical and polar elements of the battery are to the current of the helix, so (may be) the polarities of the sperm cell and germ cell to the spiral phyllotaxis of plants and symmetrical (usually double) organotaxis (a new term) of animals. A close (but reversed) analogy exists between heat force and vital force. A spark of fire may "light," and so burn successively, an indefinite amount of combustible matter. A spark of life may animate an indefinite amount, successively, of organisable matter. The former, combustion, reduces complex substances which are unstable to more stable compounds. The latter, life, elevates simple substances to more complex states, but with constant transmutation of their forms. Such analogies are as yet crude, and do not solve the mystery of life. But the facts on which they rest justify and encourage the physical investigation of vital actions, including their study under physics—organic physics. Such a view of life is in no manner antagonistic to theism or to "teleology," any more than is the now familiar reduction of digestion, circulation, absorption, &c., to the category of chemical or physical phenomena. All such analytical inquiries are moreover, legitimate so long as they are accurate, whether they point to biogenesis or abiogenesis, to the origin of types by interrupted appearances or by evolution.—A discussion on E. K. Price's paper, read January 5th, took place, in which Prof. Hartshorne, Prof. Lesley, Mr. Price, and Prof. Cope took part. Prof. Hartshorne supported the opposition to abiogenesis expressed in the paper, on the ground of insufficiency of evidence in its favour, but believed in the evolution of species. Prof. Lesley objected to the insufficiency of Mr. Price's reasoning against the labours of experts in biological science; and stated that the more attention he paid to the subject the better satisfied he became that man was descended from apes. Prof. Cope stated that Mr. Price's paper was in error as to the facts. That (1) variability of specific type was even more common in nature than under domestication, examples from many so-called "protean" genera being cited. (2) That some wild species did produce fertile hybrids. (3) That transitions between species, both at the present time and in past geological periods, were common, but were concealed by a universal *petitio principii* involved in the practice of naturalists. This consisted in uniting distinct forms or species under the head of one species as soon as the intervening connections were formed. (4) That the known cases of transition were numerous, not few; and that common induction required that we should believe of the un-

known that which we see in the known, when other circumstances are identical.

Feb. 2.—Prof. Geo. B. Wood communicated further results of his experiments with salts of potassa on vegetation, and especially on grain and fruits. He stated that in a field of grain devoted to the experiment, in which the soil had been previously exhausted by bad culture, one half was enriched by farm-yard manure, the other with the same with wood ashes added. The effects of the latter were especially marked, and much greater than with the former. The most striking results were attained by the use of the ashes of the poke, *Phytolacca decandra*.—Prof. Cope read a paper on the "Families of Fossil Fishes of the Cretaceous Strata of Kansas." The greater part of these were shown to be *Physostomous Actinopteri*, of three families, viz., the *Saurodontidæ*, the *Pachyrhizodontidæ*, and the *Stratodontidæ*. Of the first, four genera and ten species were described, some of them (*Portheus* sp.) among the most formidable of marine fishes. The peculiarities of the succession of teeth in *Portheus* and *Saurocephalus* respectively were pointed out. Of *Pachyrizodontidæ*, one genus and four species were described; and of *Stratodontidæ*, three genera and seven species. *Stratodus* was a form provided with multitudes of minute shovel-headed teeth.

PARIS

Academy of Sciences, Sept. 9.—M. Faye, President.—The first paper was by M. P. Duchartre, on the bulb of *Lilium Thomsonianum*, &c. The author finds that this Indian plant seldom flowers in Europe, and traces this to the facility with which it propagates itself by means of off-shoots from the bulb. If it is prevented from doing this it flowers well.—A letter from P. Secchi followed on "Observations on the Variation of the Solar Diameter; Observations of the Protuberances and of the Chromosphere; Observations on the Shooting Stars and of the Aurora Borealis observed at Rome on the 10th of August." Father Secchi finds variations of the solar diameter equal to 3, 4, and even 5 seconds of arc (error of observation less than 0''·5 arc). There were minimum epochs in July, the beginning of September, the middle of November, and the beginning of March and April, when the mean diameter was 32′ 1″ 5‴; and maxima in the middle of August, the middle of September, and during the whole of October and December, and the beginning of February when the mean diameter was 32′ 4″ 5‴. The maxima of diameter correspond to the minima of spots and protuberances. The next memoir was by M. Max Marie "On the elementary theory of double integrals and their periods" (continuation). A note from M. A. Potier "On the causes of Elliptical Polarisation by reflexion on transparent bodies."—A note from M. Th. Gaffield "On the results produced by insulation on various kinds of glass," was then presented by M. Chevreul.—"On the lines of Summit and of Thalweg" an answer to the observations of M. Boussinesq by M. C. Jordan.—A note was then read on the induction currents developed in the machine of M. Gramme, by M. J. M. Gaugain.—"On Lithurate of Magnesium, a new species of urinary concretion from the ox," was an extract from a note from M. G. Roster.—The empirical formula for the body in question is $C_{30}\,H_{36}\,N_2\,Mg.\,O_{1}$, it is soluble in boiling water, from which it crystallises on cooling.—A note on the Nutoscope, by M. Ch. V. Zenger, was presented by M. Yvon Villarceau. This was a description of an instrument for illustrating the nature of nutation.—Next followed a note from M. Tarry on the constitution of the stream of August meteorites.—M. Dumas then communicated some observations on the *Phylloxera vastatrix*.

Sept. 16.—M. Faye, President.—The President read a note relative to a communication from M. Hirn on the conditions of equilibrium in, and the probable nature of the Saturnian rings. General Morin then read a note on Major General Mayveski's "Treatise on Projectiles." M. Morin states that M. Mayveski, in his eleventh chapter, devoted to the consideration of the penetration of solid bodies and armour plates by projectiles, arrives at the same conclusions as were obtained by the Metz Commission, and by Capt. Nolan in England.—"Observations on the nature of the various parts of flowers," by M. A. Trécul, followed.—A letter from P. Secchi on the appearance of a meteor in the neighbourhood of Rome, and on stellar spectra, was then read. The latter portion of the letter was an explanation of the Rev. Father's views on stellar types, which he explained were not the same as those of Mr. Rutherfurd, as had been supposed by Messrs. Lockyer and Schellen.—M. le Dr. Netter then read a paper on the treatment of cholera by the administration of enormous quantities of aqueous drinks in successive doses.—Then followed the concluding portion of M. Marie's paper on the "Theory of double integrals and their periods."—Notes were received from M. Pigeon, on cholera; M. Charles, on aërial navigation; M. Bouvard, on the Postulatum of Euclid; M. Hervier, on *Phylloxera*; M. Quattari, requesting the Academy to examine his aërial telegraphic apparatus; and M. Le Comte L. Hugo presented the Academy with an engraving entitled, "The sphere is an equidomoid, or a demonstration of the pre-eminence of polygonal figures," which was submitted to the examination of M. Ossian Bonnet.—M. Yvon Villarceau presented a note by M. Prosper Henry, describing the discovery of a new planetoid 125 at the Paris Observatory. Observations on the above by MM. Ludinard, Tisserand, Paul Henry, and Prosper Henry followed.—An extract from a Report by Dr. Andrews on the total eclipse of 12th December, 1871, observed in the Dutch East Indies, was also read.—A paper, by M. Ch. V. Zenger, "On the rapidity of transmission of light in simple bodies, and on their crystalline form," followed.—"On the changes of phase produced by metallic reflexion," note by M. A. Potier, was next read; and then an extract from a paper by M. Plateau on the measurement of physical sensations, and on the law which connects the intensity of these sensations to the intensity of the exciting cause, was followed by a posthumous note of M. H. Magnan's, *à propos* of two notes by M. Cayron on the cretaceous formation of La Calape and Corbières.—M. Louis Faucon sent some observations on *Phylloxera*, made by himself and M. Gaston Bazille; and another note on the same subject and on vine disease by M. F. E. Guérin-Méneville, who believes that every observation tends to prove that the *Phylloxera vastatrix* is only a secondary agent in producing the vine disease now so destructive.—M. Yvon Villarceau then presented a note from M. Fron on the atmospheric movements which accompanied the auroræ of September 2 and 6, 1872.—M. Georges sent a note relative to the employment of calcic disulphite to the cure of vines tainted with oidium, which was sent to the Phylloxera Commission.

THURSDAY, OCTOBER 10, 1872

HOUZEAU ON THE FACULTIES OF MAN AND ANIMALS

Etudes sur les Facultés Mentales des Animaux comparées à celles de l'Homme. Par J. C. Houzeau, Membre de l'Académie de Belgique. 2 vols. pp. 1,008. (Paris: Hachette, 1872. London: Williams and Norgate.)

IF this work had appeared a few years ago it would have created for its author a considerable reputation. Even now, had it been written in Europe after a careful study of all the best authorities on the subject, it might have been made a very valuable and important treatise. But its author tells us—and the fact is clearly reflected in its pages—that it has been mainly written during a residence in the less cultivated parts of America, without the means of consulting the more recent works on the various subjects of which it treats. It is true that M. Houzeau is a close and acute observer of the habits of animals, and he has furnished us with many curious and original facts; but his own observations and experiments are so overlaid by vast masses of less trustworthy and often irrelevant matter, and are so widely scattered owing to his elaborate classification and minute sub-division of the subject, that they lose much of their force and impressiveness.

For a work written under the circumstances here stated, it is far too large and too pretentious. It aims at an exhaustive treatment of the whole series of the actions and passions of animals and of man, as illustrating their comparative mental nature. It treats in detail of each sense, each habit, each instinct, each custom, passion, and idea; and it discusses so fully the phenomena of language and society that the title should have been reversed, it being really a study of the mental faculties of Man as compared with those of Animals.

The subject of inquiry, as stated by the author, is, "whether the mental faculties of man, of which our arts, sciences, and social state are the product, have not their germs in the lower animals; whether the several parts of our intellectual and moral nature do not insensibly and successively appear in the series of the animal kingdom." He assures us that he approached this inquiry with no preconceived ideas; but we may be permitted to doubt this when we find him bringing in such forced resemblances, as the rolling of pachyderms in mud with the practice of tattooing (vol. i. p. 343), that of ruminants rubbing off their hair to the shaving of men (i. p. 348), and the existence of neuter insects with the custom of castration (i. 351). These and many other similar cases show a determination to find some point of comparison of animals with man, which diminishes the effect of the numerous real and very curious resemblances he has undoubtedly brought forward. In his chapter on the question, whether the power of animals to find their way for great distances depends on a special sense, our author comes to a conclusion which, although we believe it to be a sound one, is opposed to the facts which he adduces. He believes, for instance, that pigeons traverse an unknown country in a direct line, and that dogs and other animals find their way, in cases where neither sight nor smell could guide them. But he shows by many minute observations that animals, *in ordinary cases*, find their way by means of the same faculties which man employs to find his way, and hence he concludes that they do so *in all cases*. But this by no means explains the more extraordinary facts he has first adduced. Here we have an example of his deficiency of information. He quotes the case of the pigeons used during the siege of Paris, and evidently believes that all that was done was to take a carrier-pigeon from any part of France to Paris, when, on being let loose, the bird would infallibly return straight to its former abode. He apparently knows nothing of the fact that these birds must all be trained by means of wider and wider flights over the very country they are to traverse; and that without this precaution, a pigeon, taken by a circuitous route from Brussels or from Bordeaux to Paris, would no more find its way back to those places than would a deaf and dumb man under the same conditions.

In the chapter on the "instinct to use clothing," we have another example of our author's want of rigid impartiality. He endeavours to show that some animals use clothing, and that some men do not, and that it is, therefore, no distinctive character of man. His examples of dressed animals are hermit crabs and the larvæ of *Phryganea* and *Tinea*; and although he adduces instances of unclothed men, he has in no way accounted for that sense of shame which he maintains is not innate, and which yet has, even more than the necessity for warmth, led to the practice of clothing among so many peoples.

In the section on the Sentiments and Passions, we have an elaborate account of the wars, massacres, and cruelties, tortures and human sacrifices, among the various races of men, and we find the characteristic remark, that "the touching custom of preserving a loved one's hair is, perhaps, only a transformation of the old practice of scalping." We commend this notion to Mr. Tylor, as the *ne plus ultra* of survival of savage practices in our modern civilisation. We have also a condensed account of the tortures inflicted on their prisoners by the North American Indians, which can hardly be surpassed for terrible descriptive power; but there is no attempt to find parallels to these essentially human attributes among the lower animals.

Although our author has devoted many pages to a discussion of the principles on which evidence is to be admitted, and has laid down some excellent rules on this subject, he appears to pay little regard to them in his own work. He asserts, for instance, without any reservation, that "a large number of species of apes have a laugh altogether analogous to ours;" but the only evidence he gives of the fact is that "Turks compare Europeans to apes, because they laugh like them;" the grin of anger being here confounded with the laugh of appreciative wit. In like manner he accepts as an undoubted fact the existence of people to whom the use of fire was wholly unknown, although the two cases he gives—the Guanches of Teneriffe, and the Marianne Islanders—are highly suspicious, and have both been shown by Mr. Tylor (in his "Early History of Mankind," a book quoted by M. Houzeau) to be contradicted by many facts, and to rest on no sufficient authority.

It is in Section V., on "Ideas," that we find some of the most curious observations and suggestive remarks to be met with in the whole work. Animals we know, go mad, and they also vary in their mental capacities, but we do not remember any case of idiocy having been recorded among the lower animals. M. Houzeau, however, tells us he had an idiotic dog, which could not take care of itself, and which behaved in an altogether strange and silly manner. But the most curious thing was that its mother observed its mental incapacity, and acted accordingly. From the time when she ceased suckling it, she took great pains to provide its food, bringing it dead birds or pieces of meat, "which she had never done, even for a single day, with any of her other puppies." From this observation, and the well-known fact that animals of the same species differ greatly in their capacity to receive instruction, our author is convinced that it is only through want of observation that we do not meet with mental derangements of various kinds and degrees among our domesticated animals. The faculties of attention, observation, and imitation, exist in a high degree among most of the higher animals; and when we add to these a very retentive memory, and a certain amount of direct and voluntary instruction which parents give to their young, much may be accounted for which has been imputed to those unknown faculties which are termed instinct. Not only does M. Houzeau maintain that the higher animals constantly act by means of intellectual processes altogether comparable to our own, but he extends this view to insects. A German naturalist, Gleditsch, relates that he one day spitted a toad on a stick, which he fixed upright in the ground. A number of burying beetles (*Necrophorus vespillo*) came around it; but as they could do nothing with the toad while in the air, they mined under the base of the stick till it fell, and then buried toad and stick together. The circumstances were quite abnormal for the *Necrophori*, and they acted exactly as an intelligent and reasoning creature would do. Again, when Pierre Huber placed some humble bees (*Bombus terrestris*) under a glass with a piece of comb so irregular that it would not stand firm on its base, they at once set intelligently to work to make it secure, some holding it up while others built walls and buttresses to make all solid. So, again, when the wasp observed by Erasmus Darwin, which could not carry away a large dead fly because the wind caught the wings, cut them off, and was then able to carry away its prey, it acted exactly as an intelligent and reasoning human being would act. As our author well remarks, whenever such facts are brought forward, the usual cry is—"What an admirable instinct!" but instead of having recourse to so miraculous a faculty, able to deal with phenomena occurring perhaps for the first time in the experience of the race, would it not be more simple to suppose these creatures to possess some small portion of our faculties of observation, of memory, and reflection? The following remarks on concluding the whole subject of instinct are well worthy of attention.

"It seems difficult to regard as the effects of a blind instinct such actions as spreading out damp grain in the open air to dry, and taking care of the eggs and the young of captive Aphides. It is difficult to conceive a being performing acts so varied and complex, and so bound one to the other in a connected series of labours, without any perception of the bond of cause and effect which unites them. Animals perform automatically only simple actions depending on their immediate wants. But when the end requires a large number of preliminary and intermediate operations, of a varied character and dependent one upon the other, can we still suppose the entire line of action to be followed out in ignorance and obscurity?" And, after stating the fact of the burying beetles, who, after laying their eggs in the bodies of small dead animals, bury them in order that they may not be devoured by birds and beasts of prey, he continues:—

"If we pretend to see only instinct in this action of the insect, why should we have recourse to a different faculty when man buries his dead? Has not the act of burying for immediate end, in the one case as in the other, the securing the body from the attacks of carnivorous animals? Is there not at the same time, in both cases, a more remote end which forms the true motive of the act? The faculty of invention is doubtless more developed in man than in any species of animal; it is in him more powerful, more elevated, and often directed by nobler motives. But these differences of quantity and of nobility ought not to blind us to the existence of the faculty in various degrees of development among many animals" (ii. p. 236). Bearing also on this question, we have a curious discussion as to the power of animals to appreciate numbers. It is considered to be established that the magpie can count four, which probably refers to Leroy's experiment with crows (NATURE, iii. p. 183). The mule is supposed to be able to count as far as five at least, and this is considered to be established by the following observation. There is a short branch line of omnibuses in New Orleans, where each mule makes the journey five times successively before being changed. The veterinary surgeon of these animals called the author's attention to the fact that, whereas at the end of each of the first four journeys they are silent, as they approach the end of the fifth they neigh. But this does not seem satisfactory. The end of the fifth journey may well be determined by the estimation of mere distance, or of time, or by the sense of fatigue, or, what is still more likely, by some preparations for the change of mules which may be heard or smelt by those arriving. And this is rendered the more probable by an experiment tried by our author himself, showing that dogs cannot count even as far as two. For three successive weeks he repeated the same walk with his dogs on each alternate day; yet, although the dogs were always eager to go out when their master's preparations were seen, on the last trial, being the tenth repetition, none of them showed any knowledge that the day for an excursion had arrived. But neither is this quite satisfactory, as there is too long an interval between each trial, and it rather involves the recollection of a period of time than of a mere number. It can hardly, therefore, be held as proved that the lower animals have any sense of pure number.

Passing on to the consideration of moral and religious ideas, our author adduces the usual proofs that animals have a sense of right and wrong, but which really show nothing more than that they can be made to acquire certain habits through the fear of punishment or the expectation of reward. We next find the broad statement that the idea of duty is not universal among men, but no evidence is offered, except that no one act is held to be a

duty universally, or the contrary. But this is to misapprehend the real question, which is rather, whether there is any race of men among whom nothing is considered a duty. Is there any race with whom there are not certain acts which the majority do, or refrain from doing, independently of any fear of punishment, but because they believe them to be right or wrong? And is there, on the other hand, any race of animals whose actions are influenced in the same way? We think the answer to these questions would show a positive distinction between man and the lower animals, which distinction would hardly be lessened by maintaining that the idea of duty so defined is in savages only the fear of punishment by gods or demons, since it will not be maintained that the lower animals are ever influenced by such motives.

Passing over a curious chapter on the utilisation of the lower animals, chiefly by educating and making slaves of the anthropoid apes, we come to the subject of language, which is discussed in a manner which exhibits the author's defects and merits in a remarkable degree. He thinks it necessary to approach the subject by a discussion on the fables of speaking stones and plants, of the sounds emitted by nudibranch molluscs and fish, the hissing of serpents, and the croaking of toads. By interpreting the notes of certain birds into words, such as "Whip-poor-will," and a number of others, he arrives at the conclusion that some savage languages have fewer letter-sounds than have those of certain animals. The physiology of voice and the construction of speaking automatons is next sketched, before we come to the really valuable part of the chapter, in which the variety of sounds and calls of several species of animals are detailed, and it is thus shown that they possess a language of no contemptible extent. He also maintains that animals understand, or rather learn to understand, the language of very distinct species. His dogs, for instance, perfectly understood his poultry. Cocks and hens have one danger signal for the approach of a bird of prey, another for that of a terrestrial animal or for man. The latter would rouse the sleeping dogs, who would instantly rush out and bark, while they took no notice whatever of the former. This proves that fowls have a language capable of expressing slightly different but closely connected ideas, and also that dogs soon learn the languages of other animals.

The subject of Hereditary Transmission is very imperfectly treated. M. Houzeau is evidently unacquainted with Mr. Galton's researches, or he would not have arrived at the conclusion that "a more or less complete transmission of the physical type with independence more or less absolute of the intellectual and moral type,—such is the law of observation, the law of nature."

In his last lecture on "Sociability" the doctrine is boldly advocated that of all animals Ants approach nearest to man in their social condition. They represent semi-civilised societies; while the highest Apes only represent the lowest savage state. The varied modes of association among the lower animals and in the human race are detailed with great fulness, but with little influence on the general argument. On the question of the affiliation of races, we find some good remarks on the comparative value of the useful arts, the food plants and domesticated animals, as compared with customs and superstitions. The evidence afforded by the latter is, he maintains, absolutely valueless unless supported by the former. In the concluding paragraphs of the work are some expressions and arguments which seem to show that the author is not an evolutionist, and has no clear ideas as to whether new species of animals are now coming into existence or not, or as to whether man has or has not originated from a lower animal form. This leads to an ambiguity and inconclusiveness in the whole work which contrasts strongly with the clear and definite views of such men as Darwin and Spencer, whose works lead us on by many and varied lines of research till they converge towards a grand and impressive conclusion. The present work cannot for a moment be compared with such as these; but it has special merits of its own, and it contains a mass of curious facts, acute observations, and sound reasoning, which fully entitle its author to take high rank among philosophical naturalists.

ALFRED R. WALLACE

GANOT'S NATURAL PHILOSOPHY

Popular Natural Philosophy. By Ganot. Translated by E. Atkinson, Ph.D. (Longmans and Co.)

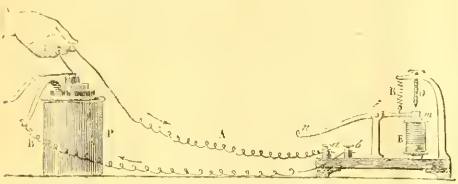
THIS is a good elementary book, giving the first principles of the subjects with which it deals in a clear and concise manner, with very few unnecessary words. The work is not an abridgment of Ganot's "Elements of Physics," but is founded on Ganot's "Cours Elémentaire de Physique," of which it is not a mere translation; but additions and alterations have been made by Dr. Atkinson, with the view of rende‑ng it more fit to serve the purpose for which it is designed, namely, to act as a "text-book of physics for the middle and upper classes of boys' and girls' schools, and as a familiar account of physical phenomena and laws for the general reader." The book is very well adapted for these purposes. It is entirely free of mathematical formulæ, which, though but sparsely used in Ganot's "Physics," are still an insuperable barrier to the use of some portions of that work by the non-mathematical reader. The subjects treated of are the same as those in Ganot's "Physics," namely—the properties of matter, hydrostatics, pneumatics, acoustics, heat, light, magnetism, and electricity. The treatment of these subjects is, however, not only more elementary but somewhat less comprehensive than in the larger book. The engravings of the instruments and of the experiments detailed are good and suggestive, and calculated to be of assistance not only to the learner but to the teacher. There is, however, a good deal of what is superfluous in a considerable number of the illustrations, and a few of the illustrations themselves are unnecessary. It is, perhaps, over-refinement of criticism to object to the superfluity of embellishment in Fig. 140, in illustration of a speaking tube. (By the way, how exceedingly small the fire is!) Fig. 139 seems quite unnecessary in explaining the experimental determination of the velocity of sound by the Bureau of Longitude of Paris.

Although, however, there may be a good deal of what is superfluous in the illustrations, there is nothing which is misleading; but, on the contrary, they are in all cases calculated to leave a correct impression of the point in question on the mind of the reader. Fig. 349, however,

of the aurora borealis hardly deserves such a favourable criticism.

As usual with almost all treatises on Natural Philosophy, we have to find fault with the character of the very few remarks which are devoted to terrestrial magnetism; but we know of no elementary book which deals with that very interesting subject sufficiently, and of hardly any which deal with it correctly.

The explanation of the principle of the telegraph is very lucid, and the diagrams connected therewith are exceedingly well adapted for enabling the learner to grasp the principle. The accompanying pair of diagrams in illustration of the principle of Morse's Telegraph leave hardly any verbal explanation necessary.



Diagrams of a self-explanatory character, and which, to a certain extent, stand in place of words, form a very useful feature in an educational text-book.

JAS. STUART

OUR BOOK SHELF

Jahrbuch der kaiserlich-königlichen geologischen Reichsanstalt. No. 1, 1872. Band xxii. (Wien.)

THIS part of the Year-book contains three papers devoted to the mining industries of Austria. In one of these—"On the Future of Mining in Austria," by Constantin Freih. v. Beust, we have concise and interesting sketches of the several mineral-bearing regions of Bohemia and Moravia, as also of the various rock formations of the Alpine districts which are metalliferous. The author comes to the conclusion that mining in Austria is capable of vast development, there being goodly stores of silver, lead, zinc, iron pyrites, and even perhaps of gold, which only require energy and enterprise to win them. The same writer contributes a second paper, "On the Direction of the principal Veins in the non-Hungarian Lands of the Austro-Hungarian Monarchy." Franz Ritter v. Hauer also gives some account of the ironstones worked by the Styrian Iron Company near Eisenerz. Dr. Emil Tietze has a long and able memoir on the geology and palæontology of the southern regions of the Banat mountains (Hungary). The descriptions of cretaceous and liassic fossils, many of which are of species new to science, and the illustrative plates that accompany the memoir, are well worthy the attention of palæontologists. In the *Mineralogische Mittheilungen*, edited by Prof. Tschermak, we have, amongst a number of other papers, one by Prof. Inostranzeff of Petersburg, giving the results of his examination of certain limestones and dolomites as bearing on questions of metamorphism. Prof. A. Exner, of Vienna, also contributes a "Chemical Examination of the Meteorites of Gopelpur." Other papers by M. Websky, A. Brezina, and F. Babanek, on mineralogical subjects, will serve to sustain the reputation acquired by our German friends in a department of science which has far too few votaries in this country.

The Metric System of Weights and Measures: an Address delivered before the Convocation of the University of the State of New York, at Albany, August 1, 1871. By Frederick A. P. Barnard, S.T.D., LL.D., President of Columbia College, New York City, &c. (New York, 1872.)

PRINCIPAL BARNARD was appointed, in 1871, by the Trustees of the University of the State of New York to attend a meeting of the Convocation of that University, who were adverse to the introduction of the Metric System, and to enlighten them as to its real nature, and the immense advantages that would flow from its adoption. He seems to have performed his duty with great ability, and we hope with equal success. This volume contains a revised edition of that address, with considerable additions in the form of notes and appendices. Principal Barnard gives a very lucid account of the origin and nature of the metric system, narrating the recent progress of meteorological reform, and answering with what appears to us unassailable arguments the objections commonly urged to its universal introduction into all civilised communities. One appendix contains a long, interesting and useful dissertation on the Unification of Moneys, with some well-arranged information on what has already been prepared and done. In another appendix he describes and discusses the various experiments which have been made to fix on a standard for measures of capacity. His third appendix is on the legislation of Great Britain and of British India in regard to the metric system; and his last appendix contains some very interesting, and what many will deem astonishing, statistics on the extent to which the system has been already adopted. From this we learn that France, Spain, Holland, Belgium (and their colonies), Portugal, Italy, the North German Confederation, Greece, Roumania, British India, and nearly the whole of the countries of Central and South America, have adopted the metric system in full; they represent a population of 336,419,595. Wurtemburg, Bavaria, Baden, Hesse, Switzerland, Denmark, Austria, and Turkey, representing a population of 84,039,209, have adopted metric values; while in Great Britain and the United States, containing a population of 70,373,091, the system is still permissive. In Sweden and Norway (population in 1867 5,897,159) the decimal division has been adopted without the metric values. Thus the peoples already decidedly enlisted on the side of the system include a total population of about 420,000,000. This looks hopeful, and there seems no doubt that this rational system of weights and measures will ere long be universally adopted. One very remarkable fact the author mentions in confirmation of this. At the close of last century, the simple measure of length called the foot had not less than *sixty* different values—probably many more—actually in use in different parts of Europe; in 1867, there could be found only *eight* of this discordant class surviving. We would recommend Dr. Barnard's book to all who wish to possess a clear and intelligible account of the system and its many advantages within a moderate compass.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Oceanic Circulation

As some of your readers may be misled by Mr. Croll's reiterated and uncontradicted assertions, that he has *demonstrated* the fallacy of the doctrine of Oceanic Circulation advocated by me, I think it right that they should be made aware that these assertions receive no support from the physicists and engineers, who must be much better judges than either Mr. Croll or I can be, as to the value of the *data* on which his computations are based. His arithmetic may be perfectly correct; but if his fundamental assumptions are wrong, or inapplicable to the case, his demonstration utterly fails.

The report, now in the press, which I have presented to the Royal Society, as to the Deep-sea Researches, on which I was occupied during the autumn of last year, contains my reply to Mr. Croll's argument. And I profited by the unexpected delay in its publication to bring the principal points of that reply before the Mathematical and Physical Section of the British Association at its recent meeting, with the view of eliciting the opinion of the authorities there assembled, as to the soundness of my argument.

I do not think that I claim too much in saying that this opinion was given by Sir William Thomson, and other distinguished physicists, most explicitly in my favour.

Having also had an opportunity of bringing the question under the consideration of Mr. Hawksley, whose experience as a hydraulic engineer is probably second to that of no one living, I found him entirely of my mind; and Sir John Rennie has repeatedly expressed himself as altogether concurring with me.

So far as I know, therefore, Mr. Croll, in his reiterated assertion that water will *not* find its own level—for that, in plain English, is the position he takes—stands "alone in his glory."

The *facts* which I embodied in a paper presented at the same meeting to the Geological Section, in regard to the contrast of temperature between inland seas and the ocean with which they communicate, seem to me inexplicable on any other view than that of a *deep underflow* of Polar water towards the Equatorial area; and this necessarily involves, as its complement, an *upper flow* from the Equator towards the Poles.

When Mr. Croll shall have given some other *rationale* of these facts, he may fairly claim consideration for it. At present I venture to submit that all the *facts* at present known are in my favour; and that Mr. Croll's asserted refutation is purely *theoretical*.

October 4 WILLIAM B. CARPENTER

Consciousness and Volition

IN an interesting review of Lankester's "Comparative Longevity in Man and the Lower Animals," which recently appeared in the *Times*, is the following sentence:—"Once commenced, its continuance (that of the act of walking) is quite involuntary, and may even be unnoticed by the consciousness." I am anxious to ascertain, from those readers of NATURE who have paid special attention to psychology, whether this is, in their opinion, a correct statement of the condition of the mind during such an habitual act as that of walking. There are undoubtedly certain actions of the body, those denominated reflex, which are performed without any exercise of the will whatever; but these are all either momentary, or, if continued, are nearly uniform and unchanging. To me it seems impossible that any action which is constantly varying can be wholly involuntary. Take, for instance, the motion of the fingers in writing: we are absolutely unconscious of the exercise of the mental faculties by which each successive change in the position of the pen is regulated; but yet is it not certain that each up-stroke and down-stroke is the consequence of a separate effort of the will? There is here an evident connection between the state of mind at the time and the action of the body; and by what other means is it possible to suppose that the mental act which conceives the word we are writing can convey its instruction to the fingers? Certainly not by any process of instinct. A better instance perhaps is in the motion of the muscles of the face and throat in speaking. These muscles are entirely under the control of the will; and every separate motion of them must surely be effected by a distinct voluntary effort, of which however we are entirely unconscious. The same seems to me the case in walking. When we sway the body out of the perpendicular in turning a corner, I am at a loss to understand how this can be performed involuntarily. The explanation seems to me to be that consciousness cannot, so to speak, work so fast as volition, and therefore cannot take cognizance of a large number of rapidly successive acts of the will. The question is not so much one of a nice metaphysical distinction as simply of a correct use of terms, although I am afraid I am opposing the views of such high authorities as Huxley and Carpenter. We have been made familiar with the term Unconscious Cerebration. Is there not also an enormous field of Unconscious Volition?

London, Sept. 28 ALFRED W. BENNETT

Phosphorescence in Fish

I HAVE noticed the phosphorescence in fish on two occasions. Once on a calm night, wind light and sea smooth, in the S.E. trades, lat. 18° S., a shoal of porpoises was playing about under the bows of the ship, and darting under her keel for a space of nearly half an hour. Each looked like a piece of burnished silver on blue velvet. They presented the most beautiful appearance. We were not within "soundings." Every wavelet was covered with phosphorescence during the whole of that night, before and after the porpoises were seen. *They* manifestly could not have been the cause of this. As I leaned over the side and watched them, it seemed to me that their phosphorescence resulted from the condition of the water. Off the coast of South America, in about lat. 22° S., long. 30° W., weather much the same, a small shark accompanied the ship for some time, and presented the same appearance. The sea was brilliantly phosphorescent. The fish could be seen deep down. In both cases I saturated paper with the sea water. When dry the microscope failed to detect any organic matter, nothing but crystals.

11, Church Row, Hampstead ARTHUR NICOLS

On a Measuring Apparatus for Direct-Vision Spectroscopes

THERE are few who possess Browning's "miniature," or other small direct-vision spectroscopes, but must have felt the want of some means of measuring the positions of spectral lines; and, indeed, little useful spectrum work is possible without it. I think, therefore, a description of a simple arrangement I have used for some time for this purpose may prove useful.

In the "miniature" spectroscope the outer face of the prism is inclined to the axis of the instrument at an angle of about 40°. Opposite this a hole of about 2 mm. diameter is drilled in the sliding tube, care being taken to avoid injury to the prism. It is obvious that, through this aperture, lateral objects will be visible superimposed on the spectrum. If now a scale be set up opposite to the hole, it will be clearly seen, and the lines may be easily measured by it. The most convenient scale is one of transparent lines on a dark ground (photographed on glass from a scale drawn in black upon white paper), and illuminated by a lamp behind. A paper scale, preferably drawn in white upon black paper, may also be employed. In this case a common retort-stand clamp serves conveniently to hold the spectroscope, while the scale is laid horizontally on the table below. A sheet of paper, may be substituted for the scale, and the instrument used as a camera-lucida. Observation of faint spectra will be much assisted by shading extraneous light with black velvet, and covering the scale on paper with a black sliding screen, with an aperture through which only one or two divisions of the scale can be seen at once. A double scale, of which one gradation corresponds with the upper and the other with the lower edge of the spectrum, is also advantageous.

With a miniature spectroscope, and scale of millimetres at 25 cm. distance, the separation of Na and Li is about 13 divisions, and can easily be read to 0·2 mm.

The arrangement would, I think, be very applicable to the microspectroscope. The small hole is no inconvenience in ordinary use, and can easily be covered by the finger or by a small piece of black paper inserted in the tube.

In conclusion, I would urge the necessity of noting a sufficient number of reference lines at each observation, and the desirability of reducing measurements to the wave-length scale, for which purpose Dr. Watts' "Index of Spectra" will be found invaluable.

North Shields HENRY R. PROCTER

Cat's Toes

AT the village of Cookham-Dean, near Maidenhead, there is a race of cats having more than their normal complement of toes. They generally have six toes on the fore feet, and the usual number on the hind feet; but I saw two individuals which had six toes on each foot, and others which had seven toes on the fore feet, and either five or six on the hind feet. The stock, as far as I can learn from the not over-bright natives, appears to have originated about seven or eight years ago in the person of a "Tom" having six toes on each of its feet. I should think there are now a score or more living in the village.

Harpenden, Sept. 19 R. LYDEKKER

NEW INSTRUMENT FOR THE PRODUCTION OF OZONE

IN the *American Journal of Science and Arts* for July 1872, Prof. A. W. Wright, of Yale College, describes a simple apparatus for the production of ozone with electricity of high tension, and intended for use with the Holtz electrical machine. "The apparatus consists of a straight glass tube about 20 centimetres long and having an internal diameter of 2·5 centimetres, the two ends being stopped with corks covered on the inner side with a thin coating of cement to protect them from the action of the ozone. Through the axis of each cork is inserted a glass tube of about 5 millimetres calibre, and 7 centimetres in length, having a branch tube inserted perpendicularly at the middle, and long enough to permit a rubber tube to be slipped upon it. The outer ends of the tubes themselves are closely stopped with corks, through which are passed straight thick copper wires carrying suitable terminals at their inner ends, and bent into a ring at the others. They are fitted so as to make tight joints, but to allow of motion in order to vary the distance between their inner ends. One of these wires carries a small ball, the other terminates in a disc with rounded edge, set perpendicularly to the axis of the tube, and so large as to leave an annular space of some two or three millimetres breadth around it. The gas is admitted through one of the branch tubes, and escapes from the other after having passed through the whole length of the tube.

"In using the apparatus the wires must be connected with the poles of the machine in such a manner that the disc becomes the negative terminal, as this arrangement gives the greatest degree of expansion and diffusiveness to the current. On turning the machine, and adjusting the ball and disc to a proper distance, a nebulous aigrette surrounds the latter, quite filling the interval between it and the wall of the tube, while the part of the tube between the disc and ball is crowded with innumerable hazy streams converging upon the positive pole, or simply causing the latter to be covered with a faint glow. A current of air or oxygen sent into the tube must pass through this, and ozone is very rapidly produced, and in great quantity. The condensers are of course not used with the machine, when this apparatus is employed.

"The great quantity of the ozone, as well as the ease and rapidity with which it is produced, render the apparatus especially serviceable for use in the lecture-room."

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

IF a good start in life is as serviceable for a society as for an individual, the French Association for the Advancement of Science must be considered as highly fortunate. There has already appeared in NATURE a short account of its first meeting at Bordeaux, and of the papers read there; but the impressions of one of its invited guests may not be altogether without value or interest.

Confessedly the French was framed on the model of the British Association, and doubtless there was wisdom in that; but our friends across the Channel showed their wisdom also in making no servile copy, but endeavouring to modify our plans, so as to suit their national character or special requirements. The reception-room, the card of admission with a map of the town on the back, the various sections in the morning, the discourses in the evening, the municipal hospitality, all reminded us strongly of our own meetings; yet there were some differences that could not fail to strike an English visitor.

In the first place, it was not so popular an assembly. This arose partly from its constitution. There are two kinds of membership; there are the foundation members, who have qualified by taking one or more shares of 500 francs each, and subscribers who pay 20 francs for the meeting or a life composition. By enrolling these members a large society was created with a large capital before ever the first place of meeting was named. And very quickly was this accomplished; for it was only about Midsummer of last year that M. Friedel talked with M. Wurtz as to the best means of extending knowledge through the departments of France, and it was only last Midwinter that the project was nearly shipwrecked by the sudden and lamentable death of M. Combes, in whose rooms the first meeting had been held, and who had been named the provisional president; yet by the aid of large-hearted friends, such as M. D'Eichthal and M. Menier ("Chocolat-Menier"), the promoters of the movement were able to announce in April a sufficient capital to start with, and before the meeting at Bordeaux the Association numbered 700 members, and possessed 140,000fr.

No provision had been made for ladies' tickets, so when the meeting opened there was a sombre uniformity of black coats. But the English visitors brought ladies with them; there was a learned lady, who was believed to be writing for the press, and another, Madame Hureau de Villeneuve, followed her husband's paper on the Steam-engine by reading one of her own on the Flight of Birds. Encouraged by these, several other ladies made their appearance, and brightened the later meetings.

The accommodation afforded by Bordeaux was singularly good. The brilliant concert-room of the great theatre (which is historically interesting from the National Assembly having been convened in it during the German war) was given as the reception-room; and all the meetings were held in the Ecole Professionnelle, a large building just erected in a very substantial manner by the Philomathic Society, with funds bequeathed for the purpose. This new edifice contains a large lecture-room, which served well for the general meetings, and no end of good class-rooms, which accommodated the eleven sections into which the Association was divided. It is intended for the instruction of the working classes of the neighbourhood in the natural sciences, modern languages, drawing, &c., and so the sittings of the large scientific body were a good inauguration of its future work.

The great subdivision of the sections naturally gave rise to but small audiences in each. As far as I could judge, the chemists and the anthropologists were in greatest force; few naturalists or geologists of eminence were present. The sectional proceedings had more the character of a sitting of one of our learned societies than of a morning gathering at the British Association; but besides a couple of hours thus devoted to more abstruse points of science, there was an afternoon sitting at which subjects of more general interest were brought forward. This came intermediate in character, as in time, between the morning sections and the evening discourses; and it is a fair matter for consideration whether it might not be advantageously copied by us.

The papers seemed on the whole superior to those brought forward at our Association, at least there were fewer communications of trivial importance, or old subjects warmed up afresh. Our neighbours, however, find discussion a difficult thing; it is apt to degenerate at once into a conversation between two heated opponents. There was evident also a want of order, punctuality, and respect for authority; previous arrangements were altered, or the decisions of the chair set aside, in the coolest manner. A want of proper organisation arose from the fact that M. Claude Bernard, the president, never made his appearance on account of ill-health; but M. Cornu, the general secretary, was a host in himself; and as M. de Quatrefages has accepted the presidentship of the next meeting at Lyons, and Prof. Wurtz, whose energy and good nature were unfailing at Bordeaux, is to occupy the post of honour the year following, we may hope that the young Association will quickly get over the diseases of infancy.

Festivities were not wanting. Chief among these was a grand reception by the Mayor at the Hôtel de Ville, but I may specially mention a *déjeuner* given by the French chemists to their brethren from England and Belgium, Holland and Spain. Some of us also will never forget the private hospitality we met with.

But the excursions were the great feature of the meeting, and in them the copy certainly surpassed the original. They played a most important part in the proceedings; Saturday and Tuesday were wholly devoted to them; and they took place on Sunday, on Monday afternoon, and through the three days after the close of the sittings.

There was the expedition to Arcachon, where the *savans* not only strolled about the pretty watering-place, but studied natural history at an aquarium which, unlike that at Brighton, was a very unpretending building, but well stocked with interesting marine animals, and paid an especial visit to the oyster-beds that have been formed on sandbanks in the middle of the land-locked sea in front of the town. Here we traced the growth of the favourite mollusc from the spat on tiles, till it was large and plump, and we had explained to us the difficulties of its cultivation, and the ravages committed by a murex called *Carmaillot* (I am spelling at random) and by the hermit crabs. There was an antiquarian expedition to Perigueux and Les Eyzies, where, on each side of the valley, the limestone cliffs are fissured with caverns, in which men lived, and worked in flint and bone, at that remote period when reindeer and mammoths roamed over the soil of France. There was an expedition to see the new "docks" and huge engineering works of the Garonne, which M. Joly carefully explained; and there was a larger excursion by boat and rail down the Gironde to the open sea, where geologists had an opportunity of inspecting the cliffs of chalk and flint, and then the Tertiary strata, beside discussing the subsidence of the Gascon shore, and the shifting of the sandhills, and seeing how they are now prevented from swallowing up villages and churches as they did of old.

But the great excursion was the final one, which extended over three days, and was unique in my experience. Twenty members of the Association were officially deputed to report mainly on the industrial establishments of the Landes and Lower Pyrenees; and any other members were welcome to join the party. Thus was secured a good nucleus of really scientific men, while the expedition had a serious purpose, and it was evidently to the advantage of the establishments visited that we should be well received. The Landes, as is generally known, is a large tract of country which, until lately, was a marsh of sand scarcely capable even of affording pasture; but now it is reclaimed, and the centre of thriving industries. Forests of pine (*Pinus maritima*) have been planted for hundreds of miles, and the trees are regularly scored for turpentine; maize and other crops are grown; and the undergrowth of heather supplies food for myriads of bees. At Labouheyre we inspected the means employed for separating the rosin from the turpentine, and the machinery for impregnating the pine wood with sulphate of copper, so as to fit it for railway sleepers and telegraph posts; and though the thermometer was at 32° C. (say 90° F.) in the shade, and anything you like to imagine in the sun, we also went carefully over some blast furnaces that are used principally for reducing by charcoal the Spanish iron ores which, being free from sulphur and phosphorus, yield an excellent metal.

Here the party was sumptuously entertained by M. Alexandre Leon; and from this stage special trains or special carriages were placed freely at our disposal by the Compagnie du Midi. The next place visited was a primary school at Morcenx, for the gratuitous instruction of the children of their *employés*, which had been carried on by M. Surell the former, and M. Simon the present director of the Railway Company. We found the boys at military drill; we took part in the distribution of prizes, the Association itself giving a reward to the best boy and girl; and as scientific men, we were particularly interested in the good provision for "object lessons," the chemical and galvanic apparatus, and the care with which the children were taught the rudiments of physical and physiological science. Rejoicing at this proof that the reclamation of the Landes was not confined to the soil, we pursued our way to Dax, and spent Friday night at the Thermal Baths, where we enjoyed the hospitality of Drs. Larauza and Delmas, the physicians of the establishment. The springs of nearly boiling water that gush from many parts of the contorted strata under the town were duly examined, and so were the deposits of rock-salt that were accidentally discovered a year or two ago, and which promise to prove an important source of wealth.

From these hot springs we travelled southwards across the Spanish frontier to Irun, and then a good walk through beautiful scenery took us among the granite mountains to the mines of Bidassoa. Here we saw how large faults in the primæval rock are filled with crystallised carbonate of iron, and how the rich ore is won.

Returning into France, where, through the kindness of M. D'Eichtal, a dinner was awaiting us, the expedition found its way back to Bayonne; and, doubtless, on the morrow some of the party visited the pre-historic camp and the ancient abodes of the Troglodytes, according to the programme; but the chemists generally preferred a quiet day at Biarritz.

J. H. GLADSTONE

THE SPIRIT OF SCIENTIFIC CONTROVERSY

As if in atonement for a prolonged neglect, the study of the organisation of fossil plants is now receiving wide-spread attention. The task first undertaken by Henry Withan has now been shared by many observers. The result is that we already possess a much more complete acquaintance with the ancient vegetation of the globe than we did even a few years ago. But whilst this is undoubtedly true, it is equally so that wide differences of opinion on important points still exist amongst those who have taken a leading part in this investigation. Thus, M. Brongniart and Dr. Dawson believe that the Sigillariæ were Gymnospermous Exogens; whilst Mr. Carruthers and myself are convinced that they were Lepidodendroid Cryptogams. In common with Prof. Schimper and Mr Carruthers, I regard the whole of the Calamites as Cryptogamic plants, having Equisetaceous affinities; whilst M. Brongniart, M. Grand-Eury, and, perhaps partially, Dr. Dawson, deem some of them to be Equisetaceans, and others Gymnospermous Exogens. Mr. Carruthers and Mr. Binney regard the fruits known

by the name of *Volkmannia Binneyi* to be the cones of Calamites. On the other hand, whilst I do not deny that such may possibly be their nature, I contend that we have neither proof nor even probable evidence sustaining this idea. Dr. Dawson says that Asterophyllites and Annularia are very distinct plants. Mr. Carruthers affirms that they are not. M. Grand-Eury and myself contend that Asterophyllites is wholly distinct, both in type and organisation, from Calamites. Mr. Carruthers believes that Asterophyllites and Annularia are alike the foliage of Calamites. It would be easy to multiply illustrations proving the existence of these opposite conclusions on important points amongst those observers who have enjoyed the best opportunities of forming reasonable opinions on such subjects. It is sufficiently obvious that some of us must be in error on these questions; possibly each of us is so in a greater or less degree; but when we regard the scientific status of the observers to whom I have referred, leaving myself out of the question, I ask, are they men whom we can accuse lightly of carelessness or ignorance? Must we not rather infer that each man has observed special facts leading him to his own conclusions, and that what we want is a careful comparison of such facts with those which have led our fellow-labourers in an opposite direction to ourselves? Whatever may be the explanation of these discrepant opinions, surely our mutual duties are clear. If any of us thinks that his fellow-labourer has made mistakes (and who has not) let him say so openly, and not suggest the idea by indulging in deprecatory insinuations. Let his opposing *argumentum* be *ad rem*, and not *ad hominem*. Further, let it be *ad rem* and not *ad alteram rem*. Let it not rest upon mere analogies, which may or may not be sound. Let us not reject a conclusion before we know all the facts from which it is drawn, merely because we think we have reason to deem it an impossible one. We have all lived to see many such conclusions take their places as undoubted truths.

One source of danger on these points, in the case of fossil botany, arises from the circumstance that though the ancient types of vegetation bear definite relations to the living ones, very remarkable differences present themselves in the combinations of the vegetative and reproductive organs in the two cases. Who, for instance, could have anticipated, from his knowledge of living plants, such an union of the usual vegetative organs of a cycad with an altogether anomalous reproductive system as we see in *Williamsonia gigas*. Many such examples will occur to those familiar with the subject. Hence, whilst a knowledge of living plants is absolutely indispensable to the student of fossil botany,—he cannot have too much of it—we must not allow our knowledge of recent combinations of vegetative and reproductive structures unduly to bias our judgment as to what may occur amongst fossil plants. Whilst we fully recognise the persistence of types, we must equally recognise the wonderful modifications which they have undergone in primæval times.

The conclusions to which these views lead me are very simple ones. The complex problems of palæophytology require harmonious and trustful co-operation amongst observers if truth is to be discovered. Let us supply this in the spirit of cordial fellow-labourers, and not as rivals in pursuit of a fleeting reputation which cannot be shared with others. We shall never raise ourselves by pulling others down. I will not quote the special expressions that are present to my mind whilst penning these lines; but it would be easy to do so, and to show that no possible benefits can accrue to science from their use. We can easily correct our mutual errors, we cannot so easily sooth wounded feelings, or restore shaken confidences. We aim at being the high priests of nature; let us try to banish all disturbing personal and selfish influences from the temple.

These words of warning may appear superfluous, because they embody mere truisms, equally applicable to every branch of human inquiry, or impertinent, seeing that in the fervour of earnest work, I may have erred in the same way as my neighbours. The fact is, that, like others of my earlier fellow-workers, I am rapidly approaching the autumn of life, and peace and harmony now appear more precious to me than they did in bygone years, when youthful ambition was alike active and inconsiderate. Happily ours are not pursuits which require us to cry *væ victis!* Just in proportion as we meet our opponents in a loving and harmonious spirit, without abandoning, in any degree, our earnest contention for what we believe to be truth, shall we, in our declining years, review our past labours with satisfaction and not with sorrow.—*Sic esto.*

W. C. WILLIAMSON

DISTRIBUTION OF HEAT IN THE SPECTRUM

PROF. J. W. DRAPER has communicated to *Silliman's Journal of Science and Art* for September a very important article under the above heading. After detailing a series of experiments on the distribution of the heat of the whole visible spectrum, of the more refrangible and of the less refrangible region, by rock-salt, flint-glass, bisulphide of carbon, and quartz, he thus sums up the results:—

"The important fact clearly brought into view by these experiments is, that if the visible spectrum be divided into two equal portions, the ray having a wave-length of 5768 being considered as the optical centre of such a spectrum, these portions will present heating powers so nearly equal that we may impute the differences to errors of experimentation. Assuming this as true, it necessarily follows that in the spectrum any two series of undulations will have the same heating power, no matter what their wave-lengths may be.

"But this conclusion leads unavoidably to a most important modification of the views now universally held as regards the constitution of the spectrum. When a ray falls on an extinguishing surface heat is produced, but that heat did not pre-exist in the ray. It arose from the stoppage of ether waves, and is a pure instance of the conversion of motion into heat—an illustration of the modern doctrines of the conservation and transmutation of force.

"From this point of view the conception that there exist in an incident ray various principles disappears altogether. We have to consider an incident ray as consisting solely of etherial vibrations, which, when they are checked by an extinguishing substance, lose their *vis viva*. The effect that ensues depends on the quality of the substance. The vibrations imparted to it may be manifested by the production of heat, as in the case of lamp-black, or by chemical changes, as in the case of many of the salts of silver. In the parallel instance of acoustics clear views have long ago been attained, and are firmly held. No one supposes that sound is one of the ingredients of the atmosphere, and it would not be more incorrect to assert that it is something emitted by the sounding body than it is to affirm that light or heat, or actinism, are emitted by the sun.

"The progress of actino-chemistry would be greatly accelerated if there could be steadfastly maintained a clear conception of the distinction between the mechanism of a ray and the effects to which that ray may give rise. The evolution of heat, the sensation of light, the production of chemical changes, are merely effects—manifestations of the motions imparted to ponderable atoms—and these in their turn can give rise to converse results, as when we gradually raise the temperature of a substance the oscillating movements of its molecules are imparted to the ether, and waves of less and less length are successively engendered."

SCOTTISH BOULDERS

THE first Report of the Committee appointed to collect statistics as to boulders, has been recently issued by the Royal Society of Edinburgh, and contains much that is interesting both to the geologist and archæologist. The first object of the committee, and that to which their labours have as yet been solely directed, has been to ascertain the districts in Scotland where any remarkable boulders were situated. Their second object will be to select those which might be deemed worthy of preservation, with the view of requesting landed proprietors and tenants of farms not to destroy them. The committee sent out a printed list of queries, applicable to boulders apparently above 20 tons in weight, one of the queries being directed to ascertain the occurrence of "kaims" or "eskars," *i.e.* long banks of sand or gravel. The following are some of the most important results educed by the inquiry :—

"1. From a tabular list we learn that Aberdeenshire possesses the largest number of boulders, and also the boulders of greatest magnitude. Ross and Cromarty stand next, then Perth, Argyll, Inverness, Kirkcudbright, and Forfar.

"2. In regard to size, the largest boulder reported is one of granite, in the Parish of Pitlochry, called 'Clach Mhor' (big stone), being about eight yards square, and estimated about 800 tons. There are two boulders between 500 and 600 tons weight, one in Ross, the other in The Lewis. There are three boulders, between 200 and 500 tons, seven between 100 and 200 tons, twenty between 50 and 100.

"3. With regard to the nature of the rocks composing the boulders, the largest reported are of granite, though there is one known to the convener of the committee, still larger, of conglomerate, in Doune parish. The most numerous are composed of compact greenstone; but these are generally of small size. The next most numerous class are of grey granite. There are also many of gneiss, graywacke, and conglomerate.

"4. The boulders reported generally differ in regard to the nature of the rocks composing them from that of the rocks of the district in which they are situated; and, in many of the reports, reference is made to the district from which the boulder is supposed to have come. Thus, in those parts of Perthshire, Forfarshire, and Kincardineshire where the Old Red sandstone formation prevails, and over which multitudes of granite, gneiss, and conglomerate boulders are lying, most of the reporters have no hesitation in pointing out that the parent rock is in the Grampian range, lying to the north or west. So also in Wigtonshire, where the graywacke formation prevails, and on which many boulders of grey granite are lying, the general opinion is that they came from the granite hills of Kirkcudbrightshire.

"5. The boulders mentioned in the reports are of various shapes. Some approach a cube, well rounded of course on the corners and sides. That is the shape mostly possessed by granite boulders. Others again are of an oblong shape, and this is particularly the case with whinstone and graywacke boulders. A point of some importance occurs in regard to oblong-shaped boulders. The direction of their longer axis, in the great majority of cases, is stated to coincide with the direction in which they have come from the parent rock, when the situation of that rock has been ascertained. Thus in Auchterarder parish, there is a boulder 10 ft. long by 6 broad, the longer axis of which points north-west. In Auchtergaven parish there is a granite boulder 10 ft. long by 8 ft. broad, the longer axis of which points due north. In Memuir parish, Forfarshire, there are two large granite boulders, the one 14 ft. by 9 ft., and the other 13 ft. by 9 ft., the longer axis of which points north-west. In each of these cases the reporters seem satisfied of the situation of the parent rock, and in each case the longer axis of the boulder points towards it. It appears, also, that where there are natural striations or ruts on the boulders, these almost always run in a direction parallel with the longer axis; and that when there are striæ crossing these the number of such oblique striæ is comparatively few.

"6. Notice in the reports is taken of the remarkable positions occupied by some boulders. Thus, the Ardentinny report refers to a large boulder called 'Clachan Udalain,' or the nicely balanced stone, so called, as the reporter states, because 'it stands on the very edge of a precipice, and must have been gently deposited there.' On Iona, near the top of the highest hill in the island, which is about 250 feet above the sea, there is a great boulder of granite. There is no granite in the island. The nearest place where that rock occurs is in the Ross of Mull, &c., with an arm of the sea intervening.

"7. With regard to kaims or long embankments of gravel or sand, there are twenty-three parishes reported to the Committee as containing them. They appear to be most numerous in Aberdeenshire, Forfarshire, and in the east of Perthshire. In Kemnay parish there is a kaim said to be 2½ miles long, running east and west. In Airlie parish there is a kaim 2 miles long, also running east and west. In Fettercairn parish, Kincardineshire, and also in Tarbet parish, Ross-shire, there are several kaims parallel to, and not far distant from, one another."

The committee proceed next to notice points of archæological interest connected with boulders, and are surprised at the large number of them possessing names by which they are known in the districts to which they belong. The names may be classified under several heads :—First, there are names having reference to the agency by which the boulders were supposed to have come into the district. Second, there are names indicative of the use to which boulders were put. Third, there are names making the boulders commemorative of certain events. Fourth, some boulders form such prominent landmarks that they have been used to mark the boundaries of estates, parishes and counties, and are still in many parts of Scotland recognised as affording evidence on that subject. On these points the committee give some very curious information which must be highly interesting to archæologists, and indeed to all who take an interest in the history of the race.

Great numbers of boulders have legends attached to them, one of the commonest being that the boulder was thrown to the spot where it lies by some giant, demon, or even by "Auld Nickie Ben" himself, for some wicked purpose of course; and it is very interesting to notice, that almost invariably, the place from which the legend says the huge stone was thrown, is the nearest spot containing the formation to which the boulder belongs. It is well known that, as a rule, boulders differ from the formation on or in which they are found, and in reference to what we have just mentioned, the place from which the giant or devil took his throw is often at a very considerable distance, sometimes on a different island. For example there is a large conglomerate boulder near the top of a hill, in the island of Edag, one of the Orkneys, which goes under the name of the "Giant's Stone." The legend says it was flung by a giant from the island of Stronsay; now there is no conglomerate rock which could have supplied the boulder in Edag, though there is in Stronsay.

The British Association at its last meeting so highly approved of the scheme of the Royal Society of Edinburgh, that it appointed a committee of some of its most influential geologists to carry out a similar scheme for England and Ireland.

The committee are very anxious that the boulders reported on should be examined by experienced geologists, who may be visiting the districts where they are situated, and are willing to lend the reports they have received on condition that the results of the inspection be made known to the committee.

ON THE FERTILISATION OF A FEW COMMON PAPILIONACEOUS FLOWERS

[NOTE TO EDITOR.—THE enclosed paper was written in the autumn of 1869, and then submitted to Mr. Darwin. With his usual kindness he encouraged me to proceed with it; and with his usual thoroughness he advised me to make it more complete than it is before giving it to the public. At the same time, he lent me various publications containing articles on the subject of fertilisation, and, amongst others, some by the Italian botanist, Delpino, who has done so much in this field. I found that he had in two or three publications in the years 1867 and 1868, anticipated most of the observations contained in the accompanying paper; and I proposed to myself to attempt a *résumé* of what had been done of late years in the matter of fertilisation of flowers by Delpino, Hildebrand, and others. But this, though a labour of love, is a greater labour than I can manage, and other calls have grown upon me. I therefore send the paper to you as it stands, begging that this note may be prefixed in order that I may not be thought to be appropriating Delpino's observations.—T. H. F., *October* 1872.]

AFTER reading Mr. Darwin's book on Orchids and his papers on Lythrum and Primula, I made some notes on the fertilisation of Phaseolus and some of the Campanulaceæ, which had the good fortune to meet with his approval, and which he had the kindness to send for publication to the Annals and Magazine of Natural History, where they appeared in October 1868. The comparison of Phaseolus with other Papilionaceous flowers led me to think that Mr. Darwin's fertile ideas might receive many illustrations from the structure and functions of this beautiful and interesting tribe; and the following are observations made during the summer of 1869 upon

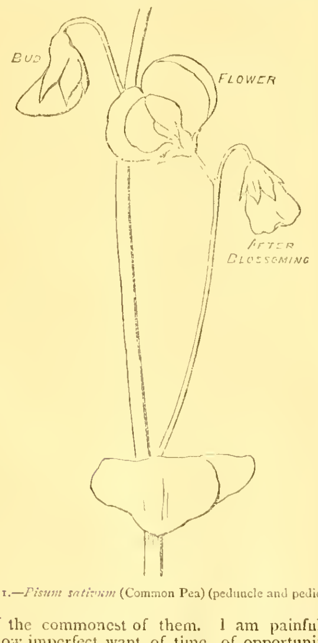


FIG. 1.—*Pisum sativum* (Common Pea) (peduncle and pedicels).

a few of the commonest of them. I am painfully conscious how imperfect want of time, of opportunity, and of knowledge has left them; and how many points there are, even in these few flowers, which require a much more careful inquiry. Indeed, every new flower has its own peculiarity; and almost every new peculiarity suggests the observation of facts in other flowers not previously noticed; so that the task is endless. Again it is difficult to feel sure of a conclusion unless the whole process of fertilisation by insects can be watched, and to a dweller in towns, ignorant of insects and their habits, it is impossible. If, however, these observations should lead to further inquiry and discussion, they may not be useless. The flowers in question are *Pisum sativum*, several species of *Lathyrus*, *Vicia*, and *Phaseolus*, *Robinia pseud-Acacia*, *Wistaria*, *Onobrychis sativa*, *Trifolium repens* and *T. pratense*, *Lotus corniculatus*, *Lupinus*, *Ononis*, *Anthyllis*, *Ulex*, *Genista*, *Sarothamnus*, and *Cytisus*.

Pisum sativum, or Common Pea.—The blossoms are generally two upon a common peduncle, and each flower has a separate short pedicel (see Fig. 1). The peduncle generally approaches the perpendicular and

FIG. 2.—*Pisum sativum* (mature flower).

maintains its position through the stages of bud, blossom, and pod, except that it gets stiffer. The short pedicels, however, change their position twice. In the bud they are bent down so that the base of the calyx is uppermost, and the upper edge of the folded vexillum lowest. In this stage the large calyx covers with a weather-proof awning the tender blossom. As the flower opens the pedicel straightens itself; and when the blossom is fully open it is quite straight, and at an angle of 45° to the peduncle. The effect of this is to raise the flower so that the keel and wings become almost horizontal, whilst the showy limb of the vexillum, bent upwards from the claw, displays a perpendicular face (see Fig. 2).

The wings are slightly attached to the keel at the base of their limbs; and the limbs project outwards and a

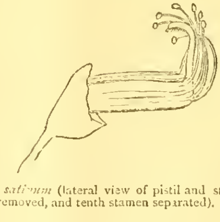

FIG. 3.—*Pisum sativum* (lateral view of pistil and staminal tube, with calyx and corolla removed, and tenth stamen separated).

little upwards in front of and above the keel, so as to make an excellent lighting place for insects. The keel is boat-shaped, recurved at the apex, and the lower edges

are joined together from the base to the apex. The stamens are diadelphous, the filament of the tenth stamen being separate at the summit and base, and separable in the middle (see Fig. 3). They are of nearly equal length, the pollen is abundant and rather moist, and is shed at the time the blossom expands. The upper parts of the filaments are stiff enough to keep their place, but not so stiff as the style. The lower parts of the filaments form a stiff tube, expanded towards the base, so as to leave a large cavity round the base of the ovary. This cavity is abundantly supplied with nectar. On each side of the tenth stamen at its base, there is a wide aperture, through which apertures, on removing the vexillum, this cavity with its nectar is easily seen (see Fig. 4).

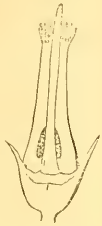

FIG. 4.—*Pisum sativum* (front view of staminal tube, with tenth stamen, front showing apertures into nectary on each side the tube).

The style is at right angles to the horizontal ovary, and curves towards the vexillum at the top. The stigma is at the extremity, and faces outwards and upwards towards the vexillum. On the inside for some distance below the stigma it is clothed with stiff hairs, which are set so as to point upwards towards the stigma (see Fig. 5). The style appears to be formed by two folds of the carpellary leaf, which bend outwards from the point where the style joins the ovary, so that the outer side or back of the style which lies towards the suture of the keel, and which has no hairs on it, is formed, not of the outer suture of the carpel, but of the edges of these folds.

At the time the flower opens the stamens have shed, or are shedding, their pollen, which lies in an abundant mass at the apex of the keel around and above the stigma.

FIG. 5.—*Pisum sativum* (pistil).

The back of the stiff elastic style almost touches the keel; and on pressing down the wings, which, as above noticed, are attached to the keel, the back of the style, which has no hairs, is pressed against the keel, whilst the brush on the front and sides of the style sweeps the moist pollen upwards and pushes it out of the apex of the keel and against any object which is entering the flower, and to which the pollen, being moist, will adhere. On removing the pressure the parts take their place again, whilst on repeating the pressure the same process may be repeated, until the whole of the pollen in the upper part of the keel is brushed out.

As soon as the flower closes and before it withers, the pedicel again droops, the flower becomes pendent, and the calyx again acts as a pent-house to the young pod (see Fig. 1).

Now, undoubtedly, the stigma of one of these flowers is always covered with its own pollen; but if self-fertilisation were the rule, the elaborate structure I have described is meaningless, whilst if the purpose is that insects shall carry the pollen from flower to flower, it becomes a curiously elaborate and complete piece of mechanism having a special object. The change of position of the flower by the bending, straightening, and second bending of the pedicel, so that the tender opening bud and the young fertilised ovary are protected from rain and cold; whilst the open blos-

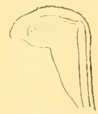

FIG. 6.—*Lathyrus* (keel and pistil).

som displays itself in the most attractive and convenient form and position for insects; the conspicuous vexillum; the wings, forming an alighting place; the attachment of the wings to the keel, by which any body pressing on the former must press down the latter; the staminal tube inclosing the nectar, and affording by means of its partially free stamen with apertures on each side of its base, an open passage to an insect seeking the nectar; the moist and sticky pollen placed just where it will be swept out of the apex of the keel against the entering insect; the stiff elastic style so placed that on a pressure being applied to the keel, it will be pushed upwards out of the keel; the hairs on the style placed on that side of the style only on which there is space for the pollen, and in such a direction as to sweep it out; and the stigma so placed as to meet an entering insect,—all these become correlated parts of one elaborate mechan-

FIG. 7.—*Lathyrus latifolius* (Everlasting Pea).

ism; if we suppose that the fertilisation of these flowers is effected by the carriage of pollen from one to the other.

I have, however, not observed the bees or other insects at work on these flowers, whilst they are to be found in abundance on the neighbouring broad beans and scarlet

runners. Do the white pea-blossoms attract night-flying insects?

Lathyrus odoratus.—This is, so far as the above functions are concerned, so like Pisum, that it is scarcely worth while to dwell on the differences. In colour and smell, of course the difference is great, and consequently in the attractions for different insects. The changing position of the pedicels; the brush to the style; the free or partially free stamen, and the nectar inside the case of the staminal tube, and the openings into that tube, are the same (see Fig. 6).

Lathyrus macrorhizus, is, so far as I have observed it, similar.

Lathyrus pisiformis is like the other Lathyri in the above points, except that in the long raceme of flowers, the whole peduncle, and not only the pedicels of the separate flowers, is pendent in the bud. It stiffens and becomes upright as the blossoms open, and the pedicels also stiffen and become horizontal. After flowering the peduncle remains stiff and upright, but the pedicels droop.

FIG. 8.—*Phaseolus multiflorus* (Scarlet Runner).

Lathyrus pratensis.—The fertilising apparatus is the same as in the above Lathyri.

Lathyrus sylvestris, or *latifolius*, or Everlasting Pea.—Here the many-flowered raceme is itself upright, whilst the pedicels bend, straighten themselves, and again bend, as in Pisum (see Fig. 7). In the fertilising apparatus the mechanism is the same as above described, with the exception that there is a very decided obliquity in the keel and in the style, though not so decided as in the following.

Lathyrus grandiflorus.—In this flower the peculiarities, as distinguished from the above-mentioned Lathyri, are as follows:—The pedicels bend, straighten, and bend themselves again, as above mentioned; but the effect generally, if not universally, is to make the large showy vexillum, and not the keel, horizontal. The vexillum, consequently, and not the keel, would be the natural alighting place for an insect. The wings are at right angles to the vexillum, and the recurved point of the keel projects between them and overhangs the vexillum. An insect alighting on the vexillum, and thrusting itself towards the nectary, must push the wings, and with them the keel, upwards, and make the style and the pollen come out; but they will come out downwards on to the back of the insect, and not on to his thorax or belly.

Another peculiarity is that the keel, and with it the style, is very oblique, and the upper part is flattened, and is twisted so that the back of the style does not press against the keel. Correlatively both sides of the style are well furnished with hairs, and both sides equally operate in sweeping the pollen out of the keel. In this respect *Lathyrus grandiflorus* seems to show a gradation towards Phaseolus.

Phaseolus multiflorus, or Scarlet Runner.—In the position of the blossom whilst flowering, in the nectar-holding cavity of the staminal tube, and in having an entrance to the cavity by the separation of the tenth stamen, this flower resembles Lathyrus and Pisum, but it offers the following peculiarities (see Fig. 8):—

The pedicel of the bud before flowering is perpendicular and stiff, and the bud consequently upright; the pedicel becomes rather more horizontal as the flower opens, and in blossom the wings are horizontal, whilst after flowering the pedicel becomes quite horizontal, and the pod gradually sinks, and ultimately becomes pendent. Correlatively, there is no large pent-house of a calyx, as in Pisum, to protect the young blossom; but the same object seems to be effected by the smooth, strong, thick vexillum, the edges of which are in the bud closed valvately over the tender folded interior petals; whilst in the bud of Pisum the whole of the petals, whilst sheltered by the calyx, are tender and unclosed. The young pod of Phaseolus, also unlike the thin glabrous pod of Pisum, is thick and covered with short hairs.

The keel, which in some Lathyri is very oblique, is in Phaseolus so twisted, and has its edges so joined, as to form an imperfect tube containing the stamens and style; it makes with them nearly two complete spiral turns, and its mouth points obliquely downwards. The stiff, elastic style is clothed with stiff hairs or bristles, forming a circular brush at the point in the tube where it is surrounded by, and in contact with, the moist, sticky pollen of the mature anthers. The stigma is on the lower side of the style, just appearing at the mouth of the tube, is sticky, and is clothed with fine hairs.

The filament of the tenth stamen is entirely separate from the others, and is furnished with a sort of tooth or appendage on the outside, upon pressing which the stamen is drawn back, and free access is given to the nectar-holding cavity. On the other hand, there is no such aperture on each side of the base of the tenth stamen as there is on each side of the base of the semi-adherent filament in Pisum and Lathyrus.

A bee lighting on the wings, or rather on the outer wing, opens for himself a way to the base of the flower. At the same time, the wing being attached to the spiral tube of the keel, he pulls it outwards, the consequence of which is that the stiff style is thrust outwards and at first downwards, so that the sticky stigma first touches the entering insect and sweeps from his proboscis any pollen he may have brought from other flowers. As he passes further, the stigma protrudes further, turns upwards, and the brush of the style, loaded with the sticky pollen of its own anthers, sweeps against, and leaves its load on, his proboscis, with which he departs for other flowers.

The mechanism of this flower is truly wonderful. For further details I could refer to papers by Mr. Darwin in the *Gardener's Chronicle* of October 24, 1857, and November 14, 1858, and to the notes of my own in the *Annals and Magazine of Natural History*, October 1868.

Phaseolus vulgaris is similar to *P. multiflorus*.

T. H. FARRER

(*To be continued.*)

NOTES

DR. T. STERRY HUNT, F.R.S., for more than twenty-five years an officer of the Geological Survey of Canada, has resigned his position there, and goes to Boston to the Massachusetts Institute of Technology, where he is to fill the chair of Geology, left vacant by the resignation of Prof. William B. Rogers. He was to enter upon his new duties on October 7.

THE examination which has been held in common by Magdalen and Merton Colleges, Oxford, for scholarships in Natural Science, terminated on Saturday, when the following elections were made:—To demyships at Magdalen College, value 95*l.*, for five years: Mr. W. J. P. Wood, Clifton College; Mr. C. H. Wade, The Owens College, Manchester. To a postmastership at Merton College, value 80*l.*, for five years: Mr. W. H. Jones, Derby.

THE centenary of Linnæus's death will be celebrated at Stockholm on the 10th of January, 1873, when a statue of the great Swedish naturalist will be unveiled.

THE Meteorological Congress will meet next year at Vienna, and the meeting will be a very important one, for which the one recently held in Leipzig was only a preparation; the condition of the Continental observatories and of the large British ones will then form a grave subject for discussion.

WE learn from *Les Mondes* that the construction of meteorological observatories on the summit of the Puy-de-Dôme is now about to commence. Two observatories, connected by a telegraphic wire, the one in a pavilion of the faculty at Clermont, the o her on the summit of the mountain, 1,160 metres above the lower one, will show every moment the difference of meteorological condition between the plain and the upper regions of the atmosphere. The money allotted to this purpose is 100,000 francs, one half being furnished by the town and department, the other half by the State.

THE Commissioners of Her Majesty's Works and Public Buildings intend to distribute this autumn, among the working classes and the poor inhabitants of London, the surplus bedding-out plants in Battersea, Hyde, the Regent's, and Victoria Parks, and in the Royal Gardens, Kew. If the clergy, school committees, and others interested, will make application to the Superintendents of the Parks nearest to their respective parishes, or to the Director of the Royal Gardens Kew, in the cases of persons residing in that neighbourhood, they will receive early intimation of the number of plants that can be allotted to each applicant, and of the time and manner of their distribution.

THE Annual Fungus Exhibition was held in the Council Room of the Royal Horticultural Society, on Wednesday the 2nd inst. There were several extremely good collections, both of the edible and poisonous kinds, many of the rarer edible species being well represented, while some of the commoner ones were almost entirely absent. Prizes for the best collections were given by Mr. W. W. Saunders, F.R.S.

AN exhibition of useful insects and their products, and also of noxious insects, with samples of the injuries caused by them, organised by the Central Society of Agriculture, and under the patronage of the Minister of Agriculture and Commerce, will be held during this month in the Luxembourg Gardens in Paris. It will comprise silkworms and their cocoons of every species, with samples of thrown and raw silk; apparatus for silk culture; with the manufacture and raw product of bees, and apparatus for bee culture; a collection of noxious insects, and apparatus suited for their destruction; other useful insects; collections of mammals, insectivorous birds, and reptiles, &c. The programme of the exhibition may be obtained of the Secretary of the Society of Agriculture, 59, Rue Monge, Paris.

THE *Journal of Botany* records the death, after a short illness, of a well-known Continental botanist, Andreas J. Oersted, Professor of Botany in the University of Copenhagen. He had travelled and collected largely in Central America, and had written much, especially on cryptogamic botany.

DR. EICHLER, of Gratz, editor of Martius's "*Flora Brasiliensis*" has accepted the appointment of Professor of Botany at Kiel, Holstein. No change will be involved in the publication of the great Flora.

AQUARIA seem to be quite the rage at the present time. A new large aquarium is to be built at Great Yarmouth on the north beach. A space of seven acres has been granted by the Corporation a short distance to the left of the Britannia Pier, and here, in addition to the aquarium, gardens will be laid out, and a museum and gymnasium built.

THE fine new Guildhall Library is almost completed, and will be open free to the public very shortly. In addition to the Library proper, the basement will be used for carefully storing the old charters and records belonging to the Corporation, and a handsome room, 80 ft. long by nearly 50 ft. wide, will be devoted to the Museum, and it is hoped will become a receptacle for all the objects of antiquarian interest found in the City of London. Above the Museum is the Library proper, a noble room, 120 ft. long by 50 ft. broad, and nearly 60 ft. in height. The open oak roof will be highly ornamented and enriched, and the windows will be filled with stained glass, the two chief windows being presented by the London and Middlesex Archæological Society, and by the inhabitants of the Ward of Aldersgate.

THE first session of the New University College of Wales at Aberystwyth was to open to-day (Thursday). The educational staff will at present consist of the Principal, a Professor of Classics, a Professor of Mathematics and Natural Philosophy, and a Teacher of Modern Languages. Arrangements will be made as soon as practicable for lectures in Geology, Chemistry, and other cognate subjects. The Principal is the Rev. Thomas Charles Edwards, M.A., to whom application for admission must be made. An examination will be held at the beginning of the session, when several exhibitions of 20*l.* each will be awarded.

WE have received the prospectus of The Owens College, Manchester, for the session 1872-73. The most important new arrangement is the separation of Geology and Palæontology from Natural History, and the establishment of a separate Chair, which is filled by Mr. Boyd Dawkins, F.R.S. Animal Physiology and Zoology, and Vegetable Physiology and Botany, remain under the charge of Prof. W. C. Williamson, F.R.S. The Manchester Royal School of Medicine is incorporated with The Owens College.

THE courses of lectures in connection with the Franklin Institute for the winter session 1872-73, to be held in the Hall of the Franklin Institute, Philadelphia, will comprise Experimental Chemistry, Mineralogy, Metallurgy, Hygiene, Physics, Technical Chemistry, Fire, and Photography.

IT is proposed to incorporate the courses of evening lectures on scientific subjects delivered at the Polytechnic Institute into an institution to be called the Polytechnic College. They are largely attended by young men, many of them engaged during the day in shops.

THE following scientific lectures will be delivered in connection with the Newcastle-upon-Tyne Literary and Philosophical Society during the session 1872-73. "The Progress of Solar Research," by J. N. Lockyer, F.R.S., Oct. 21 and 23. "New Illustrations of Divine Contrivance in Nature," by Prof. S. Haughton, M.D., Oct. 28 and 30. "Water; its Nature, Circulation, and Functions," by Prof. D. Page, LLD, Nov. 4 and 6. "The Life, Character, and Work of Faraday," by Dr. J. H. Gladstone, F.R.S., Nov. 18 and 20. "On Stellar Astronomy," by Prof. R. Grant, Dec. 6 and 13. "Oil Coals, Oil Shales, and Oil Wells," by A. Taylor, Dec. 16, 18, and 20. "On Polarized Light," by W. Spottiswoode, F.R.S., January 29, and 31, 1873. "Early Moral and Political Condition of Mankind," by E. B. Tylor, F.R.S., Feb. 5 and 7.

LECTURES will be delivered during the ensuing session in connection with the Oldham Literary and Philosophical Society, on the following subjects:—"Star Depths," illustrated by Oxy-hydrogen Lantern and Photographic Sides, by R. A. Proctor. "Flame," illustrated by experiments, by Prof. J. H. Core. "Balloon Ascents for Scientific Purposes," by James Glaisher, F.R.S. "The Origin of the British Flora." by L. C. Miall, "The Caverns of Devonshire," by W. Pengelly, F.R.S. "Sand, Gravel, and Clay; or, an Arctic Climate in Britain," by J. E. Taylor. "Folk-Lore of Natural History," by Robt. Holland. This will be the second session, the first having been decidedly successful.

THE distribution of the prizes and certificates in the Guildford Science Classes took place on September 20, under the presidency of Lord Midleton. The classes have been very successful during the past year, the members under instruction in the various subjects amounting to seventy-seven, against forty-four in the previous year; and the proportion of certificates awarded being larger than the average of all England. Guildford is showing in the institution of these classes an example that might well be followed by other towns whose opportunities are greater. We are sorry, however, to learn that up to the present time the committee has entirely borne the brunt of the elementary expenses, not one sixpence having been contributed by the public of Guildford during their three years' existence. This is not as it should be. Probably in time our country towns will learn that their own interest is involved in cultivating a knowledge of science.

THE *Astronomical Register* for October contains the first instalment of an article on astronomical allusions in Homer, Dante, Shakespeare, and Milton, Homer and Dante being treated of in the present number with great care and fulness of knowledge. The subject is an interesting one, and we believe Mr. G. J. Walker's treatment of it will be of service towards a history of the progress of man's knowledge of the heavens.

FROM the same periodical we learn that the new dome for the Edinburgh Observatory, alluded to in a recent number of NATURE, is now erected, and admirably fulfils all the expectations formed of it, such as increased space inside, greater ease of revolution, larger and more easily worked shutter, better ventilation, and freedom from vibration and bumping. This latter curious quality was a very vicious propensity of the old dome, partly from its being mounted on cannon balls, which enabled it to roll in every other direction as well as in that of the line of railway, wherein it was wanted to roll; and partly from the unprecedentedly windy and stormy exposure of the Edinburgh Observatory on the summit of Calton Hill. The new dome, therefore, may be considered a very creditable piece of engineering, and a decided success on the part of Mr. Howard Grubb.

WE learn from the *British Medical Journal*, that 300 young Russian women have claimed admission as students in medicine and surgery at the newly opened Medical School of St. Petersburg. The number of admissions being fixed, however, at 70, there will be a great many disappointed.

THE Volcano of Santorin, when last visited in October 1871, had ceased giving the small eruptions which had been common almost without intermission since the great eruption of 1866, and the summit of the crater, covered with great blocks of lava, presented the same appearance as in 1707. A little steam was still escaping, but this seemed due almost entirely to the vapour of water condensing on the cinders covering the cone. In the north the fumerolles were still active, and all around the stones were covered with sulphur. At the S.E. point the volcanic activity had not completely ceased, but had greatly diminished. All this would show that the eruption had entered on its last stage, and after a period of great central activity in 1866-67, accompanied by a diminution of activity in 1869-70, it is now again assuming a condition of rest and quietude.

THE completion of the Australian Land Telegraph is a great scientific feat, for by it London is now within a few hours' communication with Adelaide and all the other centres of population on the Australian continent. Whilst the Suez Canal, the Mont Cenis Tunnel, and the Pacific Railway, are undoubtedly great and stupendous works, the carrying of a line of telegraph across the uninhabited and almost unknown interior of Australia for 1,800 miles is a great result, especially when performed single-handed by the colony of South Australia. Some interesting discoveries have been made during its progress. The river Roper has now been ascertained to be a noble river, and the only one in Australia navigable for large sea-going steamers and ships for 100 miles from the sea, and some apparently very productive gold fields have also been found.

AURORÆ BOREALES have been very conspicuous lately. On the 25th of August one was seen at Thurso and at Hernösand in the Gulf of Bothnia and feebly also at Lisbon.—On the 26th at Sèvres and also at Stockholm.—On Sept. 2, at Sèvres, Stockholm, Reval and Windaw.—On Sept. 3, at Sèvres, Paris, Hernösand, and Rome.—On the 4th, at Sèvres, Paris, London, and Archangel.—On the 5th, at Sèvres and Paris.—On the 6th at Hernösand. So that there have been in Europe, during the period from the 2nd to the 6th of Sept., an almost continuous succession of Auroræ visible in England, France, Scandinavia, Russia, and once in Italy.

A WHITE Aurora Borealis was observed at Baumette near Angers, on the 8th of August, by M. A. Cheux, who thus describes it.—About 10 o'clock the sky was lit up in the N.N.W., by a white light; and at successive intervals white rays were shot out mostly towards the North or North-West. At about 10·30, a magnificent white ray shaped like a fan, and 22° in height, occupied the northern part of the sky. This gradually faded, and by 11·30 the sky had resumed its natural colour. This is the fourth Aurora Borealis observed in the last four months, the others having been seen on the 9th of May, the 9th of June, the 10th of July, and this on the 8th of August. The coincidence in these monthly dates is something remarkable.

PROF. O. C. MARSH of New Haven, has been diligently at work during the past summer in elaborating the rich mass of fossil vertebrates collected by him last year and the year before in various parts of the West. His latest discoveries are two large pachyderms allied to *Palæosyops*, a gigantic fossil tapir called *Hyrachyus princeps*, two carnivora allied to the *Viverridæ*, and, most important of all, two species of bats (*Nyctitherium velox* and *N. priscus*), the first of the order ever detected fossil in America.

SIEBOLD'S NEW RESEARCHES IN PARTHENOGENESIS *

AMIDST the all-absorbing discussion of the problems which have arisen out of the general acceptance among biologists of the law of evolution, the phenomenon of Parthenogenesis which, previously to Mr. Darwin's work on the Origin of Species, excited the interest and called forth the investigations of observers in much the same manner as his theory has done of late years, has met with a reverse of fortune and fallen into a subordinate rank of popularity. The distinguished naturalist, however, who fifteen years ago gave so stunning a blow to current theories of the reproductive process, by demonstrating the occurrence in moths and bees of what he designated as "true parthenogenesis"—that is to say, the development, without impregnation, of an ovum capable of being impregnated—has not let the subject drop. Professor Siebold has made further experimental researches, establishing again, and on a larger basis, his former conclusion, and adding at least one new fact of great general importance for the understanding of the process of sexual reproduction. Although upon its first appearance in 1856, the conclusion arrived at in his "Wahre Parthenogenesis" was admitted by almost all competent naturalists to be thoroughly demonstrated, and beyond the reach of criticism; yet some more and some less eminent biologists have not been wanting to deny the *Lucina sine concubitu*, and have raised such objections as that of a possible error in the condition of the experiments depending on the exclusion of males from the supposed parthenogenetic female; and again, that these so-called females were not demonstrated "not to be hermaphrodites." Indeed so deeply rooted is the conviction that eggs are made to be impregnated by spermatozoa, and that they then, and then only, can proceed to develop, that Siebold felt it necessary to add to his proofs, in order to establish his position that not only do unimpregnated eggs develop into perfect animals, but that such an event is by no means an exceptional occurrence among certain groups, and has a definitely fixed and orderly recurrence amongst them. He naturally was also anxious to extend the class-limits within which a true parthenogenesis can be said to occur, and he desired to inquire into the sex of the parthenogenetically-produced offspring in such cases as could be critically and decisively studied. Hence the renewed researches which have extended over several years, and the results of which are given in the present brochure.

Von Siebold's merit in this and his former work (but more especially in this) is not the enunciation of a new theory, or hypothesis, but the great care, ingenuity, and persistence which he has displayed in investigating cases in which for many years collectors, bee-keepers, and such naturalists of the limited, or "gardener" type, had asserted reproduction by means of unfertilised eggs to take place. It must be remembered that he was himself a strong opponent in 1850 of the supposition which he has now shown to be justified in fact, and that Leuckart in his article "Zeugniss," in Wagner's Handwörterbuch, and in other publications, preceded him as an advocate for the existence of true parthenogenesis, endeavouring, by microscopical researches, to give a solid observational basis to Dzierzon's hypothesis. It was not until 1857 that Siebold published his observations on bees, demonstrating what had been previously supposed, viz., that the queen-bee exhausts her store of received sperm in fertilising eggs which give rise to females only, and that then she lays unfertilised eggs, which become drones only, whilst the unfertilised worker-females also lay eggs which give rise to drones, and again that in certain moths (*Psyche* and *Solenobia*) unfertilised ova develop and produce females only. Leuckart followed (1858) with his "Zur Kenntniss des Generations-wechsels und der Parthenogenesis bei den Insekten." In this work, whilst asserting his claims to the merit of first espousing the cause of true parthenogenesis, Leuckart gives an excellent view of the general signification of the phenomena, and insists on the importance of extended histological observation in the examination of alleged cases of parthenogenesis. In his present work Siebold cannot be charged with in any way neglecting this part of his subject, for he has given most important and minute descriptions of the generative organs of the two principal cases studied (*Polistes* and *Apus*), containing new facts. His method is however eminently experimental, and appears to us a striking contradiction of a very superficial classification of the sciences, which is favoured sometimes by men of science unacquainted with the methods or problems of biology: we mean the division into the exact or mathematical, the experimental, and the classificatory sciences, in which last division the so-called natural history sciences are said to find their place.

The experiments which Siebold made on bees and wasps, though performed by a naturalist, are as nicely controlled, and as clear in the conclusions which they give, as any performed by exact physicists on the times or quantities concerned in this or that physical process. The style in which details of these investigations are communicated is one rare at the present day in biological works, where minute description of structure, or of the apparatus devised for a physiological research, form the staple. Here we are treated to a leisurely narrative of some years of patient work; we share the keen enjoyment of the author as he becomes acquainted with the marvellous intelligence of his wasps and their various proceedings—we feel his satisfaction in overcoming the difficulties of procuring and observing the necessary material, and admire the candour and thoroughness with which he handles the question before him.

Before proceeding to a short notice of the contents of Von Siebold's book, it will be well to give a brief statement of the signification which such inquiries as his have in the present state of knowledge. Harvey's dictum, "Omne vivum ex ovo," expressed a great law, which had to be qualified when the researches of Trembley and others made known, among Polyps, and Worms, and Protozoa, reproduction by fission. To this rapidly succeeded the recognition of a modified fission, in which the animal did not divide into equal parts, nor exhibit the power of reproduction of the whole animal in artificially detached portions of its body; but in which special sprouts or buds were found to be prepared and detached spontaneously, becoming then developed into perfect animals. This process received the name of gemmation, and was stated to occur in polyps and also in the plant-lice. Parallels for these methods of reproduction in animals were readily recognised in plants, in the multiplication by seed, by cuttings or shoots, and by separable buds. A broad line was drawn between "buds" and "eggs," however egg-like the former might appear, in the assumption that eggs were special bodies of a peculiar structure, destined to be "fertilised" by the spermatozoa of the male—after which process only could they develop. These distinctions, some twenty years ago, were the more firmly impressed in the minds of biologists by the then recently acquired knowledge of the process of fertilisation or impregnation. Then came the demonstration by Siebold of the capacity for development of true eggs, even when not impregnated. The sharpness of the limit between buds and eggs was by this at once destroyed; and the closely following researches of Leydig (antecedent to Siebold's work in some cases), Huxley, Lubbock, and Leuckart, on the structure of the supposed buds of Aphis and allied insects, and of lower crustaceans, proved that these bodies were morphologically ova—originating in ovaries, and having the essential structure of fertilisable ova. For them the term "pseudova" was introduced by Prof. Huxley, since they differ in this respect from other ova—that whereas the latter can be, and are in most cases (though with constant exceptions), fertilised, the latter cannot be.* Whilst, then, up to this period such a thing as parthenogenesis appeared to be a strange exception, the question has now shifted, and, since the essential identity in reproductive power of cuttings, buds, pseudova, and eggs is proved, the problem before naturalists is rather, "Why are eggs ever fertilised?" in short, "What is the use of the male sex at all?" We have animals and plants multiplying by fission, breaking up into two or more parts, each of which becomes a new individual; we have them giving rise by growth to masses of cells, which become detached or remain attached, and develop each into a new individual; and finally, we have them elaborating single large cells, which become detached and develop each into a new individual. Why should it be that in certain cases these last require the fusion of another peculiar kind of cell elements before they will develop? Some light seemed to be thrown on this matter at first, by the observation that the unfertilised ova of the bee always produce drones, and that only the fertilised produce females; but this indication of a possibly clearer insight into the matter is entirely upset by the fact, now fully established in the present work, that in some species of

* "Beiträge zur Parthenogenesis der Arthropoden." Von C. Th. E. von Siebold, Professor der Zoologie und Vergleichenden Anatomie in München. Leipzig: Engelmann, 1871.)

* Leuckart has more recently proposed, in describing the reproduction of the Cecidomyia larvæ discovered by Wagner, to limit the term "pseudovum" to such ova as those produced by larvæ, or imperfect forms; and not to apply it at all to the eggs of bees, wasps, &c. (which can develop without fertilisation), as was done by Huxley. The falsity implied in the prefix seems to make a rather stronger distinction than is desirable between any of these bodies; for they are all truly ova, though ova of various special properties.

insects and crustaceans the unfertilised ova always, or in an enormously large proportion, produce females only; whilst in the Aphides we know that they ultimately produce both males and females. Mr. Darwin has suggested the most satisfactory theory of fertilisation, in assigning to it the object of fusing two life-experiences in the progeny, which thus gains tendencies and acquires impulses from a wider area than does an unfertilised ovum, and is in so far strengthened. Conjugation of two cells, similarly formed but belonging to different individuals (as seen in Confervæ and Gregarinæ) is the simplest arrangement for obtaining this end; the only difference between this and sexual reproduction is that in the latter process one cell seeks, the other is sought; and this differentiation into active and passive, the wooer and the wooed, commencing in the simplest vegetable and animal cells, persists to the highest rank of development. Self-impregnation (if it have a real physiological existence) and parthenogenesis, have, then, to yield, as chief modes of reproduction, to digenesis, or the concurrence of two individuals; and this for one and the same reason. Perhaps the apparently anomalous facts that an animal—or plant, as the case may be—develops elaborate motile zoosperms and copulatory organs, merely to fertilise its own egg; and that other animals and plants develop peculiarly constructed large cells, of a kind apparently especially elaborated in the progress of the general evolution of life, to provide for fertilisation, yet which never are fertilised—are only to be explained as cases of persistent structures with modified function. In the former case, Monogenesis, being sufficient to or necessitated by the conditions of life, yet avails itself of the apparatus inherited from digenetic ancestors; whilst similarly, in the second case (pseudova), Monogenesis, having advantages for the particular case (and not being a common phenomenon in the group), instead of making its appearance through new organs, avails itself of the ovary inherited from digenetic progenitors. Thus the unsignificant form of an ovum (unsignificant, that is, so far as monogeny is concerned) takes the place of the more obviously appropriate bud or fisssion-product. The phenomenon of Alternation of Generations, usually treated of in connection with parthenogenesis, should by experiment on the physical conditions accompanying its variations enable us to ascertain a great deal more than is at present known of what is the signification of the differentiation of male and female sexual elements; and it is from further study of this and of True Parthenogenesis that progress in this part of physiology may be expected.

To return to Siebold's researches. The greater part of the book is devoted to an account of the parthenogenesis observable in the wasp Polistes. Leuckart first recorded in his work already mentioned, that the workers of wasps, ants, hornets, and humble bees lay eggs, which in one case he followed to the development of a larva, but of which he was not able to determine the sex. Siebold determined to study a species of Polistes common in and around Munich, which he identifies with much care, and after reference to specimens and authorities from many lands, as *Polistes gallica* var. *diadema* Latreille. He gives a minute description of the characters of the females and males; the two kinds of the former (queens and workers) being only distinguishable by size—the workers in all external characters as well as in their generative organs being merely smaller queens, and fully capable of copulation and impregnation. In the beginning of May, in Munich, the Polistes queens which were born in the previous summer and impregnated then, commence each to build a nest. No queen who built in the former year survives to build a second time, and the young queens never make use of the old nests. The Polistes are very particular in choosing a warm sunshiny spot, sheltered from wind and rain, and as such spots are not too common, a new nest is often begun near the weathered remains of an old one. Walls and trunks of trees, often at such a height as not to be easily reached, are the sites chosen. When the queen has constructed fifteen or twenty cells, she lays eggs in them, and is very hard-worked in guarding her nest and in providing food for the larvæ as they hatch. She feeds them on caterpillars and other soft insects, first removing the alimentary canal (as cooks take out the entrails of a fish), and carefully applying the morsel to the lips of each larva. This process takes some time for one "hand," and hence the first brood is longer in coming to perfection than later broods, in the rearing of which the elder progeny assist. In the middle of June the first lot make their appearance, all small females ready to assist their parent in the advancement of her enterprise. The later broods develop more rapidly and acquire larger size from being better nourished, and towards the end of June (no drones being as yet born) the females which come forth are as large as the old queen; they may, however, be easily distinguished from her by their comparative freshness of colour and wing. Great care is displayed in guarding the nest. At night the queen goes to sleep after having carefully inspected each cell, taking up her position at the hinder side of the nest. If she is disturbed in the night, she takes another survey of her house before again going to sleep. In the daytime if disturbed she makes an immediate attack on the enemy with her sting, and then flies back to her nest. She can sting several times, since the barbs on her weapon are not too long to allow of its being withdrawn. Ants are amongst the most common of the many insect enemies of these wasps, and when one ventures into the nest, the whole colony sting it to death, and immediately throw the body out. Birds are, however, not thus to be got rid of, and destroy immense numbers of the nests, so that Siebold was obliged to protect those he wished to study with nets. The members of one nest are not allowed to remain in another, if by chance a stranger comes in she is hustled out at once by the wasps near the entrance. Siebold convinced himself of this by painting the thorax of a number of Polistes belonging to different nests with different colours. Only late in the year, when the wasps seem to be getting careless or tired of their incessant work did he find that one or two had got mixed in certain colonies, to which they did not rightly belong. Although there is this sharp discrimination of individuals, yet it was found that by substituting one nest for another whilst the queen was away, she could often be deceived, so as to make her enter upon the possession of the substituted nest as though it were her own. Siebold found this a very useful plan when he wanted to change the position or locality of a nest so as to bring it into a safer or more accessible spot, or when a nest which he had been observing was by some accident deserted, or when a nest in a favourable position was less forward in the development of its larvæ than one less favourably situated. By making the nests moveable, and substituting the one for the other in the absence of the queen, he was able to save himself much trouble and loss. The nests were made moveable by removing them from their original support and firmly fixing them to boards which were then hung up in the original position. The queens were very anxious after this operation had been performed, investigating with great care the strength of the support and the cord by which the board was hung, and sometimes adding to it themselves additional strength. By degrees such moveable nests could be lowered a little bit each day from an inconveniently high position, or taking the nest in the night under a cover whilst all the wasps were in it, it could be removed from a distant locality to the Professor's garden; in such cases a certain proportion always came to grief by the desertion of the colony; and the queen was then sometimes found at work on the old site constructing a new nest. Although strangers are not admitted in a well-regulated Polistes nest, yet by carelessness or desertion the brood of one colony will sometimes be exposed to the attacks of the workers of another, who then make use of the unfortunate larvæ to feed their own young. It frequently happens that workers who have once indulged in this kind of thing, become what are called "robber wasps," utterly demoralised, and actually undo the whole labour of a colony by dragging out the grubs which they were lately so carefully tending in common with their fellows, to feed the still younger larvæ. When this condition of things has once begun in a colony it soon goes to ruin, and hence it is necessary to destroy any deserted Polistes nests in the neighbourhood of those under observation, lest by entering the former the members of the latter should get the bad habit of pulling grubs out of their cells, and proceed to do the same in their own nests.

The rain is a very constant source of destruction to Polistes colonies, drowning the young by saturating the cells with moisture. Light rain will not, however, do much harm. Whilst Siebold was endeavouring to remove some of the water from a nest which had been drenched in a shower, he was astonished to find the wasps themselves already busy at the work, putting their heads into the cells, sucking up the water, then passing to the edge of the nest and spitting out the fluid. In this way they are able to get rid of the effects of a wetting if it is not very severe. Though the Polistes feed their young exclusively with animal food, they yet appear to collect a sweet fluid which Siebold found in some cells, and which he thinks the workers take for their own enjoyment, since they were seen entering such cells and apparently sucking at the contents—in fact, taking a little refreshment in the intervals of their labour.

The development of the grub is carefully described by the author, and a "pseudo-nymph" stage is recognised intervening between the nymph and the pupa. The perfect insect bites off the lid of its cell, and comes out with perfect wings, deposits first of all a drop of urinary excretion, and makes a trial flight, then returns to take part in the labours of the colony. The cell is often used again for another egg. The first drones make their appearance with the beginning of July, an important fact for Siebold's experiments, for if the nest is to be used at all now is the latest moment; they have to be killed off, and all the remaining larvæ and pupæ destroyed—in order to secure a colony consisting solely of virgins. The drones play a pitiable part in the nest—sneaking about in the empty cells and behind the comb, not till the month of August are their generative organs fully developed, and then they make their first approaches to the females. Their proceedings are minutely described, and it appears that they meet with many rebuffs from the busily-occupied workers of the hive, and that it is outside at a distance from the nest that their addresses are at length accepted by those of the larger females destined to become queens. Not all the large females appear to have this destiny, and none appear to leave the nest until all the brood has been brought through, when (about the beginning of October) the nests become deserted. Only a few flattened old virgin wasps remain, who are killed off by the frosts, whilst the young queens have married and sought out for themselves winter quarters. Siebold distinguished black-eyed and green-eyed drones, and speculates upon the signification of this difference.

Having ascertained these and other matters relating to the Polistes in far greater detail than we have been able here to indicate them, Siebold was prepared to make his experiment. In the nest from which he wanted an answer to these questions, "can unfertilised Polistes females lay eggs which will develop?" and if so, "of what sex will the parthenogenetically produced progeny be?" he proceeded to destroy the queen and all the eggs, larvæ, and pupæ in the cells with the greatest care as late as possible in the season, so as to have as large a colony as possible left, the limit of the time being given by the date of the appearance of the first drone. The queens thus taken were used for careful histological study of the generative organs, and since in all cases Siebold found the *receptaculum seminis* filled with moving spermatozoa, he was able to feel assured that he had really removed the queen in each case. We will merely direct the attention of those interested in histology to the minute description here given of the ovary, which in the main agrees with Leydig's, and of the *receptaculum seminis*, which in opposition to Leydig, on account of its nerve supply, Siebold holds to be contractile. After waiting some days Siebold had the gratification of finding the first eggs laid in the cells of several of the nests from which he had removed queen, eggs, and larvæ, and he felt convinced that they could only have been laid by the small virgin workers who alone tenanted the combs. The whole affairs of the colonies proceeded just as well as when the queens were there, and the virgins watched and worked with the same assiduity as had done their queen-mother. In some cases Siebold actually saw a worker deposit an egg, and such egg-laying workers, when anatomically tested, showed, firstly, in the presence of *corpora lutea* (the precise signification of which the investigator had ascertained by his histological studies of the ovary) that eggs had been extruded, and, secondly, in the complete absence of spermatozoa from the *receptaculum seminis*, that the insect was a virgin. Out of a hundred nests which he had begun to observe in one season, and out of one hundred and fifty in another, only some twenty or so in each case came through all the long series of accidents from weather, insects, birds, &c., to which they were necessarily exposed, and some of those which promised the best results and had cost the most pains came to a bad end in the very last days of the research. In order to determine the sex of the wasps born from the eggs laid by the parthenogenetic females, Siebold in most cases only allowed the development to proceed sufficiently far to enable him to recognise the sex by anatomical investigation. The dried skin, however, of such grubs as were found dead in their cells afforded sufficient evidence of the sex. In all cases the parthenogenetic offspring was without exception male. The queen-wasps as we have mentioned also late in the season lay eggs which produce drones, which are easily distinguished from the drones parthenogenetically produced by their larger size. It occurred to Siebold when he first ascertained that the queens produce drones that such drones might visit his virgin colonies, and thus his whole experiment be invalidated. He was, however, reassured on this point by a nearer acquaintance with the Polistes; for such drones are not born till later than the period at which his small females laid their eggs, the former event taking place at the end of July, the latter at the beginning; and, furthermore, as we have noticed above, it is not till still later (August), when the experimental cells were long since all occupied with eggs, that the power and desire of sexual activity comes to these drones.

E. R. LANKESTER

(*To be continued.*)

ON INSTINCT[1]

WITH regard to instinct we have yet to ascertain the facts. Do the animals exhibit untaught skill and innate knowledge? May not the supposed examples of instinct be after all but the results of rapid learning and imitation? The controversy on this subject has been chiefly concerning the perceptions of distance and direction by the eye and the ear. Against the instinctive character of these perceptions it is argued that, as distance means movement, locomotion, the very essence of the idea is such as cannot be taken in by the eye or ear; that what the varying sensations of sight and hearing correspond to, must be got at by moving over the ground by experience. The results, however, of experiments on chickens were wholly in favour of the instinctive nature of these perceptions. Chickens kept in a state of blindness by various devices, from one to three days, when placed in the light under a set of carefully prepared conditions, gave conclusive evidence against the theory that the perceptions of distance and direction by the eye are the result of associations formed in the experience of each individual life. Often, at the end of two minutes, they followed with their eyes the movements of crawling insects, turning their heads with all the precision of an old fowl. In from two to fifteen minutes they pecked at some object, showing not merely an instinctive perception of distance, but an original ability to measure distance with something like infallible accuracy. If beyond the reach of their necks, they walked or ran up to the object of their pursuit, and may be said to have invariably struck it, never missing by more than a hair's-breadth; this, too, when the specks at which they struck were no bigger than the smallest visible dot of an *i*. To seize between the points of the mandible at the very instant of striking seemed a more difficult operation. Though at times they seized and swallowed an insect at the first attempt, more frequently they struck five or six times, lifting once or twice before they succeeded in swallowing their first food. To take, by way of illustration, the observations on a single case a little in detail:—A chicken at the end of six minutes, after having its eyes unveiled, followed with its head the movements of a fly twelve inches distant; at ten minutes, the fly coming within reach of its neck, was seized and swallowed at the first stroke; at the end of twenty minutes it had not attempted to walk a step. It was then placed on rough ground within sight and call of a hen, with chickens of its own age. After standing chirping for about a minute, it went straight towards the hen, displaying as keen a perception of the qualities of the outer world as it was ever likely to possess in after life. It never required to knock its head against a stone to discover that there was "no road that way." It leaped over the smaller obstacles that lay in its path, and ran round the larger, reaching the mother in as nearly a straight line as the nature of the ground would permit. Thus it would seem that, prior to experience, the eye—at least the eye of the chicken—perceives the primary qualities of the external world, all arguments of the purely analytical school of psychology to the contrary, notwithstanding.

Not less decisive were experiments on hearing. Chickens hatched and kept in the dark for a day or two, on being placed in the light nine or ten feet from a box in which a brooding hen was concealed, after standing chirping for a minute or two, uniformly set off straight to the box in answer to the call of the hen which they had never seen and never before heard. This they did struggling through grass and over rough ground, when not able to stand steadily on their legs. Again, chickens that from the first had been denied the use of their eyes by having hoods drawn over their heads while yet in the shell, were while thus blind made the subject of experiment. These, when left to themselves, seldom made a forward step, their movements were round and round and back-

[1] Paper read before the British Association, Section D (Department of Zoology and Botany), August 19th, by D. A. Spalding.

ward; but when placed within five or six feet of the hen mother, they, in answer to her call, became much more lively, began to make little forward journeys, and soon followed her by sound alone, though of course blindly. Another experiment consisted in rendering chickens deaf for a time by sealing their ears with several folds of gum paper before they had escaped from the shell. These, on having their ears opened when two or three days old, and being placed within call of the mother concealed in a box or on the other side of a door, after turning round a few times ran straight to the spot whence came the first sound they had ever heard. Clearly, of these chickens it cannot be said that sounds were to them at first but meaningless sensations.

One or two observations favourable to the opinion that animals have an instinctive knowledge of their enemies may be taken for what they are worth. When twelve days old one of my little *protégés* running about beside me, gave the peculiar chirp whereby they announce the approach of danger. On looking up, a sparrow-hawk was seen hovering at a great height over head. Again, a young hawk was made to fly over a hen with her first brood of chickens, then about a week old. In the twinkling of an eye most of the chickens were hid among grass and bushes. And scarcely had the hawk touched the ground, about twelve yards from where the hen had been sitting, when she fell upon it, and would soon have killed it outright. A young turkey gave even more striking evidence. When ten days old it heard the voice of the hawk for the first time, and just beside it. Like an arrow from the bow it darted off in the opposite direction, and crouched in a corner, remained for ten minutes motionless and dumb with fear. Out of a vast number of experiments with chickens and bees, though the results were not uniform, yet in the great majority of instances the chickens gave evidence of instinctive fear of these sting-bearing insects.

But to return to examples of instinctive skill and knowledge, concerning which I think no doubt can remain, a very useful instinct may be observed in the early attention that chickens pay to their toilet. As soon as they can hold up their heads, when only from four to five hours old, they attempt dressing at their wings, that, too, when they have been denied the use of their eyes. Another incontestable case of instinct may be seen in the art of scraping in search of food. Without any opportunities of imitation, chickens begin to scrape when from two to six days old. Most frequently the circumstances are suggestive; at other times, however, the first attempt, which generally consists of a sort of nervous dance, was made on a smooth table. The unacquired dexterity shown in the capture of insects is very remarkable. A duckling one day old, on being placed in the open air for the first time, almost immediately snapped at, and caught, a fly on the wing. Still more interesting is the instructive art of catching flies peculiar to the turkey. When not a day and a half old I observed a young turkey, which I had adopted while yet in the shell, pointing its beak slowly and deliberately at flies and other small insects without actually pecking at them. In doing this its head could be seen to shake like a hand that is attempted to be held steady by a visible effort. This I recorded when I did not understand its meaning. For it was not until afterwards that I observe l a turkey, when it sees a fly settled on any object, steals on the unwary insect with slow and measured step, and, when sufficiently near, advances its head very slowly and steadily until within reach of its prey, which is then seized by a sudden dart. In still further confirmation of the opinion that such wonderful examples of dexterity and cunning are instinctive and not acquired, may be adduced the significant fact that the individuals of each species have little capacity to learn anything not found in the habits of their progenitors. A chicken was made, from the first and for several months, the sole companion of a young turkey. Yet it never showed the slightest tendency to adopt the admirable art of catching flies that it saw practised before its eyes every hour of the day.

The only theory in explanation of the phenomena of instinct that has an air of science about it, is the doctrine of Inherited Association. Instinct in the present generation of animals is the product of the accumulated experiences of past generations. Great difficulty, however, is felt by many in conceiving how anything so impalpable as fear at the sight of a bee should be transmitted from parent to offspring. It should be remembered, however, that the permanence of such associations in the history of an individual life depends on the corresponding impress given to the nervous organisation. We cannot, strictly speaking, experience any individual act of consciousness twice over; but as, by pulling the bell-cord to-day we can, in the language of ordinary discourse, produce the same sound we heard yesterday, so, while the established connections among the nerves and nerve-centres hold, we are enabled to live our experiences over again. Now, why should not those modifications of brain-matter, that, enduring from hour to hour and from day to day, render acquisition possible, be, like any other physical peculiarity, transmitted from parent to offsp ring? That they are so transmitted is all but proved by the facts of instinct, while these, in their turn, receive their only rational explanation in this theory of Inherited Association.

ON THE TREE-FERNS OF THE COAL MEASURES, AND THEIR AFFINITIES WITH EXISTING FORMS *

LINDLEY and Hutton describe two species of tree-ferns from the Coal Measures, both from the Bath Coal-field. I have been able to add eight species hitherto undescribed, chiefly through the assistance of Mr. J. M'Murtrie, of Radstock. These belong to three groups, which are remarkably distinguished by peculiarities in the structure of the stems. Two of the groups belong to living forms, while the third is extinct, being confined to Palæozoic formations. *Caulopteris* and *Tubicaulis* belong to the same type as the living ferns which possess stems, including under this term the humble stems (falsely called rhizomes) of many of our British species, as well as the arborescent ferns of warmer regions; and excluding the rhizomatous forms like *Pteris*, *Polypodium*, and *Hymenophyllum*. In all these stems we have a central medulla, surrounded by a continuous vascular cylinder penetrated regularly by meshes, from the margins of which the vascular bundle or bundles to the fronds are given off, and through which the parenchyma of the medulla is continuous with that of the stipes. In most tree-ferns the medullary axis is larger, and the bases of the stipes decay down to the circumference of the stem, but in *Osmunda* the persistent bases of the stipes permanently clothe the small vascular cylinder which encloses a slender pith. To this latter form belongs the stipe with a dumbell-shaped vascular bundle, separate specimens of which I have obtained from the Coal Measures. These have been described both on the Continent and in this country, under the name of *Zygopteris*, but they belong to Cotta's genus *Tubicaulis*: and they are very closely allied to a group of fern stems which I have already placed together under the name of *Chelepteris*. The stem structure of the common tree-fern is represented by the genus *Caulopteris*, of which I have six species of carboniferous age.

The third and extinct group is represented by Corda's genus *Stemmatopteris*, only now known to be British, and by *Psaronius*, which is, however, not a separate generic form, but only the internal structure of the stems of which Corda's genus is the external aspect. The chief characters of *Psaronius* have been drawn from the structure of the aërial roots which invest the stem, from which, indeed, the generic designation was derived; while the structure of the stem itself has been overlooked. But this is really of the first importance, as will appear from the following description which I have been able to make from a finely preserved specimen of an undescribed species in the British Museum, and from the figures of Cotta and Corda. The circumference of the stem was composed of a continuous envelope of indurated tissue; within this there were perpendicular tracts of vascular tissue never penetrated by any mesh. Between these tracts the leaves were given off in perpendicular series, the large single leaf bundles coming right out from the central parenchyma, where they existed as well-formed bundles, filling up more or less completely the medullary cavity. In one form (*Zippea*) the leaves are opposite, and the great proportion of the circumference of the stem is made up of the persistent and common vascular tissue; in others (species of *Psaronius*) the permanent elements of the stem consists of three, four, six or more perpendicular tracts.

The first two groups are analogous in the arrangement of the parts of their stems to that which exists in the first year's growth of a dicotyledon. In both there is a parenchymatous medulla surrounded by a continuous vascular cylinder, which is perforated in regular manner by meshes for the passage out of the vascular elements of the appendages. The stems of the third group have a structure analogous to that which is found in the stems of monocotyledons, for in both we have the vascular

* Paper read before the British Association at Brighton in Section C, Aug. 19, by W. Carruthers, F.R.S.

bundles of the appendages existing in the parenchymatous axis, and passing out independently of any closed cylinder. The permanent elements of the circumference of these stems of *Psaronius* are, however, without any analogue in the monocotyledonous stems.

There seems, then, good reason for establishing two groups of ferns, with differences characteristic of their stems, comparable to those which distinguish the stems of monoctyledons from those of dicotyledons. But the caution I have always insisted on in dealing only with vegetative organs is specially required here, for I have discovered, I believe, the fruiting fronds of one species of this group of plants. With the Bath specimens of *Stemmatopteris insignis*, Corda, as well as with those found on the Continent, the fronds of *Pecopteris arborescens* are always associated. It is the only fern found with some of the Bath specimens. It is also to be observed that the bases of the stipes correspond with the size of the leaf scars on the stems. These facts are not absolutely sufficient for the correlation of the fronds with the stem, but they are the best evidence for this that we can expect in fossil botany short of actual organic union. Now the fruit of *Pecopteris arborescens* is so near to that of *Cyathea* that I can find no characters whereby they can be separated. Our classification based on the stems must of course yield to that derived from the organs of fructification, and our group of ferns, instead of being made into a new order, as would be the case by some who publish on fossil botany, must be grouped with a tribe of recent *Polypodiaceæ.*

It may seem that this is a forced and arbitrary grouping together of plants that in some important characters so remarkably differ; and so it is undoubtedly to those who, with rash confidence, generalise on the systematic position of plants from stem structure alone. But what can such objectors say to the practice of placing in close proximity plants that are beyond question nearly related to each other in all essential characters, though some have caudices, while others possess rhizomes; yet these two forms of stems are yet more widely separated from each other than the extinct palæozoic group is from the recent forms.

SCIENTIFIC SERIALS

THE double number (Nos. 5 and 6) of the *Annalen der Chemie und Pharmacie* commences with a paper by Carl Grunzweig, on "Butyric acid from different sources." He prepared the perfectly pure normal and isobutyric acids and their salts, and examined their properties very carefully; he then examined butyric acid as obtained from butter, which he finds to be normal butyric acid, and the acid from the oxidation of conine and that from the carob, or St. John's bread, are also the normal acid.—Von Schneider contributes a long paper upon pollen and wax formation; which is followed by a second contribution by Kachler on the compounds of the camphor group. He has accurately examined into the properties of campholic acid and some of its salts, and also into the action of bromine and phosphoric chloride on that body. The action of bromine is to oxidize the acid, forming oxycamphoric anhydride, hydrobromic acid being produced in quantity. He has also examined camphinic acid.—Weselsky follows, with an important paper on the azocompounds of resorcin, in the theoretical parts of which some most elaborate graphic formulæ are brought to life.—Liebermann and Chojnacki have again examined rufiopin, which was first obtained by Anderson from opianic acid. The authors' researches show that it belongs to the anthracene group, as by the action of zinc powder at a high temperature this hydrocarbon can be obtained from it. It therefore belongs to the same series to which the colouring matters alizarin and purpurin belong, being the next higher body in the series to purpurin.—Dittmar and Kekulé contribute a paper on an aromatic glycollic acid. The starting point for the production of this body is toluylic acid, which is acted on by bromine, and the resulting bromo-compound again acted on by barytic hydrate. The oxymethylphenylformic acid obtained forms small plates or needles as crystallised from water.—Amato has endeavoured to obtain dicyanacetic acid by treating dichloracetic ether with potassic cyanide. He has not succeeded in obtaining the acid, but seems to have produced a body which has resulted from the decomposition of dicyanacetic ether with two molecules of water.—This number contains 18 original papers, several of which, however, are translations from foreign journals.

Annalen der Chemie und Pharmacie, No. 7.—This number commences with a lengthy article on chrysanisic acid, by H. Salkowski. This acid was discovered by Cahours, in the year 1849, and has been experimented on by many chemists. Kekulé has proved that it has the constitution of a dinitrobenzoic acid, of the formula $C_6H_2(NO_2)_2(NH_2)CO_2H$. Dr. Salkowski has now made some experiments on this and its derivatives. Chrysanisic acid is obtained by treating anisol with nitric acid of 1·4 sp. gr., which converts it into nitro-anisic acid; this latter body is then treated with red fuming nitric acid, the product of which action is submitted to the action of ammonia, which yields ammonic chrysanisate. This crystallises easily, and the acid can be obtained from it in the pure state without difficulty. The author has prepared a number of the salts of this acid, which are here described in detail. By the action of hydrochloric acid and tin on chrysanisic acid, triamidobenzoic acid is produced; this acid, on heating, is decomposed into triamidobenzol and carbonic anhydride. Triamidobenzoic acid appears to possess both acid and basic properties, as it can form salts with both strong acids and bases. Both classes of salts have been prepared and are described. Thus triamidobenzoic acid forms a compound with two molecules of hydrochloric acid, and also with one of sulphuric acid. Chrysanisic acid, by the action of strong hydrochloric acid, yields trichlorobenzoic acid; and by the action of nitrous acid, dinitroparoxybenzoic acid is obtained. From this body the monethyl and diethyl derivatives can be prepared.—An interesting paper on the influence of potassium and sodium salts on fermentation, by C. Knapp, follows. He finds that both potassium and sodium salts, more especially the chlorides which he has worked with, exert a hastening influence on alcoholic fermentation, the potassium chloride being the better of the two. He also finds that a small percentage of the salt acts more vigorously than a large one.—Richard Maly contributes two papers on the colouring matter of bile, &c.; and Liebermann and Van Dorf follow with an exhaustive paper on the cochineal colouring matters.—The next paper is by Beilstein and Kohlberg, on isomerism in the benzol series. This is the fourteenth contribution from these authors on this wide subject, the present treating on cinnamic acid and metanitrobenzoic acid.

Bulletin de l'Académie Impériale des Sciences de St. Petersburg, t. xvii., No. 1.—This number contains an important paper by Prof. Kamintzin on the employment of inorganic salts as a means for studying the development of lower organisms containing chlorophyll. He studied the action of salt solutions of specified composition and various concentration on forms of algæ, chiefly *Chlorococcus infusionum* and *Protococcus viridis*. The algæ and higher cryptogams bear a higher concentration than the phanerogams. In a 3-per-cent. solution they develop vigorously; in solutions under two per cent. zoospores were produced, these again forming zoosporangia; but where the concentration was higher the development was by division into round motionless bodies. Prof. Kamintzin also studies the development of individual varieties, owing to internal causes, the external conditions remaining the same, thus extending to the lower plant forms the class of observations made by Darwin in the animal kingdom. The plasticity of various forms of algæ under the above treatment is fully shown and illustrated.—O. Grimm describes the integumental structure of one of the Crinoidea, the *Comatula mediterranea*. Certain small canals observed in an internal fibrous layer he considers to be organs of respiration, the water entering by small openings on the external surface.—There are two short papers by Dr. Levschin on the development of osseous tissue and the structure of terminal blood-vessels in the bones of the newly-born. In a paper by Dr. Gruber, the dissection of a hand having two thumbs is described, and compared with three other cases of the same kind.

SOCIETIES AND ACADEMIES

LONDON

Royal Microscopical Society, October 2.—Dr. Hudson read a paper "On *Pedalion mira*," and exhibited specimens under the society's microscopes. This curious little animal was discovered last year by Dr. Hudson near Bristol, and a figure and short description of it is given in the *Monthly Microscopical Journal* for September 1871.—The President read a paper "On the Development of the Skull of the Crow."—Dr. Woodward sent a series of photographs for exhibition, showing the resolution of Nobert's 19th band with a Tolles lens, which was not properly corrected for chromatic errors.

Academy of Natural Sciences of Philadelphia, February 27.—"On an Extinct Whale from California," by Prof. E. D. Cope. George Davidson, of the United States Coast Survey, recently presented the Museum of the Academy of Natural Sciences, the proximal portion of the left ramus of the mandible of a whalebone whale. The specimen was found in digging a well at San Diego, on the coast, in the southern part of the State, at a depth of seventy-four feet below the surface, July 27, 1871. The angle and condyle are broken from the specimen, and the distal extremity was not preserved. It possessed a coronoid process, the apex of which has been lost. The inner face is plane, somewhat convex above, behind the basis of the corodoid process. Anteriorly it becomes more convex, the surface turning inwards to the superior and inferior margins. The exterior face is convex, so that at the posterior foramen its diameter above the middle is greater than that below the middle. The inferior outline, from below the coronoid process to below the last external foramen, is straight, not decurved. It is obtuse most of this distance, but becomes narrowed at the anterior point. The superior margin is obtuse anteriorly, narrowed acute for ten inches anterior to the coronoid process; it is not truncate anteriorly. The internal foramina are large, and form a series below the upper margin, without distinct groove. The external foraminal series terminates much anterior to the interior, that is, the last external is opposite the sixth from behind of the inner row. There is no internal Meckelian groove. The Meckelian cavity of the ramus is large behind the coronoid, but small and in the upper part of the ramus at the last exterior foramen. The dental foramen is large, and above the base of the Meckelian cavity, so that its inner wall descends to the floor of the latter. Below the base of the coronoid the inferior part of the ramus is rounded, but narrower than at the dental foramen. The presence of coronoid process indicates that the present species was a finner, and allied to *Balænoptera*. Though there are no vertebræ or other elements to determine its reference to this genus or its ally *Eschrichtius*, it may be proper to refer it provisionally to the latter genus, since so many of its allies on the Atlantic coast formations have been found to be referable to it. This course is still more appropriate from the fact that the strata of tertiary age near San Diego are reported to be of miocene age, the same in which the eastern *Eschrichtii* have been found. As to its specific characters, these differ entirely from those of the latter. The ramus lacks the decurvature of most of them. In size, it approaches nearest the *E. polyporus*, Cope, and *E. priscus*, Leidy. It is much less convex externally than the latter. The exterior series of pores does not extend so far posteriorly as in *E. polyporus*, and the dental foramen has a superior position besides other differences. Size that of *E. priscus*. This whale, when living, probably attained a length of about forty feet.

PARIS

Academy of Sciences, September 23.—M. Faye, president. —The following gentlemen, members of the International Metric Commission, were present at the meeting, to which they were presented by the president:—Baron de Wrede, Sweden; M. Broch, Norway; M. de Jolly, Bavaria; MM. Stas and Maus, Belgium; General Ricci and M. Govi, Italy; Father Secchi, Pontifical States; M. Hirsch, Switzerland; M. Struve, Russia; Mr. Hilgard, U.S. America. General Fligelly, of the Austro-Hungarian Empire, member of the International Geodesical Committee, was also presented.—M. P. Favre read a note on the origin of the heat developed when the motion of a metallic disc is retarded by the influence of an electro-magnet. The author had stated in a paper read on the 11th September, 1871, that this heat is due to the "work furnished by the operator," and that the magnet expends no energy in producing it, the same effects being produced by permanent magnets which do not expend anything. He has repeated his experiments with apparatus of very great power, and finds all his statements confirmed.—M. Yvon Villarceau then presented the elements and ephemerides of the planet 103, Hera, by M. Leveau, which was followed by the "Results of a search into the characteristics of the elementary and quartic systems," by M. H. G. Zeuthen, presented by M. Chasles. The President then presented a note of M. A. Lallemand, on the "Polarisation and Fluorescence of the Atmosphere." The author attributes the blue colour of the atmosphere to "hypochromatic fluorescence," which he explains as fluorescence accompanied by change of refrangibility due to the partial absorption of the ultra-violet rays. The next paper was by M. E. Duvillier on "A new method of preparing Chromic Acid." The author mixes into a cream 100 parts of baric chromate, and 100 parts of water, then adds 140 parts of nitric acid of 40° Reaumur, boils for 10 minutes, filters, and allows the baric nitrate to crystallise out, after which the liquid is concentrated to about the bulk of the acid employed, which removes the last traces of baric nitrate, and the chromic acid crystallises after the expulsion of the excess of nitric acid by repeated evaporations.—MM. P. Champion and H. Pellet followed with a paper of great interest, on "The Vibratory Movements produced by Explosive Compounds." The authors, starting from an observation by Mr. Abel, that whilst a small quantity of fulminating mercury exploded in gun-cotton caused its instant violent explosion, the much more violent explosive iodide of nitrogen produced no effect, proceeded to investigate these two bodies with a chromatic scale of sensitive flames, arranged as recommended by Messrs. Tyndall and Schaffgotsch, when they found that the fulminate produced effects corresponding to the notes, la, do, mi, fa, sol. The iodide of nitrogen, however, produced no effect. When the explosives were brought as close as 3·50 metres to the flames, the iodide of nitrogen affected the upper notes, while the same weight of fulminate acted on the whole gamut. The weights used were in each case ·03 grm., and it was not till the iodide of nitrogen had been increased to ·2 grm. that it produced effects equal to the fulminate.—M. Duchartre then presented a note by M. J. Duval-Jouve, "On the diaphragms and fibro-vascular nets of the leaves and stalks of certain Monocotyledons;" which was followed by a continuation of M. Stan. Meunier's paper, "Observations on the Vein Action in Meteorites;" after which M. F. Garrigou read a paper on "The alluvial gravels of the plains of the Garonne at the village of Portet, near Toulouse."—A note of M. Bonvier, presented by M. Bouley, came next, claiming priority of discovery for M. G. B. Pelletan of the "Method of removal of liquids from the closed cavities of the body by means of aspiration," described by M. J. Guérin.—M. Hartsen sent a note relative to an alkaloid extracted from Isopyrum.—M. Dumas presented an analysis of the documents sent to the Phylloxera Commission by two of its delegates, MM. Duclaux and Maxime Cornu; and a note from M. J. Capello, of Lisbon, on the aspect of the sun about the 9th of August closed the meeting.

BOOKS RECEIVED.

ENGLISH.—Elementary Geology: J. C. Ward (Trübner and Co.).—An Elementary Treatise on Geometrical Optics: W. S. Aldis (Deighton and Bell).—Elementary Treatise on Natural Philosophy: Deschanel. Part 4 (Blackie and Sons).

AMERICAN.—Papers relating to the Transit of Venus in 1874, prepared under the direction of the Commission authorised by Congress. Part 1.

CANON KINGSLEY ON PHYSIOLOGICAL TRAINING

THE recent address of Canon Kingsley, as President of the Birmingham and Midland Institute, has struck a key-note which has been widely responded to. Not that he has said anything new; but truths are none the less true for being world-old. It is something to find a man of Mr. Kingsley's popularity and influence insisting on the need of physical and scientific culture; it is more that the utterance should be made to a crowded audience at one of our great centres of industry; it is still more that our daily and weekly papers should at length discern the importance of that which a select few have long been preaching in vain. We can, however, only refer to some of the more important points on which the lecturer touched, referring our readers to the report *in extenso*, in the *Birmingham Daily Post*.

The following admirable advice was given to the younger students among the assembly:—

"Let me warn you that none of you will profit by any lectures, unless you study at home the text-books recommended by the lecturer. You will be otherwise little wiser than a man who should purpose to learn arithmetic by listening to talk about the proportion of numbers without doing sums himself. You will not teach yourselves even the attitude necessary for your subject—the attitude of mind, by which the facts were discovered, by which they must be understood, by which they must be turned to use. You will not acquire, by mere lecture-hearing, the inductive habit of mind which arranges and judges of facts. Still less, therefore, will you acquire the deductive habit of mind which makes use of facts practically after they have been arranged and judged; and the lecturer will be to you but a sort of singer, a player upon a fiddle, who makes for you pleasant and interesting noises for a while, producing mere impressions which never sink into the intellect, but merely touch the emotions, to run off them at the first distraction, like water off a duck's back. Therefore, remember this for yourselves in this age of periodical literature and literature made easy: we are all too apt to forget that what we did you must do, if you wish to be as good men as we, viz., work for yourselves, as we did; that good lectures, like good reviews, are not meant to see for you, but to teach you to use your own eyes; and those you must use at home in hard study, personal study, continuous study—and study, too, rather of one subject than of many subjects, in order that, by learning how to learn one thing thoroughly, you may learn how to learn anything and everything else in its turn."

After referring to the evils of war in producing the exactly opposite results to those brought about by the process of Natural Selection, by the Destruction of the Fittest, the lecturer thus proceeds:—

"Peace, prosperous, civilised, humane, such as we enjoy now, is fraught with the very same dangers. In the first place tens of thousands—who knows it not?—lead sedentary lives, stooping, asphyxiated, employing as small a fraction of their bodies as of their minds; and that such a life must tell upon their offspring—it may be for generations to come—what medical man does not know full well? And all this in dwellings, workshops, mines, and what not, where the influences, the very atmosphere of which tend to unhealth, and not to health; to drunkenness as a solace under the feeling of unhealth and all unhealth's depressing influences. But now—and this is one of the most fearful problems with which modern civilisation has to deal—we interfere with natural selection from conscientious care of life just as much as war itself does. War kills the most fit to live. We spend vast energies in saving alive those who, looking at them from a merely physical point of view, are most fit to die. Everything which tends to make it more easy to live—every sanitary reform, prevention of pestilence, medical discovery, amelioration of climate, drainage of soil, improvement in dwelling-houses, workhouses, prisons, every reformatory school, every hospital, every cure of drunkenness, every influence, in short, which has (so I am told) increased the average length of life in these islands since the first establishment of life insurance offices, 150 years ago, by nearly one-third—every influence of this kind, I say, saves persons alive who would otherwise have died; and the great majority of these persons, even in surgical cases and cases of zymotic disease, will be those of the least resisting power, the weaklier; thus preserved to produce, in their turn, a weaklier progeny. And what will you do with it? Do I say that we ought not to save them if we can? God forbid! The weakling, the diseased—whether infant or adult—is there on earth a British citizen! no more responsible for its own weakliness than for its own existence. Society—that is, in plain English, you and I and our ancestors—are responsible for both; and we must fulfil the duty, and keep the weakly person in life, and if we can, heal, strengthen, develop to the utmost, and make the best of that which 'Fate and our own deservings' have given us to deal with."

The practical application of this teaching was then pointed out:—

"And so as to the laws of personal health;—enough, and more than enough, is known already to be applied safely and easily by any adult, however unlearned, to the preservation, not only of his own health, but of that of his children; the value of healthy habitations, of personal cleanliness, of pure air, pure water, of various kinds of food, as tending to make bone, fat, or muscle, provided only that the food be unadulterated—and you might stop the adulteration in Birmingham in a month or week if you chose. . . . Have you not here, ready made to your hands, an engine for extending sound knowledge of the laws of health? In a great manufacturing district, which specially needs those laws to be known and obeyed, you have this Institution always teaching physical science. It would not, therefore, go beyond its province in teaching the physical science of health. It teaches, happily, a people specially intelligent, specially accustomed by their businesses to the application of scientific laws. To them, therefore, the application of any fresh physical laws would have nothing strange in it. They have already, I doubt not, that inductive habit of mind which is the groundwork of all rational understanding or action. They would not turn the deaf or contemptuous ear with which the stupid, the savage, the superstitious, receive the revelations of Nature's mysteries. Surely, with such a people to work upon, it were well worth your while to expand your classes of physiology, and give one or more of them a practical turn in the direction of practical health. Your Animal Physiology Class is, I doubt not, a sound and useful one. It cannot well be otherwise, while its text-book is Prof. Huxley's Elementary Lessons; and I am glad to see that your learned lecturer is about to confine himself, for the present at least, to the physiology of the animal most abundant in, and most important to, Birmingham, namely, man. Twenty lectures are announced in your programme dealing with the tissues of the body, their structure and uses, circulation of the blood, respiration, chemical changes in air respired, amount breathed, digestion, nature of food, absorption, secretion, functions of the nervous system. Now, this is as it should be. It is admirable. Teaching of

this kind ought, and will in some more civilised society, be held as a necessary element in the school course of every child; just as important as reading, writing, and arithmetic; and is the most necessary and most important branch of technical education, namely, the act of keeping yourselves alive and well. But you can hardly stop short there. After you have taught the conditions of health, should you not teach also somewhat of the causes of disease—of those diseases, especially, which tend to lower wholesale the physical condition of dwellers in towns, exposed to the unhealthy influences of an artificial life? Should you not teach young men and women something of the causes of pestilence, of zymotic disease, and of scrofula, consumption, cerebral derangement, dipsomania, and such like? Should you not show them the value of pure air, pure water, unadulterated food, wholesome dwellings? We want set up in the centre of large towns—it will not come yet, but it will come some day—a statue to the goddess of purity. Is there one of them, man or woman, who would not be the safer himself and the more useful to his neighbours if he had acquired some sound notions about those questions of drainage on which their lives and the lives of their children may any day depend. I say women as well as men; ay, women even more than men. For it is the women who have the ordering of the household, the women who have the bringing up of the children. And if any say, as they have a right to say, 'But these are subjects which can hardly be taught to young women in public lectures,' I reply, 'Of course, unless they are taught by women—women, of course, duly educated and legally qualified.' Let them tell young women what every young woman ought to know, and what her parents will very properly object to her hearing from men, or in the company of men. This is one of the main reasons why I have for twenty years past, and shall as long as I live, advocated the training of ladies for the medical profession. And now, I am seeing the common sense of England, and, indeed, of every civilised nation, coming round to that which seemed to me, when I first conceived of it, a dream too chimerical to be cherished, save in secret; and I trust soon to see a supply of lady-doctors, sufficient to fulfil that old dream of mine, and to establish in every great town of these islands health classes for women.

"Now why should not your Institute, which has taken the initiative in so many useful enterprises, take the initiative in this too? It is already a school of many things. Why should it not be also a school of health—a school of sanitary science? Why should it not send forth year by year more and more young men and women, taught not only to take care of their own health and that of their families, but to exercise moral influence in the same direction over their fellow-citizens—to advocate as one simple, and yet most necessary and important, good deed, the teaching of the laws of health in every school, from the highest to the most elementary? Do that. Send forth healthy pupils yearly, champions in the battle against dirt and drunkenness, disease and death, and you will raise a yet prouder title to the gratitude of your fellow-countrymen than you have earned already by your scientific zeal and your noble liberality. There are those who may answer—or rather there would have been those who would certainly have answered, five and twenty years ago, before the so-called materialism of advanced science had taught us some practical wisdom about education—'And if it were so, what matter? Mind makes the man, not body. We do not want our children to be stupid giants and bravos, but clean, able, highly-educated, however delicately Providence or the laws of Nature may have been pleased to make them. Let them overstrain their brains a little, let them contract their chests, and injure their digestion and their eyes, by sitting at desks and poring over books. Intellect is what we want, and intellect makes money; intellect rules the world. I would rather see my son a genius than an athlete.' And so would I. But what if for want of obeying the laws of Nature you got neither genius nor athlete, but generally an incapable, unhappy personage? Without healthy bodies you will not, in the long run, get healthy intellects. . . Wherever you have a population generally weakly, stunted, scrofulous, you will find in them a corresponding type of brain which cannot be trusted to do good work. It may be very active, it may be very quick in catching up new and grand ideas—all the more quick on account of its own secret malaise and self-discontent; but will be spasmodic, irritable, hysterical. It will be apt to mistake capacity of talk for capacity of action, excitement for earnestness, virulence for force, and cruelty for justice. It will lose manful independence, individuality, originality, and when men act they will act from the consciousness of personal weakness, leaning against each other, swaying about in mobs and masses."

We sincerely hope that the publicity which has been given by the public press to this address by Canon Kingsley will be the means of awakening the minds of many to the vital importance of that scientific training which he, in common with every enlightened mind, advocates.

MARTIN ON MICROSCOPIC MOUNTING

A Manual of Microscopic Mounting. By J. H. Martin. (J. and A. Churchill.)

SCIENCE in this country is certainly under great obligations to *amateurs*, or *dilettanti* as they are more correctly called. The fact is there are in Great Britain but a very few men of science, that is to say, men professionally devoted to scientific careers, as compared with Germany and even France—we are very poor in this source of power. Germany has a host of universities and high-schools in each one of which there are more men whose lives are definitely told off to the cultivation of science, than there are in our greatest and richest seats of learning. Dilettantism is the fashion of some branches of science in this country, and under it they have thriven in a way of which we may be to some extent proud; but which seems likely enough to impede greatly their more systematic cultivation. Geology has perhaps more than any science benefited by the patronage of *dilettanti*; but it is not difficult to foresee the time when its problems will have become too arduous for any but trained and devoted specialists to make any way with them. The same is to a less extent true for the biological sciences, in which, besides the enthusiastic field-naturalists, the members of the medical profession have been conspicuous as *dilettanti* explorers. At the time when (some five and twenty years ago) the microscope was first brought to a state of efficiency in this country, a perfect army of amateurs entered the fields of animal and vegetable histology, equipped with the beautiful and costly instrument, and brought to light a considerable number of important facts bearing on the structure of tissues and the minuter forms of life. This was not the case on the Continent, the costliness of the instrument, in addition to the other causes which make Englishmen remarkable as scientific *dilettanti*, tending to limit the movement to this country. The taste for amusement with the microscope has by no means diminished of late years, the sales of instruments by English makers being something astonishing in point of

number and implied outlay. But it is a fact—for which we can most positively vouch—that the good work done at the present time in England with the microscope has fallen very far behind its original proportion to the number of instruments in use. In fact we have in the history of English research with the microscope, a typical case of the breaking down of dilettantism. Nearly all the discoveries easy to hand, which could be made by half-an-hour's pleasant peeping through a good microscope have been made, and the numerous observers formerly urged on by success have now become reduced to mere collectors of diatoms and mounters of fleas. On the other hand, in Germany, an efficient microscope was produced somewhat later than in this country, on a different system and at a far less cost. It was not taken up by men of leisure and means, nor were the makers tempted to produce the most elaborate and costly mechanical contrivances for no practical end but their own profit. The microscope in Germany fell into the hands of the professed students of science in the universities, and in consequence the art of applying this instrument to the study of structure has steadily advanced in that country, until not only are all the important observations which are made with the microscope made in German laboratories, or by those who have studied in them; but the whole art or "technic" of microscopy has become a German one. When we find that it is necessary, for some purposes, to watch a single cell for twelve hours or more consecutively, and that three or four months' daily labour is not considered too much to devote to advancing one small step in the knowledge of such a matter as the nerve branches which go to the glands in a frog's tongue, we are not surprised that the *dilettanti* are no longer of service in the progress of researches with the microscope. Thorough and single-purposed men are required for such work; in short, "men of science," supported by special institutions.

It is then with very mixed feelings that we contemplate Mr. Martin's book on Microscopic Mounting. It is of about as much use for scientific purposes as would be an alchemist's guide-book in a modern chemical laboratory. Foreigners who do not know of the immense number of microscopes annually sold in this country as toys, will wonder who on earth can make any use of it. Microscopic mounting is a proceeding which bears about the same relation to the genuine microscopic study of an organism, as enclosing a "subject" in its coffin does to human anatomy. The object which is aimed at by the modern student of histology is not to "mount" a pretty specimen, but to apply such staining, clarifying, coagulating reagents, and such methods of disruption, slicing, hardening, or softening, as will enable him to discriminate, describe, and draw structure; or, it may be, so to arrange the somewhat restrictive conditions of microscopical examination as may enable him to observe with the highest powers the tissues of organisms in their *living* state. He does not care a dump for "mounting," and if he has in the course of his work prepared some hundred or two preparations of an organ or organism which he is investigating, the preparations are usually thrown away when the problem under investigation is solved, or lie for years undisturbed in the catacombs of some cabinet. Mr. Martin is of no assistance whatever in all that relates to the use of reagents or adjuncts to observation with the microscope. He is evidently quite ignorant of German; he gives a number of receipts taken from a variety of antiquated English sources; others he takes without acknowledgment from the "Quarterly Journal of Microscopical Science;" see, for example, the paragraph on staining tissues, p. 144, which can only serve to mislead. Some, of course, amongst Mr. Martin's instructions are correct; but we feel convinced that he has not made trial of even the few methods which he has imperfectly described; and we decidedly object to his assuming the office of a guide, when it is but a case of the blind leading the blind.

Still, Mr. Martin's book may be looked at as an interesting specimen of the phase which English *dilettante* microscopy has now reached. Had the author been a little more careful in confining himself to what he really understood as a diligent mounter of microscopic objects, his volume would have had a genuine antiquarian interest, and would have perhaps been useful; indeed, it may even now in some ways be so to those who take a view of the microscope similar to his own.

It would hardly have been worth while expending so many words on a book in itself of so little significance, had not there been two conditions in existence which, if passed by without remark, may have some consequences which had better be avoided. Firstly, the number of persons, medical students and others, now entering on the serious study of histology, and the use of the microscope as an instrument of scientific research, is increasing. They want books to supplement the efforts of teachers in putting them into the way of working and explaining to them—if we may so say—the most useful "dodges.' Secondly, there are other books besides Mr. Martin's which profess to give instruction on microscopic manipulation, and are all *worthless*. The students may, in their innocence, be led to purchase such books. We wish them to avoid making this mistake. There is no satisfactory book in English on the subject. Beale's is the best, but too large, and not sufficiently complete excepting as to his own methods. Frey's book, which exists in both a French and a German form, is the best foreign guide to microscopic *Technik*.

OUR BOOK SHELF

Magnetism and Deviation of the Compass. For the use of Students in Navigation and Science Schools. By John Merrifield, LL.D., F.R.A.S. (London: Longmans and Co.)

THE Admiralty Manual of Compass Deviation with its auxiliary Elemenatry Manual would, after some lapse of time, appear to have been turned to good account by teachers of navigation. The small volume under review is one of a plentiful supply which appears to be now issuing from the press on a subject of vast importance to seamen of the present generation; and as such is deserving of notice.

It contains useful information of an elementary kind, although this information is not presented either in the practical form or exact and mathematical arrangement of the two manuals we have noticed as the fountain heads of the science of magnetism as applied to iron ships and their compasses.

It is to be regretted that in a subject where clearness and precision are essentials to teaching, Dr. Merrifield

should have written occasionally with looseness and inaccuracy; for example, at p. 52 we find "Vertical iron at the same place will produce the same deviation in whatever direction the ship's head may be, because a vertical line makes always the same angle at the same place with the line of force." There is confusion of cause and effect here—the deviation is not the same in whatever direction the ship's head may be, although the force remains constant or nearly so—and these are important features for the student to realise.

Notwithstanding, however, these shortcomings, Dr. Merrifield's "small manual" may in the main be received as an orthodox production, and will tend to divert the attention of his students from some singular statements and conceptions relating to the deviation of the compass on board ship and its compensation, to be found at pp. 20-23 of his Navigation and Nautical Astronomy published conjointly with H. Evers in 1868.

We hope to see manuals of this smaller class emanating from seamen, who, possessed of the knowledge of the exact requirements in the practice of their calling, can extract from original sources, and simplify the main points in the various divisions of the subject.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Solar Spectroscopic Observations

I HAVE just seen Herschel's letter to you in NATURE of October 3, and am induced to address you, lest his remarks on Indian Climate should make difficulties in respect to the British Association's proposal for a physical observatory for solar observation.

I do not think Captain Herschel has been in England since the Eclipse of 1868, and consequently he cannot speak from experience of the English climate. It is beyond all doubt that from some cause (commonly believed to be haze) there are really very few days when the protuberances can be studied in England. Herschel's letter contains evidence that that cause, whatever it be, is absent in India. We need not go further; we have the two facts (1) that it is impossible in England, with great telescopic power and great dispersion, to see the prominence lines regularly; (2) that it is possible to do so in India, even in the plains at a bad season. The result seems to be that solar investigations should be pursued in India systematically.

I may add that the facility of seeing these things, and the probability that spectroscopic inquiries into the celestial bodies would have been more successful in the earlier stages had there then been any observers in India, are to my mind a strong argument for now establishing in India, and on a permanent footing, an observatory, whose speciality shall be "Researches on the Physics of the Sun and Planets," whether by the spectroscope, or vision, or photography. When the proposal of the British Association is made formally to the Government by the Council, it will, I trust, take this form. There is no such institution now in the British dominions, and when one is established, it should be in the Tropics somewhere, and as systematically devoted to physical researches as Greenwich has been to the moon.

The Director might, probably would, as at Greenwich, in time attach other investigations; but these researches should be his primal object; and, if they were made so, there is no reason why work as standard and as useful should not result.

October 4 J. F. TENNANT

Consciousness and Volition

THE question raised by Mr. Bennett in last week's NATURE is of great importance, and of no small difficulty. During a visit to the late Sir William Hamilton in 1855, this subject came up for discussion. Sir William was then engaged on his edition of the works of Dugald Stewart. I called his special attention to Stewart's doctrine regarding the operation of Will in acts which are usually ascribed to Habit. Stewart asserts that all habitual actions are really voluntary. As he had no acquaintance with the modern doctrine of "latent mental modifications," he would naturally take for granted that there can be neither a volition nor any other act of mind without accompanying consciousness. He accounted for the non-remembrance of that consciousness by the extreme rapidity of the volitional action. (Collected Works, vol. ii. chap. ii.) To this Sir William objected. He went on to show that in many cases an act, or even a long series of acts, originally voluntary, have ceased to be so. The habit or habitude, which is a mental tendency, though not a power, generated by custom, supplies the place of volition. In illustration, he referred particularly to the well-known fact that in India soldiers will march long distances when they are asleep. Now, it seems to me that this decides Mr. Bennett's question. Here we have regulated action, determined, not by volition, but by habit. Sir William, however, failed to meet all my difficulties, because, as I afterwards saw, of his unsatisfactory theory of causation. He so frequently confounded conditions with causes. With him a cause denoted anything without which an effect could not be; hence his doctrine of con-causes, a plurality of causes for each effect. Thus, when I will to move my hand, and the movement follows, Sir William would call the volition *one* cause of the movement, whereas it is merely a condition. It is remarkable that he should fall into this error since he rejected Biran's doctrine regarding the efficiency of volition. In a subsequent conversation we discussed the points of similarity and the points of difference between Habits and Instincts. It would, however, be trespassing on your space to give the details.

I will only add that an "unconscious volition" in the sense intended by Mr. Bennett is not possible. Dr. Carpenter's expresion "unconscious cerebration" I regard as unfortunate, since it appears to rest on the assumption of the essential identity of mental, vital, and physical powers. Mr. Bennett will find many valuable observations on the nature and conditions of habitual acts in Hamilton's lectures on "Metaphysics," Morell's "Outlines of Mental Philosophy" (published in 1862), and Sir Henry Holland's "Mental Physiology."

Stamford House, Sale, near Manchester, Oct. 14

The Solar Spectrum

UPON reading the communication from Capt. Herschel in your number for October 3, upon the solar spectrum, I seem to remember a letter from a correspondent being published some year or more ago in your pages, in which it was stated the writer had seen the bright lines near the sun's limb with one of Browning's direct vision prism spectroscopes, the instrument being placed on the back of a swing looking-glass as a stand. The dispersion of this instrument would be probably rather more than that of one angular prism. I am bound to say that I have been unable myself, up to the present time, to do more than see a bright line near D, superposed on the solar spectrum, with such an instrument as, however, for other purposes, is a most convenient and sufficiently powerful one.

To my own I have added three small wedge-shaped pointers cut out of thin brass, and fixed in the eye-piece, while the slit-plate, and consequently the spectrum itself, is drawn across the field by a micrometer screw having a range of about 600 divisions between its starting point near A and G at the other end of the spectrum. In this way a bright line (say the auroral one) may be brought upon one of the pointers, and its distance from D, in a salted spirit-lamp flame, at once accurately measured and mapped down; and if the pointer is again brought on the line after the observation, it may be verified by the position of the pointer next day upon the solar spectrum itself.

It occurred to me the other evening to try the effect of a V-shaped slit, and it seems to me to have some advantages. The lower ends of bright lines being brought to a fine point, are more easily positioned on a scale or pointer, while the tapering of faint or nebulous lines or bands enables their relative intensity to be more easily compared. My experiment was a rough one, and with a home-made slit; but for working purposes, by a sliding plate a slit might be contrived of a V shape, whose width and length would be altered at pleasure; and it would, I think, for some observations give good results.

Guildford, Oct. 7 J. RAND CAPRON

A Day Aurora

A CONTROVERSY was carried on in your columns about a year ago as to the possibility of an aurora being seen during the day time. A recent communication from Padre Secchi to the French

Academy of Sciences will be found of interest as bearing on this question. Writing from Rome on the 27th of August, he says (*Comptes Rendus*, p. 613):—"On the 15th of this month we had an Aurora Borealis by day, at ten o'clock in the morning up to midday. The magnetometers were greatly disturbed, and in the heavens at half-past ten appeared an arch of light cirrus clouds, stretching from N.N.W. to N.E., and crowned along the whole of its contour by numerous and fantastic rays (*jets filamenteux*). The forms of these rays so perfectly resembled those of the solar protuberances that some of the drawings of them might easily be mistaken for drawings of solar protuberances even by people well accustomed to these observations."

Merton College, Oxford J. P. EARWAKER

Meteor

LAST night, Oct. 9-10, about midnight, G.M.T. a meteor was seen by my wife in the S., considered by her to rival the brightness of Venus, and describing a path which was so carefully sketched by her immediately afterwards as to form a possible basis of comparison; and which therefore may be thought worthy of insertion in NATURE. It seems to have become visible near ζ Ceti, probably rather *nf* that star (which, however, was not noticed by her through a dewed window-pane), and to have passed with a slow motion and a yellowish light, in a path somewhat convex towards the zenith, in the direction of β Ceti, before reaching which it vanished. For about three-fifths of its course it preserved the same aspect, as of a ball of light with sparklings round it, and some appearance of a train; but in its further progress it seemed to waste away to extinction.

Fossil Oyster

I HAVE recently noticed a fossil oyster, in what Sir C. Lyell calls the Lower Miocene, or Hampstead beds. Can you, or any of your readers inform me if it has been noticed before. I can find no mention of it, in any work within my reach. I have been a subscriber, from your first number; and have observed the kind notice you have extended to other inquirers, and have thus been emboldened to trouble you. INQUIRER

N.B.—I have no pretensions to science, or any scientific acquaintance, being merely a solitary observer.

AN ELECTRICAL BAROGRAPH

I HAVE recently designed a barograph, a brief account of which may be interesting to your readers. The advantages claimed are:—

That the record may be seen as it is going on.

That it is quite as, if not more sensitive than, the photographic barograph, and the scale is larger.

That no time is lost preparing the paper, printed forms answering the purpose.

That the first cost and cost of working are both much less than in the photo-barograph.

A photograph has been taken which shows the instrument in working order, with part of a day's record shown on the cylinder.*

The cylinder is ten inches long, and eight inches in diameter, allowing for one inch per hour of paper.

The clock, or governor, is connected by a bar to a movable inclined plane, this is again connected by a bar to the long wire parallelogram which carries the pen, and the clock, by means of an eccentric, causes the inclined plane, and with it of course the pen frame, to move backwards and forwards once every minute. The wire frame is guided by four brass friction wheels, attached to a brass frame having motion up and down only; under it are the coils of an electro-magnet, the armature of which is attached to the brass frame. So long as no electricity passes through the coils the brass frame is thrown up by a small spring high enough to lift the pen off the paper.

* A photograph and section were obligingly forwarded by the author with his description.

The barometer tube is an ordinary glass one 0·58 in diameter, and is fixed firmly to the case. Its cistern is a small glass one, one inch in diameter, and cemented to a brass arm hinged to the left side of the case, and which allows it perfectly free motion up and down, but not sideways. From this cistern projects a very light arm, also hinged, and bent at the end so as to extend over the inclined plane. One wire of the battery is attached to the cistern arm, and the other, after passing round the magnet, to the inclined plane. As soon, then, as these two parts touch, the electro-magnet brings down the brass frame, and with it the pen, on to the papers which at once begins to mark, and continues to do so until the motion of the clock draws the inclined plane from the cistern arm, and so breaks the contact; the pen remains off the paper until, by the motion of the clock, the inclined plane is brought to touch the projecting cistern arm, when the pen at once begins to write. As the barometer, when the pressure increases, must draw the mercury for its increased height from the floating cistern, the cistern becomes lighter, and rises with it, and the smallest motion may be made sensible by altering the inclination of the moving inclined plane. The accuracy of the motion of this plane is secured by making it work on two fine steel points—the same motion, in fact, as that given to the cutter of a dividing engine. The cistern floats in a reservoir of mercury.

The pen is a syphon pen, supplied with *thin* ordinary writing ink. H. C. RUSSELL

Sydney Observatory, Aug. 10

*BEAUFORT'S WIND SCALE AND THE BOARD OF TRADE**

THE Board of Trade have recently issued instructions to Receivers of Wreck and Officers of Coastguard, with reference to Beaufort's Wind Scale, so that one uniform construction should, as far as possible, be placed upon the wind scale by them. In the Circular the following passage occurs:—

"The Board of Trade are led to think that different constructions are placed by different persons upon the scale known as Beaufort's scale. In illustration, it may be remarked that the higher forces, 11 and 12, are, as the Board learn from the Meteorological Committee, scarcely, if ever, reached in the British Isles. Force 12, which is intended to represent a West India hurricane, the velocity of which is 80 miles per hour and upwards, has been reached only twice in four years on the coasts of the United Kingdom; notwithstanding high winds prevailing at the time of a wreck are frequently described by the ships' officers as storms or hurricanes."

It is here taken for granted that the positions of the anemometers of the Meteorological Committee are such as to record observations of wind fairly comparable with those felt at sea; and also that the anemometers are constructed to record those velocities of the wind which are applicable to the case in hand.

It is not stated how the two instances of velocity of 80 per hour and upwards were ascertained. Since, however, the space traversed or recorded by the anemometers at the observatories of the Meteorological Committee can scarcely be measured for a shorter period of time than 15 minutes, it may be assumed that on two occasions, and only on two occasions during four years, have the anemometers been noted to record a velocity of 20 miles or upwards in 15 minutes—that is, a velocity at the rate of 80 miles an hour or upwards. If the tracings of the Hemispherical Cup Anemometer could be read off for so short a period as five minutes, many instances of 80 miles an hour, and even several velocities of 100 miles an hour and upwards, could be taken from the records of these four

* See Circular, No. 558.

years in the Meteorological Office. Indeed, a careful inspection of the lines of wind velocity published in the Committee's Quarterly Reports renders this supposition extremely probable.

During high winds it is well known that the wind does not blow with a uniformly high velocity, but that there occur frequent gusts of comparatively brief duration, many of the heaviest being, indeed, all but instantaneous. Thus the anemometer may indicate a velocity at the rate of no more than 60 or 70 miles an hour, but during the time there may have occurred 20 or 30 sudden gusts quite equal to the Force 12 of Beaufort's scale. Now, it is these repeated heavy gusts which cup-anemometers do not record that sailors have to provide against in the management of their ships. Hence it happens that while at observatories on land, provided only with cup-, anemometers, no greater velocities than 60 or 70 miles an hour can be noted, in ships at sea, what the seaman has actually to deal with are velocities of 80 or 100 miles an hour. He accordingly enters these high pressures in his log.

It is evident that the Board of Trade are not in a position to give the assistance to sailors which they are seeking to give, till pressure-anemometers have been established at their observatories.

The Circular contains this very judicious remark:—"The Board desire to impress upon Receivers and Officers employed in reporting casualties, that the direction and force of the wind at the time of a casualty should be ascertained as accurately as possible, and that therefore these particulars should not be inserted without every precaution being taken to insure that they are in accordance with fact." It only remains that the Board of Trade furnish each Receiver and Officer with a simple pressure-anemometer, having a scale, 0 to 12, agreeing as nearly as possible with Beaufort's scale, and so constructed as to show the pressure at the time of observation, and to register maximum pressures, so that the officials may be put in a position to carry out the instructions of the Board.

SCIENCE AT OXFORD AND CAMBRIDGE

THE following courses of lectures are arranged for the ensuing term at the University of Oxford:—

Mr. R. B. Clifton, Professor of Experimental Philosophy, on "Optical Instruments and Physical Optics;" beginning Saturday, the 19th of October. The Physical Laboratory of the University will be open daily for instruction in practical physics from 10 to 4 o'clock on and after Thursday, the 17th of October.

Mr. J. O. Westwood, Hope Professor of Zoology, proposes to form a class for the study of the structure and classification of articulated animals.

Mr. W. Odling, Professor of Chemistry, on "The Succession of Chemical Ideas;" beginning Thursday, October 17. There will also be an explanatory and catechetical lecture on Tuesdays at 11 o'clock, to commence on Tuesday, October 22. The laboratory of the University will be open daily for instruction in practical chemistry from 9 A.M. to 3 P.M. on and after Monday, October 14 In addition to this two courses of instruction will be given in the laboratory—a course on the methods of quantitative analysis, and a course of elementary practical instruction in chemical manipulation, intended for those commencing the study of chemistry.

Mr. G. Rolleston, Linacre Professor of Anatomy and Physiology, on "Human Anatomy and Physiology, with special reference to Ethnology;" beginning Friday, the 18th of October. The work-rooms in the Anatomical Department are open daily from 9 A.M. to 5 P.M. for practical instruction, under the superintendence of Mr. Charles Robertson, the Demonstrator of Anatomy, and Mr. S. J. Sharkey, of Jesus College. A special class will be formed for instruction in Practical Microscopy. Mr. E. Ray Lankester, of Exeter College, will, as Deputy of the Linacre Professor, give a course of lectures on "The General Classification of the Animal Kingdom," beginning on the 19th of October.

Mr. J. Phillips, Professor of Geology, on "The Successive Conditions of Land and Sea, taken in the order of Geological Time;" beginning Monday, October 28.

The following are also announced in connection with Trinity, St. John's, and Sidney Sussex Colleges, Cambridge:—

On "Electricity and Magnetism (for the Natural Sciences Tripos), by Mr. Trotter, Trinity, commencing Wednesday, Oct. 16. On Chemistry, by Mr. Main, St. John's, in St. John's College Laboratory, commencing Thursday, Oct. 17. Attendance on these lectures is recognised by the University for the Certificate required by Medical Students previous to admission for the first examination for the degree of M.B. Instruction in Practical Chemistry will also be given. On Palæontology (the Protozoa and Cœlenterata), by Mr. Bonney, St. John's, commencing Thursday, Oct. 17. On Geology, (for the Natural Sciences Tripos. Preliminary matter and Petrology), by Mr. Bonney, St. John's, commencing Wednesday, Oct 16. A course on Physical Geology will be given in the Lent Term, and on Stratigraphical Geology in the Easter Term. On Botany (for the Natural Sciences Tripos), by Mr. Hicks, Sidney, beginning on Thursday, Oct. 17. The Lectures during this term will be on the Morphology of Phanerogamia. Mr. Hicks will also give examination papers in Botany to candidates for the next Natural Sciences Tripos, beginning Oct. 21. On the Physiology of the Organs of Sense, by Dr. M. Foster, F.R.S.; and a Course of Practical Physiology. The days, hours, and dates of commencement of these two courses will be announced shortly.

AMERICAN PREPARATIONS FOR THE FORTHCOMING TRANSIT OF VENUS

AMID the violent political agitation and the inevitable social commotion of the United States, one would imagine, judging from our own case, that neither the American Government nor the American people had any time or funds to devote to scientific objects of apparently remote utilitarian interest. That this is not the case every regular reader of this periodical must be aware, for seldom does a week pass but we have occasion to notice some scientific expedition fitted out by Government funds, or the meeting of some well-organised and efficient scientific association, or the report of work done at one of the numerous scientific schools with which the country abounds, or the results of an expensive scientific inquiry or scientific experiment; in short, the Americans seem to think it their interest and duty, as it is their inclination, to give substantial encouragement to scientific research and the spread of scientific culture and knowledge. Verily they know how to do these things better in America than in England; but, indeed, of what foreign country can this not be said? This cannot be better seen than in the action taken by the U.S. Government in reference to the forthcoming Transit of Venus.

In March 1871 Congress, instead of appointing one irresponsible official to organise all the preparations necessary for the observation of one of the rarest and most important astronomical phenomena, authorised the appointment of a Commission "to expend such appropriations as might be made by Congress for the observations of the coming Transit of Venus." This Commission is composed of Rear-Admiral B. F. Sands, Superintendent U.S. Naval Observatory; Prof. Joseph Henry, LL.D., President National Academy of Sciences; Prof. Benjamin Peirce, LL.D., Superintendent U.S. Coast Survey; and two Professors of Mathematics of the Naval Observatory,

viz., Profs. Simon Newcomb and William Harkness. These gentlemen are all thoroughly qualified, both from their attainments and position, to perform the important and critical duties devolving upon them; and from their varied experience and knowledge, as well as from their differences of mental constitution and vision, they are more likely to do their work exhaustively and with thorough efficiency, than if their task had been committed to the absolute care of a single individual, no matter how well qualified he might have been. "In the multitude of counsellors there is wisdom."

The Commission have set about their work in a thorough and business-like way, and seem determined that America shall have no rival in the perfection of the preparations organised for making the most of the momentous astronomical event. They, however, do not grudge to give the world generally the benefit of whatever important conclusions may result from their inquiries and experiments. At a meeting of the Commission in July last, it was resolved to print such papers relating to the subject as might be of sufficient interest and importance. The first collection of these papers lies before us, and we shall endeavour to lay before our readers the gist of its contents.

The first article is a letter from Rear-Admiral Sands to the Secretary of the Navy, suggesting the advisability of asking Congress to appropriate the necessary funds for fitting out expeditions to observe the transit. Congress, it appears, in 1871 had made a small preliminary appropriation of 2,000 dols., but the Commission having decided that the total cost of carrying out the work in a fitting manner would be 150,000 dols., to be expended in three annual instalments, Rear-Admiral Sands requested the Secretary to procure for them the first instalment of 50,000 dols., which were to be almost entirely spent in the construction of instruments. Judging from the indorsement of the Secretary, it seems certain that the request of the Commission has been granted.

The next letter is from Rear-Admiral Sands to Mr. Lewis, Mr. Rutherfurd requesting his advice respecting the best method of applying photography to the determination of the relative positions of Venus and the sun during the transit. Mr. Rutherfurd replies by giving a detailed description of the method of solar photography employed in his own observatory, describing the form of photographic instrument he considers best adapted for the observation of the transit. He gives directions as to the construction and manipulation of the objective, the tube and focus, and the camera-box, which seem to be in all essential respects similar to those which have hitherto been found most efficient elsewhere. His opinion as to the best form of photographic instrument is, however, worth quoting. Mr. Rutherfurd says (p. 13):—

"If the whole matter of ordering instruments for the photographing of the transit of Venus were in my control, with my present lights, I should have an achromatic objective of 5in. aperture, and 70in. focus, in a cell which would allow of the application in front of it of a lens of flint glass of such curves as would shorten the focal distance (for photographing) to 60in. At the proper point I would place between the two distances an enlarging lens so constructed that the normal image of the sun in the principal focus (then about half an inch) would be enlarged to two inches at the distance of ten inches from the principal focus, viz., at 70in. from the objective. The camera box and tube should be one tube, and the focalising rack and screw should be located at the objective end of the tube, thus simplifying the whole arrangement, and permitting the use of braces from end to end to prevent flexure; and on taking off the photographic corrector, and taking out the enlarging lens, the instrument will be all ready for vision. On consideration I do not think I would counsel a smaller telescope than the one I have named."

We are glad to see that Mr. Rutherfurd has consented to superintend the preparatory photographic constructions and experiments.

The last and longest, and perhaps most valuable, article in the pamphlet is by Prof. Newcomb, a member of the Commission, "On the Application of Photography to the Observations of the Transits of Venus." He speaks of the two methods which may be adopted for the purpose of observations. Of the first, which consists in fixing the moment at which the planet is in contact with the limb of the sun, he speaks in terms of strong depreciation, as almost entirely untrustworthy. The second method, and the one Prof. Newcomb recommends, consists in determining the relative position of the centre of the planet and the centre of the sun as often as possible during the transit. He then proceeds to examine some plans which have been suggested for the application of photography to this purpose, and to devise the combination among them which he thinks most likely to lead to the desired result. The objects to be attained he sums up as follows:—

1. To form an image of the sun with Venus on its disc of such a kind that from the outlines of the images the points on the photographic plates which correspond to the centre of the two discs, can be fixed with a high degree of precision. 2. The linear distance between these points being determined in millimetres, or other units of length, by means of a micrometer, we must have the means of deducing the angular distance to which this linear distance corresponds; or we must know the value of one millimetre in seconds of arc on each part of the photographic plate, and in each direction. 3. We must have a fixed line of reference on the plate, from which we can deduce the angle of position of the two centres relatively to the circle of right ascension passing through the sun's centre.

Prof. Newcomb then speaks of the necessity for the greatest possible accuracy in the measures; he thinks that, considering the accuracy with which the solar parallax can be found by other methods, we are justified in pronouncing it necessary that the errors at no one station rise to the $\frac{1}{10000}$ of the distance measured. In speaking of the size of image on plate, he assumes that the photographs must be taken by the "wet plate" process. As to size, he justly says that the test consists in the relative sharpness of the images; if it be found that a 2-in. image can be measured with twice the accuracy of a 4-in. one, it will answer an equally good purpose.

In reference to the modes of forming the solar image to be photographed, he thinks the only method that can be adopted is that devised by Prof. Winlock, which has been in successful operation for several years at the Harvard College Observatory, and which has been independently proposed by M. Faye, of the French Academy of Sciences. It consists in placing the telescope in a fixed horizontal position, while the sun's rays are thrown into it by a heliostat placed in front of the object-glass. After enumerating several of the decided advantages which he thinks it possesses, he proceeds to describe the appliances and methods by which the determinations are to be made in this system. What he says as to the heliostat we think very valuable, and shall endeavour to give a clear abstract of it.

If the reflecting surface of the heliostat be warmed by the rays of the sun, or if the two surfaces of the reflecting plates are unequally heated, then (1) the position of the effective optical centre of the angular value of the millimetre on the photographic plate, will be vitiated; (2) the image formed in the focus of the objective will be blurred. In considering effect (1), the problem is:—two rays from points in the heavens, at the angular distance γ, strike the reflector, whose radius of curvature is ρ, so as to meet after reflection near the optical centre of the objective; to find the difference γ' between these directions after leaving the

reflector. γ' is the angle which will be measured on the plate, γ the angle we want. Call,

S, the distance between the points on which the rays strike the reflector.

A, the angle which the line joining the points makes with the plane normal to the axis of the telescope.

D, mean distance of the mirror from the objective.

$\delta\gamma = \gamma' - \gamma$, the error produced by the curvature of the mirror in the result of the angular measurement.

Then, $S = D$ sin. γ sec. A.

$$\delta\gamma = \frac{2S}{\rho} = \frac{2D \sec. A}{\rho} \sin. \gamma.$$

Sec. A may be supposed to be unity. Since it is desirable that the error of $\angle\gamma$ should not exceed $\frac{1}{40000}$ of its value, it is desirable that we have $\frac{\rho}{D} > 80{,}000$; and since it is necessary that the error should certainly be within a limit four times as great as this, we must have $\frac{\rho}{D} > 20{,}000$.

It will probably be found that at most of the stations the reflector can be placed within a foot of the objective. If so, the limit outside of which the radius of curvature of the reflecting surface will be unimportant, will be 80,000 feet, and that within which it will be inadmissible will be 20,000 feet.

As to the second effect, that on definition, if the curvature of the reflector cannot be kept within the limit of 80,000 feet radius, or if any small deviations without it cannot be determined with certainty, a serious and fatal objection will arise to the proposed plan. The practicability of attaining this desideratum is the first thing to be determined, and it can only be determined by trial and experiment. The most necessary precaution is that the reflector should be exposed to full sunlight only at the moment of taking the picture. When it is found necessary to use the reflected light for adjustment, the heat rays must, as far as possible, be cut off by a blue or green glass. The necessary time of full exposure of the mirror need not be more than half a second, or a second at most, for each picture.

The most perfect arrangement for moving the reflector would be that of the "siderostat" of Foucault, in which the mirror is moved round two axes in such a manner that the reflected rays remain parallel as the sun passes along its parallel of declination by its diurnal motion, the change due to refraction excepted. The adjustment of the reflector must be made so that the direction of the reflected ray shall vary from that of the telescope as little as possible during the transit. The motion of the mirror must be free from all vibrations, and every instrument must be carefully tested for this condition before being used. To avoid all serious danger of vibration, Prof. Newcomb proposes that no toothed wheels shall be allowed in the moving machinery, but that all motion shall be communicated by fine and well-oiled tangent screws. Whether the mirror should be of plain glass, silvered glass, or speculum metal, is a question to be settled by experiment.

Prof. Newcomb then proceeds to give some valuable suggestions as to the objective, the tube, arrangements at the focal points, the exposing of the plate, determination of the planet's position on the sun's disc, and the angle of position. These are an admirable *résumé* of and criticism on the best results that have been hitherto arrived at on these points. His concluding remarks are worth quoting:—"The determination of the solar parallax from measures of photographs of the sun taken during the transit of Venus is beset with this serious difficulty. That the required element appears only as a minute difference between two comparatively long arcs, much longer, in fact, than are often measured with a micrometer. In order that the solar parallax may thus be determined with a precision exceeding that attained by other methods, it is necessary that the arcs in question be measured with a precision considerably exceeding any ever attained in the astronomical measurement of an arc of similar length. The difficulties of the operations are greatly aggravated by the direction and motion of the body to be photographed, which require the apparatus to be mounted on moving axes, and demand either an instrument of unwieldy proportions, or the use of an enlarging lens. In Prof. Winlock's apparatus the diurnal motion is thrown entirely upon the revolving mirror, so that all the advantages of a fixed horizontal sun are obtained. The apparatus is all firmly mounted on stone piers, thus admitting of exact measurement of all its parts, and avoiding all danger of changing the adjustments by the photographic manipulations. It seems to be that the advantages are all greatly in its favour."

We hope that the Commission will very soon be able to publish an equally, if not more, interesting and valuable collection of papers, containing the results of their own independent inquiries and experiments. We only hope that the preliminary work will be as efficiently done in other countries as there is every promise of its being done in the United States.

THE "HASSLER" EXPEDITION

We are again indebted to the *New York Tribune* for the following account of the final labours and total results of Prof. Agassiz's expedition:—

San Francisco, Cal., Sept. 2.—The steamer *Hassler* reached Acapulco on Sunday evening, Aug. 4, and remained 70 hours. The fishermen of the place were very active, and our own scientific party were not behindhand in diligence, so that these 70 hours yielded the Professor as rich a harvest as he has gathered in almost any port. Acapulco is a lovely Sleepy Hollow; its quiet little bay completely enclosed by beautiful mountains; its environs adorned with a profusion of tall cocoa-nut palms; the promenade from the town to the fort, half a mile distant, shaded by magnificent old lime trees; the town itself clean, old-fashioned, quiet; only three or four vessels in the port. If it had not been for the heat, we should have voted it the loveliest imaginable retreat. Two of the vessels in port were English, and I had one or two pleasant interviews with their captains. As we were parting, I mentioned to one of them that I had long wished to visit England. His answer was pre-eminently English:—"He thought a visit to England would be useful to me; it might remove some prejudices and hard feelings." Now, as I am absolutely certain, and do positively know, that I had not betrayed to him in any way or manner the least shade of prejudice or hard feeling toward the mother country, I must explain his remark by supposing that he was himself conscious of hard feelings toward the United States; and therefore presumed that I felt them toward England. The confidence with which an Englishman applies his English foot-rule to measure the universe is a very marvellous thing; it is as if he thought that the laws and customs of his little island are universal laws of humanity, and he seems incapable of supposing it otherwise.

We left Acapulco August 7. The scenery as we went out of the bay, passing between the islands and the main land, and for several miles after emerging into the Pacific, was exquisitely beautiful. The high hills behind the town reminded me of paintings which I have seen of Hymettus seen from the hill of the Museum. We have hardly seen on the whole voyage anything more picturesque and beautiful. The evening closed with a magnificent sunset. South of the sun were long streamers of golden clouds, and just north of it was a patch of the

bluest imaginable sky, broken by three or four projections of brilliant cloud. Our views toward the north were lovely beyond description; the sea nearer to us was the deepest blue, toward the shore becoming purple; then came a long golden beach; behind that deep green hills; behind these a line of purple hills; still farther back blue mountains, and then over all a series of clouds of varying shades. On the evening of the 9th, off Cape Corrientes, we had a heavy shower, a thing that six weeks in the rainy reason had rendered familiar to us. But the next morning we were in a different climate, cool, dry, and pleasant; and gliding on smooth seas, we reached the western edge of the Gulf of California on the evening of the 11th. By noon of the 12th we had a strong head-wind which seemed positively cold after the sweltering heats of Panama and Acapulco. At sunrise on the 13th we anchored in Magdalena Bay, where we remained thirty hours, seeing only the two great islands which form the outer defences of this magnificent harbour. We found here a small colony gathering orchilla, a lichen (*Roccella*) from which cudbear is made. The plant only grows in comparatively rainless regions, and grows very slowly, so that the gathering of a crop leaves the field barren for many years. The bushes on which this lichen grows are of but few species, and most of them of very odd appearance. The animals in the sea were very interesting, and our thirty hours yielded us a rich harvest.

Good weather and favourable winds brought us into the harbour of San Diego by noon on Sunday, August 18. We had not been here long before a telegram ordered the *Hassler* to return to the Mexican coast and sound for a rock reported to have been seen in a certain place. The *Hassler* obeyed, and was gone several days, searching for a rock which probably does not exist, the scientific party meanwhile remaining in San Diego. It was a delightful place for the naturalists and for us all. It was our own country, and we were at home; and among hospitable people who at once made us feel at home. A few Chinese (washers and ironers and fishers) seemed to be the only low people in the place, if we except a few Indians in tents in the adjoining fields. All the rest—I speak of the new town—seemed to be industrious, respectable Americans, Germans, or Spanish. The harbour is a long crescent. The protection is from a long range of hills running southward in a promontory to the west, and two flat islands on the south connected with each other and the continent on the east by a narrow strip of sea beach. On the north side of this crescent are numerous little villages, two of which, Old San Diego and New San Diego, are of considerable importance. In the new town two daily papers are published, and a steamer leaves five times a month for San Francisco. While we were there the town was intensely excited over the arrival of Col. Scott and other railroad magnates, to make arrangements for the commencement of work on the western division of the Texas and Pacific Road. The town has been built in faith that a railway communication with the Atlantic must at no distant day be opened with this the best harbour in the southern part of California. But hope deferred had begun to make the heart sick. Those who had not means of living had begun to consider the expediency of retreating to some place of greater activity. But the visit of Col. Scott, and the arrangement made by him with the citizens of the town, have put every one at San Diego into high spirits, and they look forward now, I think reasonably, to the rapid growth of their city.

The harbour is excellent. It needs some care to prevent the San Diego River from filling it with sand, to prevent the ocean from breaking the beach that connects the island, and thus obviate the present "scour" in the main entrance; and to prevent wharf and other "improvements" in the distant future from doing the same mischief. The situation of the town is fine, on a gentle slope, with a hard pan foundation for building. The climate is wonderfully equable, it is rather too dry, but windmills are cheap; the direction of the wind is so uniform that the windmill need only be set for west winds; and with a windmill to irrigate one can raise any crop. Many plants, as olives, figs, grapes, &c., only need irrigation for a time and then strike root deep enough to reach perennial moisture. Frosts come only at intervals of many years and are then exceedingly light. We ate tomatoes gathered from bushes that had yielded fruit freely every week in the year for three years past. The melons were of an excellence surpassing anything I have ever tasted. The city is well laid out, and the nucleus of citizens already there is of sterling quality. The Horton House, which is the principal hotel, is admirably kept in the neatest and most comfortable style, with gas, water, and other conveniences, and a good table. One can make oneself at home there as well as in any city of larger size. I met also many persons in private at whose houses I had evidence that some of the best fruits of English and German, French and Spanish civilisation are acclimated here. In zoology our naturalists found a rich field. Fifty-three different species of fish, and sixty or seventy species of other animals, were added to their collections, many of these species being of very rare and valuable kinds, and several probably new. Most of these were found in such abundance that the Professor could take just as many as he chose, as many, that is, as he thought he could make useful at home.

On August 28 we parted with real regret from our new-made but most cordial and hospitable friends at San Diego, and, being again greatly favoured by the weather, we made the Golden Gate on the 31st at sunrise, and dropped our anchor in the harbour of San Francisco at 9 o'clock. The expedition proper here ended, but Prof. Agassiz, with Dr. Steindachner, will remain to gather what they can in this harbour before returning. Their success during the whole voyage in collecting valuable specimens of fish and other animals has been truly wonderful; new and unknown species have apparently been everywhere awaiting their arrival to reveal themselves; rare and valuable fishes have come freely and in numbers to give themselves up, and the more ordinary species have come into their nets in superabundance, so that we have thrown back living into the sea very frequently more than half of what the seine brought up. The whole number of fish brought home from the voyage will probably exceed 30,000, and the other animals of all descriptions will probably swell the number of specimens brought home to over 100,000. It is, however, the quality and kinds that give value to their collection rather than the mere numbers; and the *Hassler* Expedition will have prominent place in the history of zoology, because of the number of new species discovered, as well as for the valuable collection of materials on which original anatomical investigations may hereafter be made. In the history of physics the exhibition will also be remembered, not for the deep-sea dredgings which circumstances beyond the control of the officers of the vessel prevented it from making, but for the valuable geological observations made for the first time in the south temperate zone by an observer thoroughly conversant with the action of glaciers and the glacial sheet north of the equator; the observer who first detected the marks, now apparent to every eye, which demonstrate the existence of glacial sheets before the birth of the present glaciers, even in their most extended form. During nine months the little company have received the courteous attention of the officers of the *Hassler*, and enjoyed the rare privileges which the Superintendent of the Coast Survey and Secretary of the Treasury had granted: nine months of continuous and varied enjoyment. The *Hassler* came round South America to survey the Pacific coast of the United States, but the long voyage has not been idle. It has been employed incidentally in a manner not less valuable than the work to which the vessel is specifically devoted.

ON THE FERTILISATION OF A FEW COMMON PAPILIONACEOUS FLOWERS

II.

VICIA SATIVA.—In the general structure and character of petals, stamens, and pistil, this flower agrees with Lathyrus; but there is a remarkable difference in the shape of the keel, and correlatively in the hairs or brush on the style.

In Lathyrus, as we have seen, the upper part of the elastic style is curved, so that the curvature corresponds with the curvature of the keel; the back or outside of the style presses against the inside of the keel, and is not furnished with hairs, there being no space for pollen on that side, whilst the inside of the style is covered with hairs set upwards, so as to sweep out the pollen which accumulates on this side.

In *Vicia sativa* the keel forms a less regular curve, whilst the style, instead of following the curvature of the keel, is set on at right angles to the ovary, and is straight and perpendicular throughout its whole length. There is, therefore, a large nook or corner outside the style, and between it and the keel, into which the pollen gets. Correlatively the style is not furnished with abundant hairs on the inside, as in Lathyrus; but there is a little tuft of stiff hairs on the outside, a little below the stigma, set on upwards so as exactly to brush out the pollen from the nook of the keel, when the keel is pressed down by an insect (see Fig. 9).

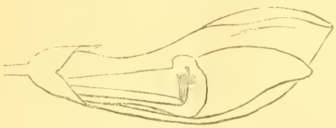

FIG. 9.—*Vicia sativa* (keel and pistil).

Vicia sepium is similar in construction to *V. sativa.* I have not observed whether there is nectar within the staminal tube of *V. sativa* or *V. sepium*, but feel assured that it is to be found there.

Vicia Faba. In the several positions of its buds and pods, Faba (broad bean) differs from Pisum and Lathyrus, and agrees with Phaseolus. The buds are upright; in the flower they are horizontal, and in the pod they are again upright; but the blossom, when open, is, as in all the other cases, horizontal, so as to afford a good lighting place for bees which seek the nectar in the interior of the staminal tube. This tube, the separate stamen, the shape of the keel of the style with its brush, are similar to those of *V. sativa.*

Robinia pseud-Acacia.—This plant bears its flowers in a pendent raceme; consequently, the position of the flower is reversed. The fifth sepal should be uppermost, and the vexillum lowest, with its back to the peduncle; and this is the position of the unopened buds. But as they approach maturity, *i.e.* as the blossom opens, the pedicel of each flower takes a half twist, so as to bring the flower into what we may call the normal position of Papilionaceæ, but with the vexillum uppermost and upright, or nearly so, and the wings and keel horizontal, the open side of the keel being uppermost. The keel is obtuse, and is free from the wings.

The filament of the tenth stamen is joined to the others in the middle, with apertures between it and the others at the base, and there is a cavity at the base of the staminal tube containing nectar. The stigma has a very small brush round it, and there are a few hairs on the inside of the style which seem to sweep out the pollen. The flowers are much frequented by bees.

Wistaria sinensis.—The pendent raceme of this plant displays, as regards the position of the buds and flowers, the same features as that of *Robinia pseud-Acacia*, which it also resembles in the free boat-shaped keel, the semi-separated tenth stamen, and the nectar-holding cavity of the staminal tube. It differs in having no hairs on the style, a difference possibly connected with the character of the pollen. But as the flower does not usually produce seed in this country, it seems unsafe to speculate on such a point.

Onobrychis sativa, or Sainfoin.—In the long raceme of this plant, the pedicels of the flower are nearly perpendicular in the bud, horizontal, as usual, in the flower, and again, after flowering, resume a position approaching the perpendicular. The wings are very small, and are not attached to the keel, and seem to play no part in fertilisation. On the other hand, the keel is large, boat-shaped, prominent,

FIG. 10.—*Lotus corniculatus* (keel).

and being joined together to the apex, and having the petals folded over one another when not joined, affords a broad and easy alighting place for insects. The tenth stamen is separate at the base, and the staminal tube so formed that it may contain nectar. Whether it does so or not I have not observed. The filaments are stiff, and the pollen sufficiently dry and dusty to come out in abundance on pressure being applied to the folded top of the keel. The stigma comes out first, and often remains outside the keel, whilst the stamens, on pressure being removed, resume their position.

Trifolium repens (Dutch Clover).—These flowers, being in an umbel, afford a good foothold for bees, and do not require an alighting place on each flower so much as in the case of larger and separate blossoms. Nevertheless, they are upright in the bud, inclined in the flower, pendent and recurved after blossoming. No flowers are upright in full blossom, and consequently the centre or summit of the umbel becomes bare. The flowers thus tend to the usual position, even though in an umbel.

The claws of the wings and keel are united, and form a half tube, containing within them the staminal tube. The tenth stamen is perfectly free, and the staminal tube, as usual in such cases, contains nectar. Bees are fond of the flowers, and must, in entering the half tubes of the keel and wings, meet the stigma and carry away pollen.

FIG. 11.—*Lotus corniculatus* (dilated filament).

Trifolium pratense.—The position of the flowers in the umbel changes as in *T. repens*, though in a less marked manner.

The long claws of all the petals, including the vexillum, are united so as to form a complete tube, at the bottom of which is much nectar. The limb of the keel is open at the top, but the aperture is small, so that an insect entering cannot fail to touch both stigma and anthers.

The filaments of the nine stamens cohere to one another, and to the tube of the corolla from the point of union of the petals, so that there is no separate staminal tube. The tenth stamen is entirely separate for its whole length. Looking to the course of the apparent veins of the petals and stamens on the tube, it seems as if the vexillum really formed the tube, and as if the nine united filaments of the stamens by themselves would

leave a large aperture, and were widely separated from the tenth stamen. If so, it is curious to see the nectar-holding cavity so often formed by the stamens here formed by the vexillum. The entire freedom and wide separation in the tenth stamen, in a flower displaying such a tendency to cohesion, is also curious. Possibly this is necessary in order to preserve a sufficient aperture to give access to the nectary.

Lotus corniculatus.—The flowers of this plant again, though in umbels, when open assume the normal position with the vexillum uppermost.

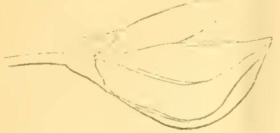

FIG. 12.—Lupin (flower with one wing cut off).

The wings are free from the keel. The keel is long, pointed, and united for some distance above as well as below, with an aperture at the apex (see Fig. 10). The tenth stamen is free, and is separate from the others at the base; the staminal tube is stiff and enlarged at the base into a cavity, which contains nectar. The pollen is moist and abundant. The style is capitate and stiff, but without hairs or brush. How then can the moist pollen be forced out of the narrow mouth of the long pointed keel so as to meet an entering insect? In a very curious way. Five

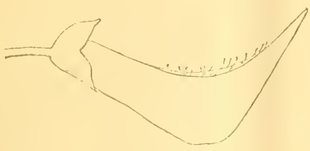

FIG. 13.—Lupin (keel).

of the stamens, viz. those of the inner whorl, are shorter than the others, and their filaments are dilated at the top. These filaments are stiff, and, I believe, continue to grow after the five anthers of the other whorl have shed their pollen. The dilatation of the filament is wedge or club-shaped, the broad end of the wedge being uppermost (see Fig. 11). Consequently, on any pressure being applied to the keel, the broad ends of these wedges, supported by their stiff filaments, collect the pollen, and push it before them to and out of the mouth of the keel, where it is seen to adhere to

FIG. 14.—Lupin (Stamens in bud)

the body of the insect which is passing down the keel. It is to be observed that the shape of the dilated filament is such that, whilst pollen might work past it from below upwards, the broad flat upper end of the filament meeting the narrowing tube of the keel can scarcely allow it to pass downwards.

Garden Lupin (common tall blue and white).—In the long raceme of this plant the pedicels are nearly perpendicular in the bud, become horizontal whilst the blossom is open, and rise so as to approach the perpendicular again afterwards. The wings are attached to each other below, are blunt, and are folded over at top so as to afford an excellent resting place. They are not attached to the keel, and move downwards more easily than it does. The keel is very long, very pointed, and the upper edges are slightly connected with an opening at the apex so as to form an approach to a tube. The apex just appears between the wings. The upper edges of the keel are furnished with a few hairs (see Figs. 12 and 13).

The filaments of the stamens are entirely joined together so as to form a close fitting tube round the ovary. There is no cavity within the tube for nectar, no apertures into it at the base, and it is too long and too close fitting for an insect to thrust its proboscis down.

FIG. 15.—Lupin (keel with one side cut off).

There is a cavity at the back and base of the vexillum in which I have not been able to find nectar. But the bees, which constantly visit these flowers, certainly go to this cavity for what they want, and not to the staminal tube. Five of the stamens compose, I believe, what must be the outer whorl, are longer in their filaments than the other five, and have longer anthers (see Fig. 14). These are mature, and before the flower opens have shed their pollen, which remains in a moist mass towards the mouth of the pointed keel. Their filaments then wither and contract. The other whorl of stamens are shorter, and the anthers much

FIG. 16.—Lupin (style and stigma).

smaller, but they are later than the first whorl, and their filaments grow and remain stiff after the filaments of the first whorl have withered. They consequently, on pressure being applied to the keel, thrust the mass of pollen upwards to its mouth. The style is long, and a ring of hairs surround the stigma, of which the upper and inner are the longest, and all of which are set upwards, so that on pressure being applied to the keel the hairs sweep out the mass of moist pollen which the stamens have thrust to the mouth (see Figs. 15 and 16). It is quite pretty to watch the little stream of bright orange pollen

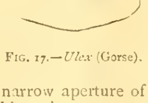

FIG. 17.—*Ulex* (Gorse).

emerging from the narrow aperture of the blue keel, and between the bright blue wings.

The shorter yellow and blue garden lupins and *Lupinus arboreus* are similarly constructed. In the latter flower the folding over of the wings at the top, and the cavity at the base of vexillum, are strongly marked.

What is the use of the hairs on the edges of the keel?

Ononis arvensis.—The vexillum in the opened flower is perpendicular or a little bent back; and the wings, which are small, are also perpendicular, so that an insect may light either on the vexillum or on the wings, and has to thrust itself between the vexillum and the wings.

The keel is long and pointed as in Lotus and Lupin: and the stamens push out the pollen as in those flowers.

The stamens are quite monadelphous, the staminal tube is close fitting, and there is no nectar and no space for nectar within it. The humble-bee certainly does not put his proboscis down the tube, but between the tube and the vexillum.

Anthyllis Vulneraria.—This flower being in an umbel needs no peculiar position to give insects a foothold. Its peculiarity is that the large calyx, the sepals of which cohere up to their narrow mouth, forms a dilated tube or vessel which contains abundance of nectar. The limbs of the wings are attached to the keel, but the claws of all the petals are long, narrow, threadlike and perfectly free, so as to leave free access to the nectar when the proboscis of an insect has once passed the mouth of the flower.

The aperture between the vexillum and the coherent wing and keel is however very narrow, so that an insect in passing it cannot fail to push the keel outwards and bring out the stiff style and stamens. The filaments are entirely joined together, and form a long close fitting tube in which there is space neither for nectar nor for the proboscis of an insect.

Ulex nanus (Autumn Gorse.)—This flower is upright in the bud, assumes the usual horizontal position when in blossom, and reverts to the upright position in the pod. The bud is protected by a stout, large and hairy calyx, and the pod is stout and hairy.

The wings are perfectly free from the keel, and the rounded lobes of the keel are separate from one another at the extremity and for a considerable part of the lower side, so as to make the flower comparatively open. The stamens and pistil are stiff, and come out on the keel being pressed down; and the pollen, which is dusty, comes out in a cloud.

The staminal tube is perfectly closed and close fitting. There is no cavity in it for nectar, and no aperture at the base. There are traces of nectar on the veins and in the hollows of the vexillum, especially on the midrib and in the hollow towards the base. The bees are fond of it. They settle on the keel and thrust their heads between it and the vexillum, pushing the latter upwards. In struggling to do this their legs are in violent motion on the top of the keel, pressing it down. In doing this they invariably open it, make the anthers project, and dust their own body with pollen ready to meet the stigma of the next flower (see Fig. 17).

The contrast between the free wings, the obtuse and semi-attached lobes of the keel, the stiff filaments, the hairless style, and the dusty pollen of Ulex, and the adherent wings, closed keel, moist pollen, and brush-clad style of Pisum, Vicia, Lathyrus, &c., and the correlation between these differences, having regard to the ultimate object in both cases, viz. the conveyance of pollen by an insect, are very striking.

Ulex Europæus is similar to *Ulex nanus*, and I have seen bees upon it in April. But are there enough of these insects abroad during the winter season, when this flower blossoms, to fertilise it?

Genista Anglica.—The wings are separate from the style, the keel is straight and horizontal, but is reflexed after maturity, probably when it has once been visited by an insect. The anthers have stiff filaments and dusty pollen, all of which is shed when the flower is once opened.

The style is stiff, and coils back on the opening of the keel, whilst the stigma is oblique. When so curved back the stigma would touch an entering insect. I have not ascertained where the nectar is in this flower, but probably not in the closed and close-fitting staminal tube.

Sarothamnus (Broom.)—The keel is perfectly free from the wings, is obtuse and closed when the flower first opens. In this stage the style is bent against the keel in such a way that its stigma (which is at the extremity) is turned away from an entering insect. At a touch the keel opens and falls down by a sort of hinge, and does not recover its position. The stiff stamens shed their dusty pollen, as in Ulex and Genista. The elastic style at the same time coils itself inwards towards the vexillum. In a few moments it has curved back so far as to complete one spiral coil, and bring the stigma round so as to meet an insect subsequently entering. In opening the flower with the finger or a pencil, the stigma does not catch its own pollen, but after recoiling can hardly fail to rub the next body which enters.

The staminal tube is complete, and there is no space for nectar or aperture into it. I have not ascertained where the nectar is to be found, but not, I think, in the thin, close-fitting staminal tube.

Cytisus (qu. nigricans?)—common in London green-houses.—The raceme is terminal; the peduncle is nearly horizontal. The pedicels are set on all round the peduncle, but in blossoming are so bent upwards as to make the vexillum of each flower nearly upright, and the keel and wings nearly horizontal, *i.e.*, so as to bring the flowers into the normal position.

The separation of the petals, the reflexion of the keel, the closed staminal tube, and the dusty pollen, are the same as in Sarothamnus and Genista. There is no nectar, and no place for any in the staminal tube.

The above details seem to point to some generalisations concerning papilionaceous flowers.

1. The position of the flowers in blossom, whatever their other wants and habits, is such as to make them attractive and convenient to insects. In general the showy vexillum is upright, and the keel and wings horizontal. This is effected in various ways: by the raising and straightening of the stalk, as in Pisum and Lathyrus; by the lowering of it, as in Faba, Phaseolus, and Ulex; or by giving the pedicel a half twist, as in Robinia, Wistaria, and Laburnum.

2. The cohesion of the petals (which in this single tribe is so various) is in each flower correlated to the position of the nectary, the structure of the fertilising apparatus, and the nature of the pollen. Thus in Ulex, Genista, and Sarothamnus, the cohesion of the petals is at a minimum, the wings do not adhere to the keel, and the keel itself is comparatively open. Correlatively the filaments are stiff and the pollen dusty, and the insect gets freely dusted with it, without aid from any union of the petals. In Pisum, Lathyrus, Vicia, Phaseolus, and others, the wings not only serve as a landing place for insects, but, being united to the keel, serve to pull it down and force out the pollen. In Trifolium, the coherence of the petals is at a maximum, and produces a complete long tube containing much nectar, and having the organs of fertilisation in the access afforded by its narrow mouth. In Anthyllis the claws of the petals are so thin and so free from each other as to afford no receptacle for nectar, whilst the staminal tube is closed and tight fitting, but the want of a nectary is made up by the cohesion and form of the calyx. The various degrees of cohesion between the petals of the keel—from the comparatively free keel of Genisteæ, through the prolonged acute keels of Lupin and Lotus, and the oblique keel of Lathyrus, to the spiral tube of Phaseolus—and the adaptation of each of these forms to its own stamens and pistil, is no less remarkable.

3. The degree to which the cohesion of the stamens is carried (so remarkable a feature in this tribe) appears to depend on the necessity for access to nectar. In

those flowers in which the stamens are monadelphous, viz., Ulex, Sarothamnus, Genista, Cytisus, Ononis, Lupin, there is no symptom of nectar within the staminal tube, no space for it, and no access to the interior. In some, at any rate, of these, viz., Ulex, Ononis, and Lupin, the bees certainly resort to other parts of the flower. On the other hand, where the tenth stamen is entirely free, or where it is separated at the base, so as to give an insect access to the interior of staminal tube, as in all the other flowers I have described, there is a cavity for nectar within the staminal tube, and there is nectar within this cavity.* As regards the double aperture, viz., one on each side of the base of the separate stamen, which so often occurs, Mr. Darwin suggests that, one aperture being necessary, the law of symmetry will account for there being two.

4. Other points in the structure of the filaments, anthers, and pollen seem also to be more or less related to and to depend upon the same function of fertilisation by insects. In Ulex, Genista, and Sarothamnus, where the flower is open, and in Lupin and Lotus, where the agency of the filaments is required to drive the pollen out of the keel, the filaments are stiff. In Phaseolus, where the style performs this function, they are limp. In Lotus and Lupin, the peculiar form and growth of the second whorl of stamens, and their adaptation to this function, is most remarkable. In Pisum, Lathyrus, Vicia, Phaseolus, and Lupin, where the pollen is moist, there is an apparatus for sweeping it out. In Ulex, Genista, and Sarothamnus, where it is dusty, the flower simply opens and it comes out of itself.

5. The structure of the style and stigma is in every case adapted so as to bring the latter in contact with an entering insect. In some cases, *e.g.*, in its emergence from the spiral keel in Phaseolus, and in the recoil of the style in Sarothamnus, this is effected by a very elaborate process. But the most peculiar function of the style in many of these flowers is that of sweeping out the moist pollen of its own flower from the keel. For this purpose it appears to be furnished with hairs or bristles, placed in different flowers on different parts, but always so placed as to perform the function in question. In Pisum, and, generally, in Lathyrus, the brush is on the inside of the style; in *Lathyrus grandiflorus* on both sides; in Phaseolus all round the style, but more thickly on the side next the entering insect than on the other; in Vicia on the outside of the style; in Lupin at the very extremity; but with all these differences it is always so placed as to find the pollen and sweep it out of the variously constructed keels. In this respect these flowers remind one of the brush-clad styles of the Campanulaceæ.

6. It is scarcely necessary to repeat that the nectar is found in various parts of the flower—within the staminal tube, in the vexillum, and in the calyx. But in all cases the correlation of the parts is such that an insect seeking the nectar must touch the stigma and carry away pollen.

These generalisations, if even partially correct, seem to me to be of considerable interest, not simply as illustrations of the mode in which insects fertilise flowers by carrying pollen from one to the other, but because by connecting the facts of morphological structure with living physiological functions, they give meaning and interest to the former, and possibly indicate the direction in which the true cause of that structure is to be sought.

It is but right to add that there is one genus, *Coronilla*, which, so far as I have been able to observe it, forms an exception to the above generalisation; but I have not been able to procure sufficient flowers to enable me to state any positive conclusion with respect to this genus; and I only mention it in order to call the attention of other observers to it.

T. H. FARRER

* I have not actually looked for and found nectar in *Onobrychis sativa* and *Lathyrus macrorhizus*, but have no doubt that it is there. I have found it in all the rest.

NOTES

DURING the absence of Prof. Tyndall in America, the opportunity is being taken to rebuild the laboratories of the Royal Institution on a considerably enlarged scale.

IT will be seen from our University intelligence that Mr. E. Ray Lankester, Scholar of Exeter College, Oxford, has been appointed Deputy to the Linacre Professor of Anatomy and Physiology at the University.

THE open Scholarship in Natural Science at St. Mary's Hospital Medical School has been awarded to Mr. Alfred Tilley, and the Exhibition to Mr. W. H. Weddell. Both these gentlemen are students of the London University.

THERE are now no fewer than five separate organisations at Cambridge for the improvement of female education—all of them thriving. 1. The examination of women, senior and junior girls, and of schools managed by a syndicate, of which the Rev. G. F. Browne, M.A., St. Catherine College, is the secretary. 2. A system of lectures for women, associated with four exhibitions, and a fund for assisting governesses, managed by a mixed committee of ladies and gentlemen, of which H. Sidgwick, M.A., Trinity College, and Mrs. Bateson, St. John's College Lodge, are the treasurers. 3. A series of classes by correspondence arranged by Mrs. Peile. 4. A lending library for students, managed by Miss J. Kennedy. 5. A college for women, called Merton Hall, of which Miss A. J. Clough is the principal. We understand that this last establishment is rapidly filling. The lectures commence this week.

THE Vestry of St. George's, Hanover Square, advertised some time ago for a medical officer of health and analyst for the parish, and a considerable number of candidates have, we understand, come forward. It has been suggested in various quarters that the Vestry would do well to appoint two officers instead of one; and on this point minds are divided. While some are in favour of a double appointment (with, we suppose, double pay?) others say that the Vestry are not likely to do this, and that it is undesirable that they should, seeing that their real want is an accomplished scientific sanitarian, who will, if necessary, appoint an assistant to do the routine chemical work, just as he has an inspector to do the routine sanitary work, but who will supervise everything and be responsible for everything. It is further urged that it is absurd to suppose that chemical knowledge is not continually required from a medical officer of health, quite apart from the provisions of the Act for the Adulteration of Food and Drugs, and equally absurd to suppose that a medical man without previous special sanitary experience is at all fitted to become at once medical officer of health to so important a parish as that of St. George's, Hanover Square. We confess we have a leaning to the latter view.

AT the last meeting of the Council of the Pharmaceutical Society, it was resolved unanimously that the resolution passed in 1862, prohibiting ladies from attending the lectures, be rescinded, and that ladies be admitted as students to the lecture classes of the Society. At present but one lady has taken advantage of the privilege offered; but as soon as the resolution becomes more widely known it is probable that the liberality of the Society will be recognised by ladies, who will avail themselves of this excellent opportunity of studying practical chemistry and botany. The lectures on chemistry are by Prof. Redwood; those on botany by Prof. Bentley, commencing early in October. The chemical lectures are continued three days a week until the end of July; the botanical lectures, lasting for the same period, being delivered on two days in the week. During the summer months they are delivered in the Botanical Gardens, Regent's Park.

A RUSSIAN lady, who desires to be anonymous, but is rumoured to be "still very young, and a native of Siberia," has

offered 50,000 roubles for a medical course for ladies, to be given at the Imperial College of Physicians. Classes are to be formed ostensibly for midwifery, but this will not exclude the higher studies of medicine. The course is to be one of four years' duration. The threat from Zurich no longer to admit the "unprepared Russians" proves thereby a wind that blows somebody some good. "I hear," says the correspondent of the *School Board Chronicle*, "that Madame Souslof's practice at St. Petersburg is actually undermining that lady's health."

THE nationalities represented at the International Commission on the Metric System recently sitting at Paris, are the following:—Great Britain, Germany, Austria and Hungary, Bavaria, Belgium, Denmark, Spain, France, Greece, Italy, Holland, Portugal, Russia, the Papal See, Sweden, Norway, Switzerland, Turkey, Wurtemburg, United States, Chili, Argentine Republic, Colombia, Equador, Hayti, Nicaragua, Peru, San Salvador, Uruguay, Venezuela. We believe, though it is a fact not generally known that Her Majesty's enlightened Government at first refused to allow England to be represented!

THE foundation stone of the New Watt Institution and School of Arts, Edinburgh, was laid on Wednesday, 9th inst., in Chambers Street, the spacious new street which runs on the north side of the College, and in front of the Industrial Museum.

THE vestry of Lambeth have appointed Mr. James Muter, F.C.S., analyst to the borough.

DR. J. E. EDDISON will deliver a course of eight lectures on "The Physiology of Circulation and Respiration," in connection with the Leeds Philosophical and Literary Society. The lectures will be strictly elementary, and as much practical illustration as possible will be introduced. The following single lectures will also be delivered during the ensuing season:—"Hill and Valley Sculpture," by Prof. Archibald Geikie, F.R.S., November 5 and 7; "The Meteorology of the Sun in connection with that of the Earth," by Prof. Balfour Stewart, F.R.S., December 3; "Radiant Light and Heat," by Prof. Balfour Stewart, December 13; "The Sense of Hearing," by Michael Foster, M.D., F.R.S, January 21, 1873; "The Primitive Social Condition of Man," by E. B. Tylor, F.R.S., February 4; "The Exploration of Moab," by the Rev. Canon Tristram, F.R.S., March 4; "On some new Phenomena associated with Magnetism," by W. F. Barrett, March 18.

THE following is the syllabus of the twenty-third session of the Manchester Scientific Students' Association:—The Physiography of Europe during the Pleistocene Age, by W. Boyd Dawkins, F.R.S., October 14. On the Glandular Hairs of the Fraxinella, Nettle, and Malpighia, by Charles Bailey, October 21. On Comparative Anatomy, by Herbert W. Oakley, October 28. On the History of a Mountain, by John Plant, November 4. On Meteors and Meteorites, by Rev. Joseph Freestone, November 18. On Horology, by Thomas Armstrong, December 2. And the following syllabus of papers is announced to be read at the Microscopical Club:—Glandular Vegetable Hairs, first paper, by Charles Bailey, October 3. On some Improvements in Oxy-hydrogen Illumination as applied to Microscopic Objects, by John Barrow, October 24. The Tetraspores of the Algæ, by John Hardy, November 14. The Polyparies of the British species of Hydrozoa, by Thomas S. Peace, November 28. The Micro-Spectroscope, by John Angell, December 12.

DURING the latter part of September, we learn from the *Times of India*, Bombay was visited by terribly destructive rains, causing not only serious injury to property, but great loss of life. Among the many instances of destruction on September 19 was that which occurred at the Library of the Asiatic Society—the largest collection of books, perhaps in India. The library is located in a series of rooms in the northern wing of the Town Hall, and before the commencement of the monsoon the roof had, as usual, been inspected, and, as it was supposed, made thoroughly water-proof. Whether owing to bad repairs, or to the excessive force of the downpour, the water found its way into one of the rooms—the room in which the librarian has his office—and completely saturated and more or less destroyed about three thousand volumes, chiefly works on jurisprudence. The expensive illustrated books, which are kept in the same room, fortunately escaped the general drenching. The injured volumes were spread out in the Town Hall to dry, but it is feared that the larger number of them are totally destroyed.

AURORÆ BOREALES were visible on the 3rd of August at Stettin and Cracow, on the 4th at Emden, on the 8th in North America, on the 9th at Emden and Thurso, on the 15th at various localities in England and Stettin. On the 7th of August a smart shock of earthquake was felt at Innsbrück, which was followed by three more on the 8th of the same month.

ON the 9th and 10th of September a severe hurricane passed over the islands of Guadaloupe, Martinique, Dominica, St. Kitts, Barbadoes, &c. Sixteen vessels, including the steamer *Isleman*, was wrecked at Martinique, and several lives lost. Every vessel in the port of Dominica was struck to pieces, and there also many lives were lost. Several ships were driven on shore at St. Kitts. The gale lasted all day on Tuesday, the 19th instant, the barometer commencing to fall from ten o'clock on the previous morning.

THE following is from the *Athenæum*:—A singular controversy has occurred at Constantinople. The Government have determined that instruction in the Imperial School of Medicine shall be given in Turkish, and have removed all the professors who cannot speak the national language. Of course this has occasioned an outcry on the part of the friends of those French-speaking professors who have spent many years in the country and have not chosen to acquire its language. The Turks say they started their school as a national school, and not as a foreign one; that the pupils receive inadequate instruction from its being conveyed in a foreign language; and that they have not been supplied, as they expected, with manuals in Turkish. The authorities have, therefore, determined to run the risk of the change, and attempt to get for this school, as for others, books and teaching in the vernacular. They maintain that, as medicine has for ages been taught in Arabic, it can be taught in Turkish.

THE *Moniteur Scientifique* informs us that at Proskau, in Upper Prussian Silesia, near the Prussian-Polish frontier, an agricultural college on a large scale has been established by the State, in which everything relating to agriculture, horticulture, arboriculture, and the rearing of cattle, horses, bees, and poultry is practically taught. In addition to several smaller lecture-rooms, there are two large amphitheatres, which will accommodate 200 students each; three separate chemical laboratories; a large distillery; beetroot sugar works; model brewery; museum for mineral and botanical collections; collection of agricultural implements; library containing 6,000 volumes; four farms. 5,000 hectares of forest land, and 4,000 hectares (= 2·47 acres to the hectare) of arable meadow land are attached to this institution, in which instruction is given by a staff of twenty-four professors. Proskau has 1,900 inhabitants, of whom 1,500 are Poles.

THE *Times of India* of August the 16th states that an agricultural society, to be called the "Bombay Presidency Agricultural Society," composed of influential gentlemen, has been organised in Bombay. The object of the society is to diffuse agricultural knowledge amongst the people in the Bombay presidency, by establishing a journal and issuing separate tracts on agriculture in Marathi and Guzerati, and, if possible, by founding schools for this special purpose. The journal and tracts will

supply a want that has been felt for some time past, and the new society is one that ought to succeed, and, if properly managed, will be sure to be of immense service in the Bombay Presidency.

WE learn from the *Garden* that the directors of the Alexandra Park Company have requested Mr. M'Kenzie to prepare a scheme for establishing a school of horticulture, for which purpose about twenty acres of the grounds attached to the building will be set apart. As we have no school of horticulture in this great gardening country, we hope something more may come of this than of its short-lived and feeble forerunners.

THE Portuguese *Jornal de Horticultura Pratica* announces a forthcoming "Flora" of that country, by Señor Barao de Castello de Piava, who was formerly Professor of Botany in the Academia Polythenica. Great things are expected from the new work, in which the subject will be brought up to the level of the knowledge of the present day, including all the discoveries which have been made since the time of Brotero, whose once celebrated "Flora Lusitanica" is now seldom to be met with for sale.

A NEW *Revue des Sciences Naturelles* has recently been started at Montpellier under the management of MM. Dubreuil and Kecker, to be published every three months.

WE learn that the publication of the *American Journal of Conchology* has closed with the completion of its seventh volume. This quarterly, edited by Mr. George W. Tryon, has appeared under the auspices of the Academy of Natural Sciences in Philadelphia, and has included, from time to time, a great many very important conchological monographs, chiefly presented to the Philadelphia Academy, many of them accompanied by coloured plates. Hereafter, such communications will be published in the Journal of the Proceedings of the Academy itself.

THE Second part of the *Quarterly German Magazine*, just received, contains translations (still into very indifferent English) of only two articles: Dr. J. Rosenthal on Electric Phenomena, and Prof. de Bary on Mildew and Fermentation.

Les Mondes has a long description, with illustrations, of the new "Horloges electriques" of M. C. F. Milde, the principal of which is a commutator for distributing the hours in all directions. It consists of an electro-magnet proportioned to the requirements, whose armature, at the moment of attraction, acts upon the arm of a lever, which governs a sector, whose centre of rotation is upon a pillar.

AN apparatus has been recently devised in Germany for obtaining specimens of water at any desired depth of the ocean. A strong, heavy vessel, entirely closed and empty, has a valve through which water may be admitted, but which is only put in motion by means of powerful electro-magnets connected therewith. These magnets are also connected with a wire which accompanies the rope, by means of which the apparatus is lowered from the ship. When the empty vessel, which is in fact a plummet, has reached the required depth, an electric current is sent from the battery on shipboard to the coils below; the magnetism thus generated opens the valves, and the vessel is filled and ready to be drawn up.

ACCORDING to the correspondence of the *New York Herald*, an ingenious plan has been adopted by Prof. Agassiz's expedition for determining how far the submarine regions are pervious to light. A plate prepared for photographic purposes is inclosed in a case so contrived as to be covered by a revolving lid in the space of forty minutes. The apparatus is sunk to the required depth, and at the expiration of the period stated is drawn up and developed in the ordinary way. It is said that evidence has thus been obtained of the operation of the actinic rays at much greater depths than hitherto supposed possible.

THE BIRTH OF CHEMISTRY

II.

Thales of Miletus—Later beliefs in his doctrine—Anaximenes—Empedokles—Herakleitos—Anaxagoras—Demokritos—The Atomic Theory—Aristotle—The Ethereal Medium—Transmutation of the Elements—The Four-element Theory—Mode of interpreting it—Cause of the absence of Natural Science among the Ancients.

THE elements of the Greek philosophers were, as we shall presently show, rather *principles* than elements in the sense in which we speak of the sixty-five elements now known to chemistry. There was a marked tendency in the earliest period of Greek philosophy to make one element or principle fundamental, and to evolve the other elements and the world from it. Thales, of Miletus, who lived in the sixth century, B.C., and who was called "the first of natural philosophers" by Tertullian, and the "first who inquired after natural causes" by Lactantius, affirmed that water was the first principle of things, perhaps, according to some writers, because Homer had made Okeanos the source of the gods. At least we are reminded of the boundless watery chaos of older cosmogonies. This doctrine of Thales was not without its supporters during the Middle Ages, and, indeed, the convertibility of water into earth and air was not absolutely disproved until about a century ago. One of the ablest supporters of the dogma was Van Helmont (b. 1577, d. 1644), who affirmed that all metals, and even rocks, may be resolved into water; animal substances are produced from it, because fish live upon it; and vegetable substances may be also produced from it. This last assertion he endeavoured to prove by what would appear to be a very conclusive experiment in those days, when neither the composition of the air nor of water was known. He took a willow which weighed five pounds, and planted it in two hundred pounds of earth, which he had previously carefully dried in an oven. The willow was frequently watered, and at the end of five years he pulled it up and found that its weight amounted to one hundred and sixty-nine pounds and three ounces. The earth was again dried, and was found to have lost only two ounces. Thus it appeared that 164lb. of wood, bark, roots, leaves, &c., had been produced from water alone. Hence he inferred that all vegetables are produced from water alone; not knowing, as was afterwards proved by Priestley, that a constituent of the atmosphere called carbonic acid had furnished the solid part of the tree, although, indeed, there was much water with it. Boerhaave devotes a page of his big book to a discussion of "whether water be convertible into earth." He concludes that the small earthy deposit observed when rain-water is distilled, arises from the particles of dust which had settled on the water before its introduction into the distilling vessel. Mr. Boyle had previously affirmed that "a very ingenious person, who had tried various experiments on rain-water, put him beyond all doubt about this transmutation, for he solemnly affirmed, on experience, that rain-water, even after distillation in very clean glasses, near two hundred times, afforded him this white earth." Finally, Lavoisier, in 1770, communicated to the *Académie des Sciences* an elaborate paper, "On the nature of water, and the experiments by which it has been attempted to prove the possibility of changing it into earth." In this he conclusively proved that water cannot be changed into earth, although it be distilled backwards and forwards for many successive days. Here then we find the old Thalesian theory at last disproved, but not before it had endured for twenty-four centuries; and this is by no means a solitary example of the permanence of old ideas. We shall become acquainted with yet older theories, which are still admitted, and which seem to be essential to physical philosophy.

On the other hand, Anaximenes regarded air as the primal element, Herakleitos fire, Pherekides earth, and some philosophers grouped two elements together. Anaximenes held that clouds were caused by the condensation of air, rain by the condensation of clouds; he appears to have clearly connected condensation with cold, rarefaction with heat. Archelaus affirmed that air when rarefied becomes fire, when condensed, water. It was very generally believed during the Middle Ages that water when boiled was converted into air. Empedokles introduced the idea of four distinct elements—earth, air, fire, and water, not capable of passing one into the other, but forming all things by their intermixture. These elements are acted upon by two principles, a uniting force of amity, a separating force of discord, corre-

sponding somewhat to our attraction and repulsion. He endeavoured to prove the four-element theory by the following crude experiment: wood is burnt upon a hearth, fire seems to be evolved from it, the smoke is air, moisture is deposited on the hearthstone, while the ashes are earth, hence wood is made up of earth, air, fire, and water. Empedokles was one of the first to materialise the Homeric gods; he applied his four-element theory even to them, declaring that Zeus was the element of fire, Here the element of air, Nestis the element of water, and Aidoneus the element of earth. Herakleitos (about 460 B.C.) made fire the primal element, and assumed that it condensed itself into the material elements, and that air, water, and earth were respectively formed as the fire became more condensed. He asserted, moreover, that all things are in perpetual motion and change, the moving force being fire; "fire is to him," says Schwegler, "even in individual things, the principle of movement, of physical as of spiritual vitality; the soul itself is a fiery vapour." We find in the fire of Herakleitos to some extent the attributes of what we now call a physical force; thus it is precedent to matter, and is the motive power of the universe, it influences and changes matter, it is perpetually undergoing transformation, but ultimately returns to its own form. Prof. Max Müller speaks of Herakleitos as "one of the boldest thinkers of ancient Greece." We can well understand why fire should, at a very early date, be regarded as chief of the elements, and the motive power of the universe; it had long been worshipped as a symbol of the deity by the Chaldæans; a worship which possibly originated with the Scyths; for Zoroaster, who introduced fire worship among the Medo-Persic races, is supposed to have been a Scythian. Again, Agni, the god of light and fire, was placed first in the Hindu Trinity.

Anaxagoras of Klazomene (B.C. 500) asserted that originally all things existed in infinite disorder; before the creation there was a chaos of mingled particles of matter, which were arranged in order by a designing intelligence or mover of matter (νοῦς). The primitive constituents of things are not definite elements, like those of Empedokles, but are *homœomeries* (ὁμοιομέρειαι) that is *like parts*, small particles of matter like the masses they produce when they aggregate. Thus a mass of iron is produced by the aggregation of an infinite number of iron-homœomeries brought out of the chaos by the νοῦς, which latter possesses vortical motion which enables it to separate like parts and bring them together, somewhat on the principle of gold-washing. If a dish containing substances of different relative weight, such as cork, sand, and lead shot, intimately mixed together, be caused to rotate, like particles will come together, the lead in one place the sand in another, and this experiment will help us to realise to some extent the meaning of Anaxagoras when he assumes that the vortical motion of the νοῦς caused homœomeries to aggregate and form the world. Leukippos taught that the world is produced by the falling together of small indivisible particles or *atoms* (from α and τεμνω), which are the principles of things, and which possess rapid circular motion. Demokritos (460 B.C.) extended the atomic theory of Leukippos; he contended that the principles of things are atoms and a vacuum. The atoms are invisible by reason of their smallness, indivisible by reason of their solidity, impenetrable and unalterable. They have no other qualities, neither heat, nor cold, nor colour. Atoms are infinite in number, the vacuum is infinite in magnitude. Atoms differ from each other in size, shape, and weight. They are actuated by necessity or fate (ἀνάγκη), and possess an oblique motion in the vacuum, which causes atoms of like shape to collide and group themselves together, by which means all things are formed. The vacuum is necessary, otherwise motion of the atoms would be impossible, because there would be no place to receive them. Long before the time of Demokritos an atomic theory had been proposed in India by Kanáda, the founder of the Nyaya system of philosophy, of which this theory forms the distinguishing feature. The theory of Leukippos is attributed by Possidonius to Moschus, a Phœnician. During the Middle Ages many writers made the atomic theory a prominent part of their system. Descartes adopted it in a somewhat modified form, and associated with his particles the vortical motion possessed by the homœomeries of Anaxagoras. Finally, almost in our own day, the atomic theory was introduced into chemistry by Dalton, and its introduction marked an important era in the science. At the present time the doctrine of atoms forms a principal feature in chemistry, and other branches of science find the conception most conducive to the philosophical explanation of phenomena. The definition of an atom given by Demokritos is almost as absolute and precise as that which we find in our most modern treatises. Thus the theory has endured for more than twenty-five centuries, and is likely to endure until there shall be no more science. It offers a striking example of the oneness of physical thought; the conception seems to be essential to Natural Philosophy; the most stupendous phenomena may be referred to atomic motions. S. Augustine has well said, "Deus est magnus in magnis, maximus autem in minimis."

The Hindus not only possessed the idea of the atomic constitution of matter, but further associated an attractive force with the atoms. This is well shown in the following extract given by Sir William Jones, from the poem of "Shi'ri'n and Ferhád, or the Divine Spirit, and a human soul disinterestedly pious":—"There is a strong propensity, which dances through every atom, and attracts the minutest particle to some peculiar object; search this Universe from its base to its summit, from fire to air, from water to earth, from all below the moon to all above the celestial spheres, and thou wilt not find a corpuscle destitute of that natural attractibility; the very point of the first thread in this apparently tangled skein; is no other than such a principle of attraction, and all principles beside are void of a real basis; from such a propensity arises every motion perceived in heavenly or in terrestrial bodies; it is a disposition to be attracted, which taught hard steel to rush from its place and rivet itself on the magnet; it is the same disposition which impels the light straw to attach itself firmly to the amber; it is this quality which gives every substance in nature a tendency towards another, and an inclination forcibly directed to a determinate point."

The most prolific writer on Science amongst the ancients was Aristotle (b. 385 B.C., d. 322). He was the author of various treatises, on the Heavens, on Generation and Corruption, on Physics, on Respiration, on Audibles, &c., and his views as well on metaphysics and ethics, as on science, were nearly universally accepted during the Middle Ages. Indeed, the scientific writings of Aristotle influenced science for nearly twenty centuries. Few, however, of his opinions concern us here. He was the first to introduce into Greek philosophy the *ether*, which he regarded as a fifth element (hence afterwards called *quinta essentia*) more subtle and divine than the other elements. The word quintessence is frequently used by the alchemists and early chemists, and is found in our most recent English dictionaries. The idea of an infinitely rarified and all-penetrating matter had long existed in physical philosophy, notably in the Hindu systems; it was probably recognised as a fifth element prior to the ninth century B.C. Aristotle is said to have called it αἰθὴρ from ἀεὶ and θέω, because he conceived it to be always in motion, and to be the moving agency of the other elements; but we cannot admit this derivation now, and prefer to trace it to αἴθω and *indh*. In the present day we find it impossible to explain various phenomena, notably those connected with radiant heat and the polarisation of light, without assuming the existence of some rare ethereal medium, cubic miles of which would not weigh a milligramme, and we still call it the ether. Few physical systems have avoided this supposition; we make less use of it in chemistry than in physics; but it would be difficult to account for such actions as the combination of chlorine and hydrogen under the influence of light, without it. Aristotle held that the four elements are mutually convertible, and he assigned two qualities to each, one of which was common to some other element. Thus he said:—

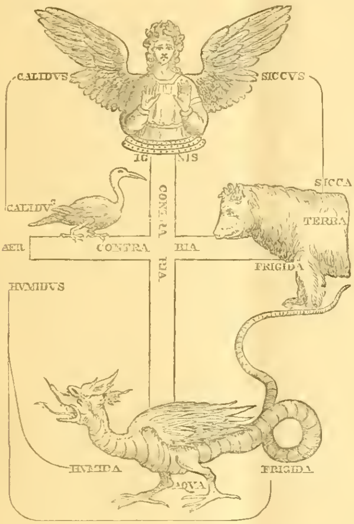
Fire is hot and dry.
Air is hot and moist.
Water is cold and moist.
Earth is cold and dry.

In each of these one quality is dominant. Thus fire is more hot than dry, air more moist than hot, water more cold than moist, and earth more dry than cold. If the dry of fire be vanquished by the moist of water, air will result; if the hot of air be vanquished by the cold of earth, water will result; if the moist of water be vanquished by the dry of fire, earth will result. This idea of the transmutation of the elements was adopted generally in works on alchemy; the following figure which embodies it is from a work entitled "Preciosa Margarita Novella," published in Venice in 1546.

Aristotle's method of expressing the transmutation of the elements does not seem to differ much from that of earlier philosophers; it would appear that he means to imply that if water be heated air is produced, while if it be heated more strongly so as to evaporate it to dryness, earth is left. His account of the generation of fire from air and earth is based on the most shallow and meagre observation, and shows to what results the most

astute mind may be led if unaided by experiment. The generation of fire, he says, is made evident by the senses, for flame is notably fire, but flame is burning smoke, and smoke is from air and earth.

It is not here that we may tell how the philosophy of Aristotle was introduced into Europe by the Arabians, how from it arose that stupendous mass of false philosophy and perverted Aristotelianism called Scholasticism, and how for centuries the blind acceptance of the Peripatetic dogmas retarded the progress of science. Worse than all, Averroës, who has been called "l'âme d'Aristote," and who scattered Aristotelianism broadcast over Europe, did not know Greek, and the Latin versions of Averroës were "Latin translations from an Hebrew version of an Arabic commentary on an Arabic translation of a Syriac version of a Greek text." We may not, therefore, blame Aristotle for the results which followed from the too general and literal acceptance of his philosophy. Mr. Lewes has well said, "However he may have been impelled to systematise on imperfect bases, and to reason where he should have observed, it is not too much to say that had he reappeared among later generations, he would have been the first to repudiate the servility of his followers, the first to point out the inanity of Scholasticism. His mighty and eminently inquiring intellect would have been



Alchemical Representation of the Transmutation of the Elements.

the first to welcome and to extend the new discoveries. He would have sided with Galileo and Bacon against the Aristotelians."

We have spoken above of the endurance of the Thalesian theory, that all things are formed from water, and of the yet older theories of the existence of an ethereal medium, and of atoms; but the theory which affirms that the world is composed of the four elements—earth, air, fire, and water, is yet older, and is, indeed, the oldest physical theory of which we have any knowledge. It certainly existed before the fifteenth century B.C., it was adopted in India, Egypt, and as we have seen, in Greece at a very early date. Then in the case of those philosophers who made water, air, fire, &c., primal elements, this element was first transmuted into the three other elements, and the world was formed from the four. We must be careful, however, to remember that these four elements are not to be understood too literally, they were rather principles or types of qualities than actual elements. Several philosophers divided fire into a purer and grosser part. Seneca tells us that the Egyptians extended the theory by assigning to each element an active and a passive form: thus fire was divided into light which shines, and into fire; air into passive atmosphere and active wind; water into fresh and salt water; and earth into cultivable land on the one hand, and rocks on the other. These elements were extended yet more. In later times *Fire* would come to signify everything appertaining to ignition; thus light, whether accompanied by heat or otherwise, flame, the heat inherent in all bodies, incandescent bodies, stars, fiery meteors, lightning, and all visible manifestations of electricity, would be included under the term. *Air* would include smoke, steam, all vapours, and whatsoever approached to the nature of a gas. When gases were first discovered a hundred years ago, they were called *Airs;* thus we read of *fixed air*, *nitrous air*, *dephlogisticated air*, &c. *Water* would include all liquids, of which, no doubt, blood, milk, wine, and oil, were in early times the most familiar; the words *aqua fortis*, *aqua regia*, *aguardiente*, *eau-de-vie*, &c., are vestiges of the old practice. *Earth* included all rocks, however dissimilar they might be, all kinds of cultivable land, metals, and whatever appertained to solidity. Every solid was regarded as a kind of earth at first. A century ago many substances were called earths. At the present time out of the sixty-five elements known to the chemist, eight are classed as "earths" and three as "alkaline earths." The fact is, the four ancient elements were types of great classes of which the whole world was constituted. In their most general sense, *earth*, *water*, *air*, signified *solidity*, *liquidity*, *gaseity*, while *fire* was the force exercising itself upon matter. We have seen that the elemental fire of Herakleitos is the mover of matter, the principle of movement, that which produces perpetual changes around us. Fire was the ψυχή, the anima, the soul, the vivifying spirit. The mythological side of the belief is seen in the story of Prometheus, who is fabled to have stolen fire from Heaven and therewith vivified mankind. The philosophical side of the belief is seen in the dogmas of Herakleitos. The four-element theory evolved itself from the crude ideas about ether and chaos, mind and matter, before discussed; it is one of those crude physical theories which is enunciated and accepted by races the most diverse in character, country, faith, destiny. There is great oneness in the human mind in the matter of broad principles in crude cosmical ideas. And let us not forget that the four-element theory was universally accepted during the Middle Ages, and was only disproved a century ago, when air was proved to be a mixture of two gases, water a combination of two gases, fire the result of intense chemical action, and earth a mixture of some dozens of elementary bodies, some combined, some single. We do not deny that during the continuance of the four-element theory it may often have been taken in its strictly literal sense; but we do venture to assert that the richer and more cultured intellects regarded it in the light we have above described.

We can quite understand why there was so little natural science among the ancients, when we remember the absence of all experimental method and means, and the obstacle presented by the habit of mind which induced them to apply reasoning in place of experiment in the study of nature, to reason upon an immature or ill-observed fact, and to generalise upon altogether insufficient data. A simple sophistry applied to observation could lead to the most monstrous results. Take, for example, the argument of Diodorus, as given by Sextus Empiricus to prove that nothing is moved:—"If a thing be moved, it is either moved in the place where it is, or in the place where it is not. But not in that wherein it is, because it rests in the place wherein it is; neither in that wherein it is not, for where a thing is not, there it can neither act nor suffer. Therefore nothing is moved." Again, Sokrates and many of his followers taught that it was unwise to leave those affairs which directly concern man, to study those which are beyond his control and external to him. Thus, to inquire into the nature and distance of the stars seems an useless speculation, because even if we could ascertain these things, we could neither alter the course of the stars nor apply them to any benefit of mankind.

We have, however, seen above that many of the Greek philosophers had more or less definite notions concerning matter and force, and that they frequently insist upon the transmutation of matter from one form into another; so far and so far only are we concerned with their dogmas in our inquiry into the Birth of Chemistry. But we must not fail to notice the existence at a very early date of the four-element theory, of an atomic theory, of the idea of an ethereal medium, of the idea of transforming one kind of matter into another by the agency of some motive principle. Neither let us forget to note the similarity of principles in diverse philosophies; thus the homœomeries of Anaxagoras and the atoms of Leukippos are clearly related, so, too, are the

νοῦς of Anaxagoras, the ἀνάγκη of Demokritos, the actuating form of fire of Herakleitos, the moving ether of Aristotle. The links which bind together ancient and modern physical thought are strong and enduring, and since they have lasted during the rise and fall of many nations, and during the most profound changes in the mode and tone of thought, it is not unlikely that they will endure as long as the chain itself.

G. F. RODWELL

THE DIATHERMACY OF FLAME

I HAVE just read Mr. Ericsson's paper on "The Sun's Radiant Heat" in NATURE, October 3, p. 458, and find that he has made some experiments on the diathermacy of flame closely resembling those which I made in 1869, and described in chap. viii. of "The Fuel of the Sun" published January 1870. Although the object of our investigations was identical and the method of proceeding very similar, the results obtained are so contradictory that one of us must be quite wrong, and therefore I think the subject demands discussion.

Referring the reader to the engraving illustrating Mr. Ericsson's paper, I may easily describe my apparatus. Like Mr. Ericsson's, there was a gas-pipe from the side of which projected a row of burners, each provided with a separate stop-cock. My burners, however, differed from his in being perpendicular to the main pipe which was always used in a horizontal position. My blackened bulb thermometer was similarly fixed at one end of a chamber or vessel, the other end of which was open to receive the radiations from the flames. This, however, was much simpler than Mr. Ericsson's. It had not the double chamber with intervening wall, nor was it surrounded by water, but was simply a thin tube of tin plate *polished inside* to prevent absorption of radiant heat. The thermometer was insulated from metallic contact with this tube, and thus could only receive heat from it by radiation, which the polishing reduced to a minimum. The sectional form and opening of the tube was made to correspond nearly with that of the presented side of the gas flames, but was somewhat larger.

At first I used Bunsen-burner flames, then flat flames like those figured by Mr. Ericsson, afterwards simple jets formed by the gas issuing from a small pin-hole, the jets being far enough apart to be quite independent; finally a row of such jets so near to each other that they came in contact, coalesced fully, and formed one sheet of flame, the edge of which was presented to the mouth of the polished tube containing the thermometer.

Guided by results obtained in a previous series of photometric experiments on the transparency of flames to their own special radiations, and by the first experiments I made on diathermacy, I relied on the arrangement last described, viz. the coalescing jets. The reason for this will presently appear.

My mode of proceeding differed in another respect from Mr. Ericsson's. Instead of lighting one jet at one end and then another and another in succession towards the thermometer, I always worked with an odd number of flames, and began with the middle jet, then lighted one on each side, next one on each side of those three, then one on each side of those five, and so on. My flames were thus maintained at a constant mean distance from the thermometer.

By means of a well-constructed experimental gas meter, with micrometic regulator, and a minute alarum clock, the supply of gas was accurately adjusted, so that each additional jet, or pair of jets, should consume an exactly equal differential increase of gas. The results obtained were as follows:—

Number of Jets	Consumption of gas in cubic feet per hour	Highest reading of Thermometer
1	1·0	19°·0 Cent.
3	1·5	23°·0 ,,
5	2·0	27°·0 ,,
7	2·5	31°·0 ,,
9	3·0	35°·5 ,,
11	3·5	39°·0 ,,
13	4·0	43°·5 ,,
15	4·5	48°·0 ,,
17	5·0	53°·0 ,,

Here, then, is a serious discrepancy. I get an increase of 4° by the first addition of two flames, and by eight of such additional pairs obtain an increase of 34°, instead of the 32° due to theoretical diathermacy. These 2° of excess (being due to the latter end of the series) I attributed to the increased temperature of my apparatus.

Mr. Ericsson obtained an increase of only 7°·9 instead of 17°·6, the theoretical requirement.

Without any disposition to underrate the value and importance of Mr. Ericsson's researches, I think that in this matter he has been deceived by overlooking some important sources of fallacy.

1. He tells us nothing about the quantity of gas consumed. His jets all issue from the same main pipe, which he describes as supplied with "gas at ordinary pressure." Now with such a supply the quantity of gas burning from each jet would steadily diminish as he turned on the additional jets. On turning the second jet the first would diminish; when the third was turned the supply to both first and second would be reduced; and so on, to an extent depending upon rates of sectional area of the supply pipe to that of the jet holes. If Mr. Ericsson's drawing is made to scale, the error due to this was of great magnitude.

A second source of error is described in Mr. Ericsson's own words; he says, "It will be observed that the prolongation of the axis of the conical vessel upwards passes through the central portion of the flames at the point of maximum thickness and intensity." Now the point of maximum thickness of a flame is just that part which is hollow, and consists of a central core of unburnt gas with an outer coating of true flame, and the central portion of such a flat flame as Mr. Ericsson represents includes much of the blue portion of the flame, consisting of hydrocarbon not yet in full combustion. Mr. Ericsson, therefore, was not experimenting upon the diathermacy of ten flames, but upon the diathermacy of ten discs consisting of a mixture of flame proper and unburnt hydrocarbon. Now Tyndall has demonstrated the remarkably high resisting or absorbing power of such hydrocarbon in reference to the radiations from a flame produced by hydrocarbon combustion. The flame itself might therefore be perfectly diathermous, and yet, when examined in this manner, exhibit a considerable degree of athermacy.

There is still a third source of error in Mr. Ericsson's mode of proceeding, the magnitude of which I am not yet able to estimate, though some experiments made since publishing my first results lead me to suspect that it is sufficiently important to demand very careful elimination. I allude to the arrangement of a series of separated flat flames, with the broad surfaces presented to the thermometer.

What must we have between each of these separated flat flames? Obviously each flame is coated with a film of vapour, the product of the combustion of those portions of flame lying below it; these vapours, though rapidly rising, must form a layer of sensible thickness equal to an important fraction of the whole thickness of such thin flames. When operating with the whole eleven flames, there were twenty-one such films between the first flame and the thermometer. Now, we know from the experiments of Tyndall, that a large proportion of the rays of heat emitted from a hydrocarbon flame will be absorbed by such intervening strata of aqueous vapour, carbonic acid, and carbonic oxide. It is true that the middle or blue part of the flame, having less combustion going on below it, must have a thinner coating of such vapours than the upper part; and thus in Mr. Ericsson's arrangement this third source of error is diminished in the same proportion as the second is increased. It was these theoretical considerations, confirmed by results of preliminary experiments, that induced me to abandon the flat flames in favour of the simple round jets, and finally to adopt the continuous flame formed by the coalescent jets.

As I stated on the first publication of the results of these experiments on the diathermacy of flame, I do not regard them as sufficiently delicate to be finally and quantitatively conclusive; the means at my disposal rendered them less satisfactory than those I made on the transparency of flame. Still, I think they are not open to any such serious sources of error as those I have here pointed out.

I hope that Mr. Ericsson will not be offended by the candour of my criticism, nor by the egotism which is inevitable in an unaffected defence of one's own philosophical bairns.

My experiments, like those of Mr. Ericsson, were made with the direct object of throwing some light upon the great mystery of solar radiation; and the fact that we have arrived at such opposing conclusions will, I hope, lead to further investigation,

and finally to a settlement of the important fundamental physical question, whether the properties of flame, in reference to the absorption and transmission of heat and light, are, as I have ventured to suggest, diametrically opposite to those of gases and vapours—whether flames are specially transparent and diathermous to rays of their own emission, and resist the passage of heterogeneous rays; that a flame is thus not merely heated gas, but another and distinct form of matter, or rather is matter in a different state of activity.

If this be established, we shall be driven back upon "the wisdom of the ancients," and be forced to admit the classification of the four elements, "fire, air, earth, and water," or flame, gas, solid, and liquid; remembering, of course, that they used the term "element" with a different meaning to that of our modern acceptation. They described elementary or necessary conditions, not elementary constituents. It was the philosophy of material existence, not the composition of material substances, which chiefly occupied their attention. From this point of view their classification may, after all, prove to be correct.

I must reserve for another communication some remarks I proposed to make on the application of the above to Mr. Ericsson's researches on the radiation of the chromosphere.

W. MATTIEU WILLIAMS

SCIENTIFIC SERIALS

THE part of the *Transactions of the Linnean Society* just published, forming the 2nd part of vol. xxviii, consists of two elaborate botanical papers; "Memoir on the Spermogones and Pycnides of Crustaceous Lichens" by Dr. Lauder Lindsay; and "On the Hippocrateaceæ of South America" by Mr. Miers. Of the important features of the latter paper we gave a sketch on the occasion of its being read before the Society. It is illustrated by seventeen very beautiful plates executed by the author. The first is an extremely elaborate paper, illustrating the great variation in the spermogones and pycnides in the same species of lichen, and even in the same individual. For this purpose as many as twelve or even 20 specimens of the same species, preserved in various herbaria, are in some cases minutely described. This paper is also illustrated by eight coloured plates.

THE *American Naturalist* for August does not contain so many original articles as usual. The Rev. Samuel Lockwood describes a new Entozoon from the eel, belonging to Duvaine's type, the Acanthocephala or spiny-heads, but forming a new genus; the name proposed is *Koleops anguilla*. Dr. J. J. Woodward has a paper on the use of monochromatic sunlight, as an aid to high-power definition; and the Rev. H. J. Bruce describes some of the familiar birds of India. Among the shorter articles there are some very interesting notes.

The number for September opens with an interesting article by Mr. S. H. Scudder, the curious history of a butterfly. The American butterfly *Brenthis bellona* occurs in two different forms produced at different times of the year, in both cases the larva hibernates, but with one set when just out of the egg, with the other when half grown, the butterfly appearing in one case in May, in the other in September; and it seems impossible that these two parallel races of the same species can ever mingle. Prof. N. S. Shaler has a paper on the Geology of the Island of Aquidneck and the neighbouring parts of the shores of Naragenset Bay; and Dr. R. H. Ward sends a microscopical contribution entitled "The new Immersion Illuminator." Mr. C. V. Riley, who has paid great attention to the *Phylloxera* and other diseases of the vine, has some valuable remarks on the cause of the deterioration of some of the native grape-vines, which he has contributed to his report as Entomologist to the State of Missouri.

THE *Quarterly Journal of Science* for October commences with two meteorological articles, the Origin of the Great Cyclones, by Prof. T. B. Maury, and an anonymous paper on Weather Prophecies. The author of the former article considers it proved that cyclones are formed chiefly, if not exclusively, along the edges of the great atmospheric currents, the surface currents and the upper currents alike, the polar streams which descend into our valleys, and the aerial gulf streams which move invisibly over our heads. Capt. Oliver continues his series of papers on the Amorpholithic Monuments of Brittany, and in continuation of a previous series we have an article on Natural and Artificial Flight—an Aerial Ship. Mr. F. C. Danvers, on Paper in the International Exhibition, gives a slight sketch of the history of the manufacture of paper and of the various specimens to be seen in the Exhibition. The Physiological Position of Tobacco, by Mr. E. A. Axon is a powerful attack on the use of the weed as not only unnecessary and destitute of any beneficial results, but positively injurious.

THE first paper in the *American Journal of Science and Arts* for September is by Prof. J. W. Draper, "Researches in Actino-Chemistry," from which we have already reprinted an extract on the distribution of heat in the spectrum. Prof. Shepard concludes his account of the Corundum region of North Carolina and Georgia; and then follows a sketch of Barrande's account of the origin of Palæozoic species. Mr. A. A. Hayes has a long article on the red oxide of zinc of New Jersey. In Prof. O. C. Marsh's continuation of his preliminary description of new Tertiary Mammals are descriptions of a large number of new genera and species.

IN the *Geological Magazine* for October (No. 100), the Editor, Mr. Henry Woodward, gives us notes, illustrated with excellent figures, on some British Palæozoic Crustacea belonging to his order Merostomata. These notes include a full description of *Hemiaspis limuloides*, a species originally established by Mr. Woodward in 1865, and also shorter characters of three other species of the same genus, namely, *H. speratus* (Salt ms.), *H. horridus*, sp. n., and *H. Salweyi* (Salt). These Silurian forms are particularly interesting as they constitute a connecting link between the suborders Eurypterida and Xiphosura.—Of the latter group Mr. Woodward here notices some species of the genus *Bellinurus*, and describes a new form under the name of *B. Königianus*, also a new *Prestwichia*, *P. Birtwelli*, both from the Coal measures.—Mr. W. T. Aveline publishes a short note on the continuity and breaks between the various divisions of the Silurian strata in the Lake district, and Messrs. Davidson and King some remarks on the genera *Trimerella*, *Dinobolus*, and *Monomerella*. In this paper the authors propose the establishment of a new Brachiopod family, Trimerellidæ, allied to the Lingulidæ.—Dr. H. A. Nicholson describes a new genus of fossil tubicolar Annelides founded upon a division of the fossils hitherto referred by Palæontologists to *Tentaculites*. The so-called genus *Tentaculites*, according to Dr. Nicholson, includes forms belonging to the Pteropodous Mollusca and others which are true tubicolar Annelides, the former being free shells, the latter attached to other bodies. He proposes to retain the name *Tentaculites* for the Pteropods, and to establish a new genus, *Ortonia*, for the Annelides. He describes and figures a new species of the latter from the Cincinnati group of the Lower Silurian of Ohio under the name of *Ortonia conica*.—The concluding article in the number is a further instalment of Prof. Nordenskiöld's account of the Swedish Greenland Expedition of 1870.

SOCIETIES AND ACADEMIES

PHILADELPHIA

Academy of Natural Sciences, April 2.—Prof. Leidy made some remarks on specimens of fossils of extinct mammals from the Tertiary of Wyoming. One of these is an upper jaw fragment with two molars; the other a lower jaw fragment with a single molar. The upper molars have crowns composed of four lobes, of which the outer are like the corresponding ones in *Anchitherium*. Of the inner lobes, the front one is much the larger, and is prolonged outwardly in advance of the antero-external lobe. It is homologous with the antero-internal and antero-median lobes as existing in *Anchitherium* in a completely connate condition. The postero-internal lobe is the smallest of the crown. It is conical and conjoins that in front. A barely perceptible trace of a postero-median lobe is seen. A strong basal ridge incloses the crown, except externally, where it is feebly produced. The three upper molars occupied a space of 8 lines. The first molar is $2\frac{1}{2}$ lines fore and aft and $3\frac{1}{4}$ transversely; the second is $2\frac{3}{4}$ lines fore and aft, and the last one $2\frac{1}{4}$ lines. A question arises as to whether these teeth pertain to any of the animals previously indicated from lower jaw specimens with teeth. They are too large for the known species of *Hyopsodus* or *Microsyops*. They nearly accord in size with the lower molars of *Notharctus*, and perhaps belong to this genus. *Limnotherium* appears not to differ from this, as the number of teeth and their constitution are the same. The lower jaw fragment accompanying the upper one may belong to the same animal. The molar it contains, though resembling those of *Notharctus*,

differs in several points. I propose to refer the fossils to a species with the name of *Hipposyus formosus*. Prof. Leidy further remarked that he had recently the opportunity of examining the tooth described by Prof. Marsh under the name of *Palæosyops minor*. The tooth evidently belongs to the curious pachyderm with the beaver-like incisors named *Trogosus castoridens*. On observing the molar tooth, which is not worn away like those in the jaw specimen upon which the latter was named, it at once called to mind, the tooth which had been described under the name of *Anchippodus riparius*. On comparison, it would appear as if the specimens referred to *Palæosyops minor* and *Trogosus castoridens*, really belong to the same genus and species. The tooth of *Anchippodus ripparius* was obtained from a tertiary formation, Miocene or Eocene, in Monmouth Co., N.J. If the determination is correct, it would go to show that the Bridger Tertiary formation of Wyoming was contemporaneous with the Tertiary deposit of Monmouth Co., N.J. Prof. Cope stated that the largest mammal of the Eocene formations adjoining those of Wyoming, *i.e.* of the Wahsatch group of Hayden, was the *Bathmodon radians*, Cope, of about the size of Rhinoceros. It was an odd-toed ungulate, with peculiar dental characters. The incisors were well developed above and below, as in the tapir, but the dental series was little interrupted. The crowns of the upper molars were all wider than long, and presented mixed characters. On the outer margin one only of the usual crescents of ruminants was present, but a tubercle represented the anterior one. The one which was present was directed very obliquely inwards. Inner crescents were represented by two angles, the posterior forming the inner angular margin of a flat table, the anterior a mere cingulum at its interior base. The arrangement of these parts was stated to be of interest in connection with the relation ships between the types of hoofed animals. The single outer crescent was a ruminant indication, while the inner table resembled the interior part of the crown of *Titanotherium*. It differed, however, in its early union with the outer margin, its edge being thus possibly homologous with the posterior transverse crest in *Rhinoceros*. The premolars had two or three lobes with crescentic section arranged transversely. He regarded the genus as allied to *Chalicotherium*. He stated that the mammalian fauna of Wyoming and Utah more nearly resembled that of the Paris Basin than any yet discovered in our country, and that it had been discovered to contain a still greater number of generalised mammalian forms. One of the most marked of these was the genus just described by Dr. Leidy.

Paris

Academy of Sciences, September 30.—M. Chevreul, president.—The following members of the International Committee on the Metric System were present at the meeting:—MM. Stankart and Bosscha, for the Low Countries; Mr. Chisholm, for England; General Ibanez, Spain; MM. Lang and Herr, Austria. The following papers were read:—"On the demonstration of the formula which represents the elementary action of two currents," by M. J. Bertrand, a long mathematical paper on Ampère's law of electrodynamical attractions; "On the immediate determination by the principle of correspondence of the number of points of intersection of two curves of any order which meet at a finite distance," by M. Chasles.—Next came a note on the stability of colours on stuffs in general, and on silk in particular, by M. Chevreul. The author refers to a paper he read before the Academy twelve years back, when he drew attention to the unstability of many of the aniline colours then recently introduced. He now again calls attention to these colours, and considers that the use of them cannot fail to have a disastrous effect on French commerce and industry.—A paper by Father Secchi followed, entitled, "Solar Spectroscopic Researches." The author calls attention to the following extract from a letter to Herr Schellen, written by Mr. Young, of Dartmouth College, U.S. A. Mr. Young was stationed on Mount Sherman, 8,300 feet above sea level, and used a telescope of 9·4 inches aperture. He says, "The spectrum of the sun, although not entirely reversed at the border of the disc, became continuous, as Father Secchi has seen in Italy. When the air is calm the height of the region where this occurs is not greater than 1″. The lines rays of the chromosphere were remarkably augmented in number. H_1 and H_2 were seen reversed, as was *h* and the other hydrogen lines. In the spectrum of each spot the lines of hydrogen were reversed in a region slightly more extended than the penumbra; this has been verified for at least twenty different spots." Father Secchi states that these observations confirm his own made at Rome in 1869.—M. Bertrand then presented the Academy with a posthumous work of M. Duhamel, entitled "An Essay on the application of scientific methods to the moral man," upon which he made some remarks. He was followed by M. Max Marie's concluding paper "On the theory of the residues of double integrals." Next came MM. A. Rabuteau and F. Papillon's "Researches on the Physiological Action and Antifermentable properties of Sodic Silicate." The authors have added various quantities of this body to different kinds of fermentable matter and find a quantity of two grammes to completely stop all fermentation of whatever kind. Its action is exactly analogous to that of borax but more energetic. Two grammes of the latter injected into the veins of a dog produced no effect whilst one gramme of the silicate produced violent purging and vomiting and ultimately death after an interval of nine days.—On the effect of vegetable parasites in altering bread by MM. F. Rochard and Ch. Legros was referred to the commission appointed to examine the *Oidium aurantiacum*. M. Bertrand then presented a note "On the movement of the Planets around the Sun according to the Electrodynamic Law of Weber," by M. F. Tisserand. M. Yvon Villarceau presented a note by M. Stephan on the "Elements and Ephemerides of Planet 122. M. Yvon Villarceau remarked that M. Stephan had also calculated the orbit of 121, and he then presented a note by M. R. Luther, on an "Observation of the Planet 95, Arethusa, made at the Observatory of Bilk-Düsseldorff," which was followed by a note of M. Trève, "On Magnetism."—M. Milne-Edwards then presented a note by M. N. Joly, entitled, "Observations on the Metamorphoses of Osseous Fish in general, and particularly on those of a small Chinese fish of the genus Macropoda, recently introduced into France."—This was followed by a paper by M. H. Sicard, "On the Connection which exists between the Nervous and Muscular Systems in the Helices."—And then came a note by M. Lichtenstein, "On a Process for the Destruction of *Phylloxera*," by the burying and subsequent destruction of the young shoots. Papers on the same subjects were received from MM. A. Rainaud, Peyrat, and Louvet, and were sent to the Phylloxera Commission.

THURSDAY, OCTOBER 24, 1872

AGASSIZ AT SAN FRANCISCO

THE completion of its labours by the United States *Hassler* Expedition presents many points of almost dramatic interest. We have the veteran naturalist, a native of the little republic of the old world—having transferred his home to the great republic across the Atlantic, and settled himself to his scientific work at the University in Massachusetts which derives its name from the old seat of learning on the banks of the Cam,—there gathering about him a band of earnest students, the master and his disciples together building up at Cambridge, in the course of a few years, one of the best appointed schools for practical instruction in Natural Science, and one of the finest Museums of Comparative Zoology in the world. The citizens of the Great Republic are constantly discovering within their own vast territories some extraordinary natural production which in old times would have ranked among the great wonders of the world: now a grove of gigantic trees in California; now the marvellous cañons of Colorado; now a wonderful assemblage of hot springs and geysers in Nebraska. But not content with the Government exploration of their own domain, the munificence of a private citizen of Massachusetts fitted out this *Hassler* coasting survey expedition with the necessary appliances, and placed the veteran Agassiz at its head, for the purpose of investigating the natural features of the extremity of the Southern Continent, and the inhabitants of its seas, the latter department being specially placed under the management of the accomplished naturalists Pourtales and Steindachner. Our readers already know how the experienced eye of Agassiz detected in Patagonia the same evidences of extensive glacial action with which he was already so familiar in the northern hemisphere; and the contents of the dredging nets will furnish employment to the staff of American naturalists for many a month to come. After cruising up the Pacific Coast of South America, the voyage of the *Hassler* finally ended in United States territory at San Francisco, where the expedition met with such a reception as has probably never before been accorded to any body of scientific amateurs. The *Alta California* thus welcomes the great naturalist on his return to his adopted country :—

"San Francisco has in its midst a man of science than whom none in America, or out of it, more richly deserves the love and homage and respect of our people. He has come all the way around our Southern Continent, not for gold, as many came, not for silver, as many came, not for diamonds, as many would come or go, but for scientific knowledge, for discoveries in the hitherto unsearched waters of the seas, the unexhausted treasuries of Nature growing, budding, and blossoming along the shores of a continent. When such a man, if there be any other such, chances to visit a distant city, he is quite likely to be made the guest of it, to be *fêted*, and to be made to feel that his merits of head and heart have endeared him to the people, and that the city feels itself honoured particularly, instead of honouring him. All the dukes and princes that ever stepped foot in America, never deserved a tenth part of the attention which is due to Prof. Agassiz. There is in America no man living who, as a scientist, compares with this gentleman in acquirements in his lines of study, and in the triumphs achieved. Many of our citizens have called upon him, and extended such courtesies as private parties may, and perhaps quite as extensively as is agreeable to him. But the question is, what does this city owe to itself in this matter? A public reception by the city would be a very graceful courtesy extended to a very great and most worthy gentleman, and the honour to herself would be one of which every citizen might well be proud. We hope it may be done."

The same paper and the *San Francisco Morning Bulletin* both print full reports of the professor's address on the occasion of his reception in the Pacific Hall by the California Academy of Sciences, heading their article, in genuine American style, by sensation headers of the following description :—"Agassiz. Grand Reception under the Auspices of the California Academy of Sciences. Pacific Hall in a Blaze of Intellectual Light. From Polyp to Mammal. Modified Darwinism—The Prophecy and Advice of a Man of Science."

From the address itself we may be permitted to make a few extracts, for the purpose of illustrating what are the subjects that are now uppermost in the minds of our scientific friends on the other side of the Atlantic. But, first of all, let us cordially congratulate the representatives of Science in that remote State, on the honour which has been reciprocally conferred upon them and upon Agassiz and his fellow workers by the enthusiastic welcome which they have given him, and on the encouragement which his visit has afforded for the further prosecution of their arduous labours. In the words of Prof. Davidson, the Principal of the California Academy of Sciences :—

"Less than one month since, the great master of modern scientific thought and research addressed a few earnest students of science, who have patiently and bravely kept their lamp trimmed and burning. The magic of his words thrilled our hearts and cheered our hopes; but, best of all, that gave renewed confidence to friends who had an abiding faith in our efforts. That you might have a richer feast, we have prevailed upon him to break a long and comparative silence, when he most needed rest and repose. In less than one hour after our last Academy meeting, the seeds sown by him had borne fruit in giving to the Academy a greater number of life members than we had gathered in ten years. Within a fortnight the Agassiz Professorship of Oriental Languages and Literature was established for the Universities of California by the munificent endowment of our fellow citizen, the Hon. Edward Tompkins; and now, after eighteen or nineteen long years of arduous and desperate struggle with poverty in this State of marvellous wealth and boundless properity, the California Academy of Sciences is amply rewarded in being the instrument of introducing to the citizens of San Francisco Prof. Agassiz."

In the opening of his address, Prof. Agassiz made the following remarks on the present aims of science :—

"For the last three years I have been prevented from appearing in public, owing to the indifferent condition of my health. I venture this evening to address you. I have been asked to give some account of the voyage of the *Hassler*, which has terminated its cruise in the harbour of San Francisco. I am afraid that the incidents of that scientific expedition are too monotonous to be very entertaining; and willing as I am to accede to the request, I think I will submit to your attention remarks upon the present aims of Science, which may at least have a more solid foundation than our past efforts during that voyage, to increase the bases and material foundation of knowledge. Allow me to say that this examination, as I may call it, has been entirely incidental to the necessities of the Coast Survey. The good ship which brought us here is

intended to continue the work of the Coast Survey along this coast; but instead of allowing us to make this voyage empty, some scientific gentlemen were invited by the Superintendent of the Coast Survey to take passage in her, and make the most of the opportunity. Liberal citizens of Massachusetts added means to the good will of the Superintendent—so that whatever collections and investigations should be made during the voyage should not be an additional expense to the great international undertaking, or to the Navy.

"I think it desirable that these facts should be known, in order that not too great expectations should be entertained concerning the scientific results of the *Hassler's* voyage; for all that which could be done was done by means supplied by private individuals, and not by the large resources of the Government. Unfortunately, it is almost everywhere still so, that Science has to take the humblest place in the world, as if equal opportunities were yet granted with a reluctant hand. It is only in recent times that the value of research begins to be felt; and I hope to live, old as I am, long enough to see the community, the enlightened community, which has become my second fatherland, appreciate what Science is doing for the general prosperity, and then contribute to the necessities of Science with that generous liberality which characterises the acts of the American people. It is not generally understood—and perhaps we scientific men are at fault in this matter—that Science is at the foundation of all natural progress in the community, in industry, in the arts, in almost everything."

After a few details as to the objects of the study of natural history, he proceeded to explain that "the only difficulty in the way of the study lies in the fact that there are no teachers; that the community lacks teachers in this department; and wherever there are a few educated, they are at once swallowed by the numerous institutions of learning which are organising everywhere. And we cannot educate a sufficient number of them, for the simple reason that there are other walks in life which are more promising in the rewards they secure for their devotees. So Science is always behindhand, and yet it is she who furnishes the primary material for all the progress in modern times."

We need not follow the speaker through his singular misrepresentation of the theory of evolution as taught in this country, viz., that the various forms of life, as we now see them, "may be the work of blind forces, of forces without intelligence, without discriminating power, and without forethought," and that the object of the study of nature is "to determine whether we ourselves are descended from monkeys or whether we are the work of a beneficent Father." We will rather pass on to his peroration, which sets forth some truths at least as applicable to us as to the audience he was addressing:—

"It will no longer do for the coming generation to say, I will accept this or that doctrine, because knowledge is pressing at your halls: but I will say to you, you may know it because you must know it, and unless you are willing to learn it you may grope in ignorance. That is the condition that stares us in the face for the future, and it becomes on that account the duty of every man to foster knowledge and to prepare the coming generation with all those appliances which lead to an independent opinion on all those matters. And that question is pressed upon you for the first time. You have for the first time in your existence as a State a generation which is about ready to enter the University. You have not had that in past generations, in past years, but your children approach the time when they may prepare for college. It is your duty that you have, then, a college which will set measures of the highest aspiration for the coming generation. And you cannot be willing to depend for their education upon the bounty of other States when in your prosperity, when you have rivalled all civilised communities. When I see luxury here, as in the oldest States of the world; when I see here the appliances for all the efforts of man carried to the highest degree, are you willing that your children should go and beg for information at the doors of other countries? It is for you to educate them and to give them those means which will make them find at home those advantages which otherwise you will have to seek for them by parting with them during those very years when their character is shaping. But there is another consideration than that of your immediate necessities here. No community can be utterly great without culture. Culture is the background of every great community. It is, in fact, the true and only test of real greatness."

Are not we in this country also forcing our children "to go and beg for information at the doors of other countries"? As long as we do not provide at home those educational advantages which so many go abroad to seek, we must submit to have to sit at the feet of our own daughter, and to learn from America both how to honour our really great men, and how to attain that scientific position among the nations to which our wealth and our material resources entitle us. The lesson is hard to learn, but it is one which must be learnt either by us or our children; and the longer we leave the task unlearnt, the harder will it be to learn.

RAILWAYS AND SCIENCE

Life of Richard Trevithick, with an Account of his Inventions. By Francis Trevithick, C.E. 2 vols. (London: E. and F. Spon, 1872.)

Life and Labours of Mr. Brassey, 1805-1870. By Arthur Helps. (London: Bell and Daldy, 1872.)

Railways or no Railways; or, The Battle of the Gauges Renewed. By Robert F. Fairlie. (London: Effingham Wilson, 1872.)

THESE three works are directly concerned with railways, though each of them deals with a different aspect of the many-sided subject. It would be out of place in these columns to review in detail each of the publications; they may, however, suggest a few thoughts not inappropriate to the columns of a scientific periodical.

The first on the list takes us back to the birth of the steam-engine, carrying us on through its chequered and roughly-handled youth to the time when it was fairly set agoing on that wonderful career, by means of which the whole face of the earth has been changed as if by the breath of a god, the relationships of nations and of men altered entirely, and civilisation hurried on at a rate almost bewildering. The benefits conferred on humanity by the discovery of the simple scientific principle on which the steam-engine rests, are incalculable, and not to be realised in anything like their fulness by those who, like most now living, have been born to these benefits, and who can only grumble that the advantages of the legacy left them are not by any means what they might be, were they not marred by the officiousness, the avarice, the prejudices, and the blundering stupidity of those who have constituted themselves its trustees. That this has

been a cause of complaint all along is one of the many lessons to be learned from Trevithick's life; and so will it ever be, until the simple but stupendous and widely beneficent principle which the man of science, by reverent asking, has obtained from the liberal hand of Nature, is not only more thoroughly understood and more scientifically applied by those who undertake to put it to the uses of humanity; but until Science holds supreme sway over all the actions and thoughts of men universally, until she holds the same place as a guiding principle for the lives of men, and their relationships to each other and to the surrounding universe, that superstition and wild imagination have held for ages. It will only be when education is founded upon a thoroughly scientific groundwork, when men are trained from their youth upwards to regard human and extra-human phenomena with the clear, bold, intelligent vision of science undimmed by superstition, unwarped by prejudice, and unshortened by selfishness, that the full significance of scientific discoveries will ever be realised. Only then will they have a chance of making unobstructed way in conferring upon mankind the innumerable benefits with which many of them are fraught, and in raising the race higher and higher in the scale of civilisation, till that golden age be realised which poets dream of as in the unknown past, but which assuredly lies in the certain though, it may be, far distant future.

These remarks are suggested by the "Life of Trevithick," which, read in the light of the present day, makes one feel somewhat sad, and certainly sorry for the great and unselfish mechanical genius who scattered his inventions broadcast among his fellows, to the great enrichment of the latter, while he himself led a chequered and almost homeless life, dying, at last, penniless among strangers. Trevithick himself was not a scientific man, and seems to have had only a vague notion of the scientific principles upon which his numerous applications of the expansive power of steam were founded. But he was not like many so-called "practical" men, who work only by rule of thumb, and profess contempt for the scientific principles which they put to practical use. Trevithick appears to have had the greatest respect for science, and invariably submitted a new invention, or application of the one simple principle which governed all his inventions, to his scientific friend Mr. Giddy (afterwards Gilbert, and President of the Royal Society), in order that they might be submitted to the rigid test of scientific theory. Had a similar course been followed at a much earlier period, and had the earlier manipulators of steam been animated by the same spirit as well as the enthusiasm, and penetration, and disinterestedness of Trevithick, the steam-engine, instead of remaining the clumsy and unpliable machine it did for so many years, might about a century and a half ago have reached the perfection and wide applicability it has attained at the present day. And it was only in proportion as mechanicians clearly realised for themselves the full significance of the simple laws of steam, and fearlessly allowed them, under judicious control, to work with a powerful purpose upon properly constructed machinery, that anything like the wide-spread benefit was derived from them that they were calculated to confer; in other words, it has only been in proportion as engineers have grounded the rules of their art upon scientific principles that the steam-engine has attained to its present comparative perfection and innumerable labour-lessening and therefore blessed uses. In this it is that the great merit of Watt and Tevithick lies, both of whom had the penetrative genius to perceive that the mighty power which lies latent in a cup of water was almost entirely frittered away for want of proper guidance and a suitable channel wherein to work; and within a very few years after these men had made their important inventions, the development of the steam-engine had made infinitely more rapid progress than it had done during a previous century,

The history of the application of steam to machinery, the gradual development of the steam-engine, and especially its use for locomotive purposes, must be known to all our readers, and therefore we shall not attempt to repeat the oft-told story. It is one of those "fairy tales of science," which are more wonderful and often more bewitchingly beautiful than any of the thousand myths by which our "rude fore;athers" blindly but naturally attempted to explain the many mysteries of the universe; and they have the additional merit of being true and therefore undying and never leading to disappointment and distrust. Nor shall we attempt to adjust the relative claims of Watt and Trevithick to priority of invention, or try to show their respective shares in the discovery from which the world is now reaping so much benefit. It is humiliating to think that Watt and Trevithick lived for a considerable time only a few doors from each other in a small Cornish town, each bent upon accomplishing a beneficent and highly useful purpose, and yet never spoke to each other, but on the contrary regarded each other with considerable bitterness all their lives; and this simply because the one advocated high pressure while the other was pushing the adoption of low pressure engines. Mr. Francis Trevithick, naturally enough no doubt, but with very bad taste and we believe much injustice, speaks of Watt frequently with great bittterness and depreciation as his father's rival, and jealous and ill-speaking opponent. To revive these squabbles serves no good purpose, but merely gives occasion to the world which lies in ignorance to sneer; the merit of Watt was very great, and so was that of Trevithick, and there is no need whatever to exalt the one at the expense of the other; each has a lofty and enduring pedestal of his own. We also think it displays considerable want of reflection and of the philosophic spirit to tirade, as Mr. F. Trevithick does, against the ingratitude of mankind towards those men who have conferred upon them great benefits in the shape of useful inventions, and against the deafness of men in place and power towards their claims for assistance and reward. The fact is that all great inventors, like all men of supreme penetration and foresight, are often too far in advance of their own generation to meet with much sympathy and appreciation from it. Mankind are not to be sweepingly blamed for this on any score. The race is yet a long way off perfection; and if the world ran so close on the heels of its great men as to be able at once to comprehend and appreciate them, these men would not be so great after all. The world, on the whole, acts very honestly, however hardly, to her man of genius, and when she does reach his standpoint, she erects a monument to him if he be dead, or if happily he be still alive, she rewards him with a pension. That Trevithick

should have died penniless was pretty much, we think, his own blame, attributable to his own reckless imprudence, and his decided and blameworthy weakness of character in being unable to manage the affairs of his own household. It was no merit in him, and no sign of unselfishness, but simply a defect in his character, as it is in that of all men who act as he did.

That Trevithick is entitled to be called the "father of the locomotive" there seems to us to be no doubt, from the tediously full statements in the biography by his son; not only so, but he conceived and sketched, and even modelled, many of the improvements, perhaps in a crude form, that have been most recently introduced. In 1796 he made a model of a locomotive; in 1801 he ran one on a rough common road in Cornwall; and in 1803 he astonished the Londoners early one morning by driving the then uncouth creature through ten miles of the streets of the metropolis. Trevethick, however, reaped little benefit or credit from this wonder-working invention, for which the world at the time was not ripe. Of the numerous other applications of steam which Trevethick either thought of or embodied, we may mention the principle of the screw-propeller, the steam dredging-machine, the application of the steam-engine to an infinite variety of purposes in mining and tunnelling, the invention of something very like the borers used in the Mont Cenis tunnel, and the application of steam to nearly every important agricultural and manufacturing process; indeed he actually constructed several thrashing-machines, which many, no doubt, consider quite a recent invention.

It is by reading a biography like this, which takes us back to the middle of last century, and brings us down to nearly the middle of the present, that we are able in some small degree to estimate the benefit which science has conferred upon man in discovering the great but simple principle which underlies every application of steam as a moving power. Not only has it in almost every direction brought manufacturing processes to the highest degree of perfection, increased almost infinitely the power of production, but it has been the means of lessening, directly or indirectly, the severity and the amount of manual toil, thus making the mechanic's life sweeter and easier, and leaving him leisure for self-culture; and in general advancing to a distinctly appreciable amount the civilisation of the race. Especially, as we have already said, has the whole face of the earth been changed by the application of steam to locomotion; and even in this one direction it would be difficult to estimate the benefits conferred upon the race by science. The train and the steamer have done much to lessen and stamp out old national and district prejudices and animosities, by making the men of various nations more thoroughly and generally known to each other, have enabled populations to circulate more freely, and men to bring their talent or their craft to the market where it was most in demand, have made emigration possible to almost all who care for it, and thus peopled and civilised the waste and barbarous lands of the earth, brought the products of the most remote quarters within easy reach, brightened the existence of many thousands by putting it in their power to see some of the many beauties of this lovely earth—made the world, in short, more manageable, drawn its inhabitants closer together, increased decidedly the sum of human happiness, and helped to bring on the time "when man to man the warld o'er shall brithers be, and a' that."

As to the manner in which Mr. F. Trevithick has written his father's life, we are sorry we cannot speak favourably; either he does not know how to write biography, or he has been either so lazy or so short of time as to give to the public the crude and tedious material out of which a biography might have been constructed, instead of a well-digested and clearly-arranged narrative. The two volumes number upwards of 750 pages, and we believe not 50 of them are Mr. Trevithick's own. It is one of the most confused, most ill-put-together books we were ever compelled to read, and were it not for the intrinsic interest of the subject, it would certainly be the most tedious. The illustrations, type, and paper are excellent, and the book will no doubt be found useful by engineers

The next book on the list, Sir Arthur Helps's "Life of Mr. Brassey," is, it is needless to say, as a work of literary art, infinitely superior to the former, though the subject is one of not nearly so great intrinsic interest and importance. Had the work of writing the life of Mr. Brassey fallen into any other hands, it might have been a very dull and uninstructive affair indeed; but it is impossible for the author of "Friends in Council" and "Thoughts upon Government" to write uninterestingly or inartistically about anything. This life of the great railway contractor has all the quiet and soothing charms of Sir Arthur Helps's well-known style; and dry as the subject looks at first sight, it is full of interest and novelty, of details that few are acquainted with, and which are yet well worth knowing. The book is worth publishing, were it for nothing else than to make the world acquainted with a man of the late Mr. Brassey's exceptionally superior character and great power of organisation; indeed the author tells us that it is as an example of skilful organisation that the life of Mr. Brassey has especial interest for him. We do not intend to give any sketch of the life of the great and universally loved and respected railway contractor; his life, in one sense, takes up the story of the steam-engine where Trevithick's leaves it off. Trevithick and such as he show how steam may be applied to the purposes of locomotion, which brings into play a new set of men, a new profession, as it were, that of contractor, whose business it is to see that suitable roads are made for this horse of man's creation to run upon. That this may be done it is necessary for the contractor to procure an army of navvies and others, officered by all grades of superintendents, from the ganger up to the sub-contractor or agent. Of how much importance careful organisation is in a case like this must be seen by every one, and of as much importance is it that every one, from the engineer and contractor down to the ganger should have a thorough and intelligent—in other words, a scientific knowledge of the department of which he has immediate charge. This was what distinguished Mr. Brassey above many others in his position; he did not work merely by rule of thumb, but raised the business of contractor almost to the dignity of a science; and the thoroughness which was the result of this, combined with the man's noble character, obtained for him the great reputation and extensive employment which he all along possessed. One lesson which this work teaches

above others is that the better educated, the more intelligent, in short, the more scientific, are all, from the highest to the lowest, who are concerned with the practical carrying out of the application of any scientific principle, the more thoroughly and satisfactorily will the work be performed.

The author does not say much—indeed little could be said—about Mr. Brassey's personal life, the greater part of the book being occupied with exceedingly interesting and varied details as to railway construction. Mr. Brassey, as a contractor, we believe, was more or less intimately connected with the construction of many thousand miles of railway in all parts of the world—Europe, Asia, North and South America, Australia—thus bearing a large share in carrying one of the greatest blessings science has conferred upon humanity, to all the ends of the earth. Not only was the railway itself a great benefit to the country into which it was brought, but the mere process of construction was a boon to thousands of its inhabitants. There are extensive districts in France in which the material prosperity of the inhabitants has been permanently raised by the savings which the French labourers realised at the construction of the Paris and Rouen railway. With whatever railway, in whatever country, Mr. Brassey had to do, he always liked to have the principal work done by English navvies; this was even the case in Canada; and some of the most interesting pages of the biography are those in which the railway labourers of other countries are contrasted, in point of character, powers of work, &c., with those of England. Taking them all in all, the latter cannot be beaten for quantity and quality of work. Sir Arthur Helps adds a chapter on "Railways and Government Control," in which he seems to think that it is now high time for Government to take the railways out of the hands of ignorant, irresponsible, conscienceless speculators, and work them itself solely for the public good, which is the last thing thought of by the present managers. One sentence is worth quoting here; we wish we had room for more:—"It has always appeared to me to be one of the most miserable instances of the hide-bound nature of our official system, which is hampered by so many checks and so much dread of small expense, that the most needful undertakings have to be passed by, or touched but lightly, which require the best intellectual force of the nation to be brought to bear upon them."

Mr. Fairlie's book, "The Battle of the Gauges Renewed," proves the truth of what we have already said—the necessity there is that all who are officially connected with railways should be able to perform their work on the basis of scientifically-grounded knowledge, and not in the light of tradition and custom, by unintelligent rule-of-thumb. Both by Mr. Herbert Spencer and Mr. George Darwin it has been recently pointed out that the construction of our railway carriages, instead of being based on a rational attempt to adapt them to new and previously undreamt-of circumstances, is simply a continuation, or rather development, of old forms belonging to the lumbering stage-coach and rude tramway days. That it is so with regard to the common gauge of wheels (4 ft. $8\frac{1}{2}$ in.) is well known, though one would at first sight be inclined to believe that the odd half-inch was significant that this gauge was the result of a careful calculation grounded on the best mechanical principles. That this is not so can be learned from Mr. Fairlie's vigorous, clear, and, notwithstanding the apparent dryness of the subject, really interesting book. When railways were first constructed, about forty years ago, men were too much absorbed in the excitement of the new means of locomotion to give any thought to such an apparently trifling detail as the width that should be maintained between the two rails; and thus the gauge which was in general use among the old and rudely constructed tramways was adopted at mere haphazard, without any thought as to whether there was any good reason for adopting the 4 ft. $8\frac{1}{2}$ in. How old the gauge is, and how it originated, probably no one knows, though we believe that even now not a few railway directors, and even engineers, will be found who maintain that it is a heaven-born institution, and that to alter it would be the height of irreverence and sacrilege, betraying an independence of thought and action worthy only of a nation like America, destitute of tradition. It is not our purpose here to advocate any one gauge as preferable to another, but simply to say that one lesson taught by the three books at the head of this article is, that the present condition of our railways is, to a large extent, the result of mere guess-work, and that only when the construction of every detail, from the steam-engine down to the gate at a crossing, or a pointsman's box, is conducted on rational, *i.e.* scientific principles, can the public, as well as the shareholders, be able to reap without drawback all the advantages which the great application of the power of steam is calculated to produce. On every ground it seems difficult to resist Mr. Fairlie's arguments on behalf of the 3 ft. 6 in. gauge, or even a narrower gauge under certain circumstances; it has been extensively adopted in America, and exclusively in Norway; and, we dare say, most people would be astonished to hear that at Festiniog, in Wales, on the face of a steep mountain, with gradients of 1 in 68 and 1 in 79, and with curves varying in radius from 8 chains to $1\frac{3}{4}$ chains, there has been at actual work for some years a railway with the miniature gauge of 1 ft. $11\frac{1}{2}$ in. "It is, in fact, the most perfect miniature railway in existence, and deserves to be studied in all its details." Both as a passenger and mineral railway, it has done hard and perfectly efficient work for some years. This, at least, shows that the question of "gauge" is worth being inquired into, as indeed ought every other point connected with the construction and management of railways.

The revelation which results from one inquiry after another, and the harrowing effects of the dreadful accidents which are almost daily occurring, will doubtless have their effect on the public mind, and urge the people of this country either to compel Government to take the railways into their own hands, or, at least, to see to it that they are managed in some kind of rational and intelligent way, for the good of the public, and not for the sole benefit of a few obtuse directors.

M. de Quatrefages, in his opening address at the meeting of the French Association, was too sanguine when he said, "Science is at present supreme," though we believe he was right in asserting, "She is becoming more and more the sovereign of the world;" and only when Science reigns supreme over all the practical affairs of men, shall we be on the high road to perfection, in this direction at least.

OUR BOOK SHELF

Elementary Geology. A Course of Nine Lectures, specially adapted for the use of Schools and Junior Students. By J. C. Ward. (London : Trübner & Co.)

THIS little volume is a praiseworthy attempt to popularise the study of Geology. The descriptions and explanations are, for the most part, well done, and will be easily followed by those for whom the book has been written. The introductory "lectures," which treat of the origin and classification of rocks, of geological agents, of waste and renovation, and of physical geography, are the most satisfactory. When the author comes to deal with the geological history of the English formations, the necessity for condensation often leads him into obscurity ; but upon the whole he has managed to give a more readable account than will be found in other introductory lesson books. As the lectures are addressed to a popular audience, we ought not, perhaps, to object to the fine writing in which the author is prone to indulge. But if his little book should come to a second edition (as we hope it may). he might tone down the "beauties," and his work be none the worse, but all the better for the process. Especially would we advise him to expunge the absurd and incoherent "Geological Dream on Skiddaw," and substitute for it a simple and intelligible summary, such as we are sure he is quite capable of giving. The illustrations are unequal ; none of them are very creditable works of art, and some are so smudgy as to be almost illegible ; but for the most part they serve their purpose.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

London University Examinations

MR. CHRISTOPHER HEATH, in his Introductory Address at University College, puts forward the following question, set in the Preliminary School Examination, in support of his remarkable statement that Mechanical and Natural Philosophy have little to do with Medicine :—

"Calculate the quantity of heat lost per hour from each square metre of the surface of an iron steam boiler 0·8 centimetres in thickness, when the temperature of the inner surface of the boiler is 120° and that of the outer surface 119½°, the coefficient of conductivity of iron being 11·5° (referred to 1 cm. as unit of length, 1 min. as unit of time, and the quantity of heat required to raise the temperature of 1 gramme of water from 0° to 1° C. as unit of heat).

"*Solution :* A difference of temperature of 1° in a thickness of 1 cm. of iron will give a loss of 11·5° in 1 min. from a surface of 1 sq. centimetre."

But a difference of ½° in the thickness 0·8 cm. is at the rate of $\frac{1}{2} \div 0·8 = \frac{5}{8}°$ in the thickness of 1 cm. Hence the loss in 1 min. from 1 sq. centimetre is $11·5 \times \frac{5}{8} = 7·1875$. Hence the loss in the same time from 1 sq. metre is 71875 units. The loss of heat per hour will now be evident.

Now this is what Mr. Heath designates as a problem on steam boilers which a medical man can never want to solve ; would he say that it is entirely foreign to the subject, and expect any member of Senate or Convocation to bear him out, if the examiners inquired how much heat a man would lose through a blanket or through a sealskin coat 0·8 cm. in thickness, &c. ? Yet the question is the same, and the iron jacket of the boiler or the sealskin coat are only accidents. Should not a medical student have some idea of the relation between the surface temperature of the body, the quantity of heat passing away from it, and the amount of heat generated in the body by the food given to a patient ? Is the production of heat in the human body by the consumption of food carried on on principles so entirely different from those of the production of steam in a boiler that a medical student can afford to be ignorant of and to despise the simplest principles of heat, and to be unable to answer the mildest questions in that subject ? Moreover, is it so clearly shown that "the two learned professors have such singularly incorrect ideas as to the requirements of medical students" when they ask a simple question as to the loss of heat from a hot body ? It may be that Mr. Heath passed his first M.B. examination before it was considered a matter of importance to note the changes of temperature of the body, or before the use of thermometers by the Faculty, and that he regards those who are guided by such things in their treatment of a patient as altogether Utopian in their ideas. The above consideration of the question may perhaps be a sufficient answer to the shallow statement of the editor of the *Lancet*, in support of Mr. Heath, that "the relation of the question to medical requirements is absurd on the face of it."

As regards the examiners, Mr. Heath is not quite correct in his statement of facts, for the present examiners are not the examiners on whom the sub-committee of Convocation reported four years ago. With regard to the candidates who are rejected at the preliminary scientific examinations, has it ever occurred to the sub-committee of Convocation to inquire of the examiners what standard is actually required for the Pass Examination? If they have not obtained this information from the examiners themselves, their decisions can have very little weight, for they cannot be in a position to judge whether it is from the high standard set by the examiners or from the bad quality of the work that so many are rejected.

What stronger evidence could be adduced of the great value of the Preliminary Scientific Examination than the report of this Committee that "it has tended to give prominence to theoretical and scientific knowledge," seeing that it is in consequence of such knowledge that medical science has advanced with such rapid strides, and that in many cases the whole course of medical treatment has been changed.

The pages of the number of the *Lancet* in which Mr. Heath's lecture is contained, show clearly that to the surgeon, as well as to the doctor, a knowledge of mechanical as well as natural philosophy is of the first importance. Take, for instance, the case reported on page 490 of that journal.

How natural for a man who understands the laws of pressure of air, to apply the cupping-glass for the elevation of depressed cranial bone, in place of an operation which kills in seventy-five cases out of a hundred ! Can a surgeon dare to be ignorant of these laws, when the consequences of neglecting them may be so disastrous

It is satisfactory to find, on turning to other medical schools, that it is not the general opinion that the study of Natural Philosophy may be neglected, but rather that "it is matter for regret that more prominence is not given to Physical Science ;" for "it is in Physics that we find the explanation of a great mass of medical phenomena ; and to the student who has not attained considerable proficiency in that science, many of these phenomena must be unintelligible."

Such being the case, the student will readily see that it will be for his best interests, and will best promote his future usefulness as an intelligent medical man, to acquire a thorough knowledge of the first principles of Mechanical and Natural Philosophy : in so doing, he will have the additional advantage that he will not run such risk of being landed among those who are rejected at the examinations of the University of London, and that not by a severe examiner, but through the ill-advice of which he has been the victim.

Physical Laboratory, King's College, Oct. 19

Solar Spectroscope Observations

IN NATURE of the 17th inst. there appear letters from Col. Tennant and Mr. Capron, who seem to doubt that the solar prominences can be seen in England with the facility described by Capt. Herschel in India. I might almost apply Capt. Herschel's words to my own experience last month. With a seven-prism direct-vision spectroscope of Browning (open slit) attached to a 2¼ inch glass mounted on a drawing-room stand, not only the bright lines, but the forms of the prominences, could be plainly seen and were sketched. Of course there were many cloudy days which prevented observations, and there would be many more such in England than in India ; but it does not require exceptionally fine weather, only a great deal of practice. Experience only will tell the exact distance at which the slit must be from the sun's limit, and the slightest movement will either put the prominence out of the field or swamp it with a flood of light.

J. P. MACLEAR

An Additional Note on American Arrowheads

As Mr. Evans has commenced his remarks on North American arrowheads with the assertion, "A prevailing type," &c., it naturally leads one to conclude that that form to which he refers is "the" prevailing type. I judge, further, that by "prevailing," he means "predominant," *i.e.*, in excess of other types or shapes of these relics. I do agree with Mr. Evans that it is *one* of the principal forms, but not so far a "prevailing" type as to merit the assertion of Mr. Evans, made *as* that assertion is.

As to the leaf-shaped form, I have but to remark that, in my own collecting experience, the true leaf-shaped, *i.e.*, the rounded-based, straight-sided, acutely-pointed form, such as Mr. Evans's Fig. 282, constitutes about $4\frac{1}{2}$ per cent. of those gathered in my own neighbourhood; and this I know to be the experience of other collectors, in other and distant localities. This, I submit, is sufficient to show that this form is not even "comparatively rare," but may be better described as "not uncommon."

And so far as workmanship is concerned, I have only to say that if narrow, thin barbs, acute points, sharp edges, and smoothness of the broad surfaces of arrowheads, constitute what has been termed "delicacy of workmanship," then the American forms in horn-stone, jasper, chert, quartz, agate, and some finely-grained slates, cannot be excelled by similar relics found elsewhere, or made from other material. This remark I base on the specimens collected by myself here in New Jersey, which State is not the best locality, by any means, for gathering these objects; and I have found that the western, northern, and southern specimens have excelled those I have collected here at home.

From the above paragraph I have purposely omitted the mineral obsidian, because the arrowheads of this material excel all others wheresoever found, and I wish to make good my assertions without the help of Californian specimens.

I take the liberty of referring those persons interested in these matters to a large series of arrowheads collected here in New Jersey, and now in the collection of Sir John Lubbock. If some of these are not equal to *any* English specimens, I must simply "give in." CHAS. C. ABBOTT

Trenton, New Jersey, U.S.A., Oct. 10

Merrifield on the Deviation of the Compass

As a review of my little manual on "Deviation," &c., has appeared in NATURE for October 17th, in which I am accused of having "written with looseness and inaccuracy," perhaps you will kindly allow me a small space to answer my critic. He has selected a most unfortunate example to bear out his assertion; and I contend for the accuracy of my statement. "Vertical iron, at the same place, will produce the same deviation in whatever direction the ship's head may be." Here I do not pretend to say (as my reviewer insinuates), that the whole deviation is the same in every position of the ship's head; but I maintain that that part due to *vertical* iron remains constant for the same place until a change of secular variation becomes cognisable. I am at a loss to discover either looseness, inaccuracy, or substitution of cause for effect in what follows, and I am inclined to think, if any exists, it must be on the part of my reviewer

Again, I am not aware of any "singular statements and conceptions" in the larger work on "Navigation and Nautical Astronomy," which are at variance with the matter contained in the small manual under consideration. Perhaps you will kindly permit my reviewer to mention some.

I grant there may be differences of opinion on the merits of any work (as is fully proved in the present instance); but when public statements are made of "inaccuracies," these should either be substantiated or withdrawn.

JOHN MERRIFIELD

Navigation School, Plymouth, Oct. 19

Earth Currents

It may be interesting to record that during the past few days we have been subject to electric storms, I think I may say unparalleled in their frequency, intensity, and duration. On Oct. 14 a severe one raged from 9.30 A.M. to 1 P.M., and in the evening from 10.20 P.M. to past midnight. On the 15th a still more severe one raged from 9.30 A.M. to 1 P.M., and in the evening from 7 P.M. to 9.5 P.M. On the 17th inst. the currents were very embarrassing from 11.20 A.M. to 12.45 P.M., and from 2.10 to 9.0 P.M.; and on the 18th they were again troublesome.

They differed but little in their character from those usually observed, the currents continually varying in intensity and duration during the periods named. The interruptions to business on the 15th were serious, and many stations could only be communicated with by looping the wires, when more than one existed, into metallic circuits. Circuits running east and west were mostly affected, those running north and south, for instance, between London and Brighton, being but little disturbed. I regret to say that no precise measurements of the strength of these currents have yet reached me.

Southampton, Oct. 21 W. H. PREECE

Aurora Borealis

On Saturday, Oct. 6, I was walking in our large playground with a friend, about 8.40 P.M., when we saw above us a magnificent red "way" whose direction was E.N.E. When we first looked, this broad band was bifurcated towards the E. end, one fork going more to the east, and the other to the north. In a minute or two this bifurcation disappeared, and in three minutes more the whole had disappeared, leaving the sky as before. It could be nothing but an aurora; at any rate, it was not the light of any fire, it was too magnificent, and for the time that it lasted of too great a length. I took no notes at the time, but feel that I have given you a correct account of the phenomenon, as far as it goes.

Christ's Hospital, Oct. 20 F. JEFFREY BELL

Ocean Currents

It is to be regretted that the correspondents of NATURE, who for some weeks past have been writing on the subject of Ocean Currents, should ignore the consideration that it is primarily a question of geographical fact, and that any theory which runs counter to that needs no more elaborate confutation than a bare statement of the fact, supported, if necessary, by authoritative evidence. Thus, then, when we find the effect of the earth's rotation put forward, in the way it has lately been, by Mr. Ferrel and Prof. Everett, it is quite needless to examine the calculations which have been adduced; it is sufficient to say that the conclusions arrived at are contrary to geographical fact; that currents do not by any means universally turn to the right in the northern, or to the left in the southern hemisphere;—to name a few amongst many, the Gulf Stream turning to the left round Cape Hatteras, and again towards the coast of Ireland, Rennell's current, the Agulhas current, the Cape Horn current as it turns south near Chiloe, the current through Behring's Strait, are cases in point, currents turning in a manner exactly opposite to that deduced from the theory.

Similarly, when Dr. Carpenter, whether supported or not by several distinguished phycisists, argues from the effect of great differences of temperature in a small trough, as to the effect of much smaller differences of temperature in the incomparably larger ocean, it is unnecessary to follow him into his reasonings, for the conclusion, as he has lately stated it, that there is "necessarily an upper flow from the equator towards the poles," is geographically false. Over a very great part of the North Atlantic there is no prevailing set at all; in the South Atlantic and in the South Pacific the set has a general though slight tendency towards the north; the East Greenland current, the North African current, the South African current, the Peruvian current, and many others, run strongly towards the equator; there is nothing at all resembling a general "upper flow from the equator towards the poles."

As a question of abstract mathematics, Mr. Ferrel is undoubtedly at liberty to prove that every current in the northern hemisphere turns to the right, as much as he was, a few years ago, to prove that there is no air within some twenty or twenty-five degrees of the poles; and as a point of experimental science, Dr. Carpenter's illustrations are pretty, and can be understood without the authority of the distinguished men whose names he brings forward; though I should be loth to believe that Mr. Hawksley, or any other experienced hydraulic engineer, would agree with his idea that water will always find its own level.

But the application of the mathematical problem or the experimental illustration to the case in point is quite a different thing;

they lead to conclusions which we know to be geographically false, and we therefore refuse to accept them.

Royal Naval College, Oct. 16 J. K. Laughton

Fossil Oyster

Ostrea callifera from the Hampstead beds is described at page 145, and figured on Plate I., of Forbes's "Tertiary Fluvio-marine Formation of the Isle of Wight." Perhaps this is the one "Inquirer" has found. T. G. B.

THE PENNATULID FROM WASHINGTON TERRITORY

I PRESUME this disputed organism, referred to in two communications in your number for September 26, is specifically identical with a specimen from Frazer River, British Columbia, presented to me in the autumn of last year, for the Museum of the University, by Mr. Selwyn, Director of the Geological Survey of Canada, and which had been obtained by Mr. Richardson, one of his assistant geologists. I at once recognised it as the axis of a Virgularia, or some similar creature; but there being no means of reference here for the West Coast species, I submitted it to Prof. Verrill, of Yale College, who had no doubt as to its nature, but believed it probably to belong to an undescribed species. There being no sufficient materials for its description, Mr. Whiteaves of this city, who undertook the description of the marine animals procured by the Survey in British Columbia, merely noticed it in his report as an undescribed pennatulid. Its characters were stated by him in a paper read before the Natural History Society of Montreal last winter, and printed in abstract at the time. Mr. Richardson, who returned to British Columbia in the spring, has undertaken to procure, if possible, a perfect specimen, and to have it preserved in alcohol. Should he succeed, we may hope soon to have materials for the description of the species. Mr. Selwyn's specimen, though it has probably lost several inches of its length, being broken at both ends, is five feet one inch in length. It retains, attached to the granulated lower extremity, some traces of animal matter, in which I think I can detect, under the microscope, a few club-shaped spicules.

McGill College, Oct. 11 J. W. Dawson

DR. HOOKER'S REPLY TO PROF. OWEN

THE Blue Book issued in August last, containing the correspondence between Dr. Hooker, Mr. Ayrton, and others respecting the management of and control over Kew Gardens, included also, in the form of an appendix, a statement addressed to Mr. Ayrton by Prof. Owen, containing various allegations detrimental to the present management of the gardens, herbarium, and museum. The following reply by Dr. Hooker to these allegations has just been printed by order of the House of Commons:—

"Prof. Owen divides the 'aims and applications' of the Royal Gardens of Kew, according to his view of them, under seven heads.

"It is sufficient to state that some of these are recognised by the Government, and specified in their instructions under which the Director carried out his duties; but that others, and those of a most comprehensive nature, have no place there, and are not such as pertain to botanical gardens elsewhere. Amongst these are the agricultural operations specified by Prof. Owen, 'the application of manures, demonstrations of the fittest species of grasses for particular soils . . . methods of irrigation, subterranean pipe, conveyed liquid manures, and so forth,' all of which are being carried out with vigour and success by various agricultural societies and private individuals throughout the country.

"To establish such operations at Kew would involve an enormous expenditure, and occupy many acres of ground now devoted to the legitimate purposes of a botanical garden.

"Illustrations of rock-works, garden sculpture, and ornamental waters, also recommended by Prof. Owen, appear to be equally out of place.

"Prof. Owen is in error in stating that the arrangement of plants in natural groups, with conspicuous labelling, &c., is at Kew 'at present limited to the herbaceous grounds;' as he is also in implying that there is no illustration of 'geographical distribution,' which is, in truth, carried out to an incomparably greater extent at Kew than in any other garden known to me at home or abroad. Prof. Owen cannot have visited the houses devoted to ferns, orchids, succulents, aroids, &c., nor the arboretum, fruiticetum, and pinetum, nor observed the arrangement on the shelves of the two great buildings, the palm stove and the temperate house.

"The fact that a first-rate herbarium and library must be maintained for the purposes of a botanical garden, and in immediate proximity to it, has not only been uniformly admitted and acted upon by successive Governments, but is so universally recognised by naturalists everywhere, that I am surprised that Prof. Owen should dispute it.

"I am sure that were he acquainted with the nature and amount of the duties devolving on this establishment, he would abandon his opinion without hesitation.

"In support of the contrary opinion he refers to that early period in the history of Kew, when its new and rare plants were named at the Banksian herbarium in London. But the naming of a few new and rare plants cultivated at the beginning of the century in a private garden of nine acres, probably at no one time containing more than 4,000 species, is a very different matter from keeping accurately named public collections that occupy 300 acres, and are estimated to contain 20,000 species; and this in an establishment that is annually called upon to name literally thousands of plants from other botanic gardens and nurseries in England and similar institutions abroad. A great deal of the naming, and keeping correctly named, the plants at Kew, can be conducted only by skilled botanists visiting the grounds daily. Large classes of plants are now cultivated that must be named in the houses where they grow; and many more, the tropical especially, could not be sent to a distance to be named, without serious damage *in transitu*.

"To this must be added the necessity of naming and ticketing with copious information the vegetable products of economic interest, in three museum buildings, the illustration of which products by specimens, Prof. Owen admits to be a legitimate object of the Gardens of Kew.

"Nor was the naming of the Kew plants carried out in London, as is supposed; there was a large herbarium in constant use at the Royal Gardens at the very period alluded to, the breaking up of which, when it was proposed to give up the Gardens, necessitated the formation of another.

"No comparison whatever can be instituted between the needs in these respects of the Royal Gardens at Kew and the Zoological Society's Gardens in the Regent's Park.

"The reflections that follow on the conduct of the late and present Directors of Kew Gardens are not suited for official discussion.

"Prof. Owen is in error in asserting that the main end or drift 'of Dr. Hooker's evidence before the Scientific Commissioners is to impress upon them the necessity of the transfer of the collection of dead plants' from the British Museum to Kew.

"My evidence is unequivocally opposed to such a transfer.

"Herbaria are not costly establishments, but the least expensive of all natural history collections; and the objects and applications of botany in its largest sense, are now so numerous and so important, as to render a division of the subject necessary; whence the expediency of

maintaining a country and a metropolitan department, each with a herbarium, as the most essential, but least expensive of its adjuncts, may readily be demonstrated.

"So far from desiring that the British Museum herbarium should come to Kew, I should propose to recruit it from that at Kew, which could be done to its very great advantage.

"Prof. Owen's approval of the saying of 'a great wit and original thinker,' that 'the net result' of a herbarium is the 'attaching barbarous binomials to dried foreign weeds,' will not find an echo amongst those conversant with the subject. Had it been otherwise, successive ministers would hardly have tolerated the existence of the Kew herbarium, or of that at the British Museum either.

"The disparaging remarks that follow on the views of his duties held by the late director, and on his performance of them, are not best dealt with by the counter assertions of his son; they are best disposed of by certain passages in the Treasury Minute that follows Prof. Owen's statements, and by the unanimous verdict of the late director's countrymen and foreigners everywhere.

"The suggestion is offered that an official inquiry should be made of leading gardeners to ascertain 'the kind and degree of information and aid which they derive or have derived from the National Establishment.'

"The answer to this has already been given, in the addresses to the Premier by the Royal Horticultural Society as a body, and separately by its Floral, Fruit, and Scientific Committees; and by the meeting of botanists and horticulturists held in London; and by the concurrent evidence of gardening periodicals throughout this country.

"The statement that the Royal Gardens had not fulfilled their function of introducing new, rare, and beautiful plants is best met by a reference to the pages and illustrations of the *Botanical Magazine*, a work that has issued monthly (and without a month's intermission) from Kew, ever since 1840, edited by the Director, and which is devoted to new, rare, and interesting plants, the larger proportion of which have flowered at Kew.

"The passage relating to the avenue of deodars and limes along the Syon vista, the formation of which is censured as a failure at the cost of 'hundreds or five hundreds' of trees, is founded on a complete misapprehension. Without going into detail, it is sufficient to state that not twenty deodars have been sacrificed, and no limes at all.

"The censuring of the Director for removing the araucarias from Richmond Park to Kew is equally founded on a misapprehension. These araucarias were twice offered to Kew before they were accepted; they stood in a private piece of ground, whence their removal was considered by their possessor to be a necessity; and the alternative of removal to Kew was their destruction.

"My predecessor is censured for neglect of the great araucaria, which, it is implied, is consequently inferior to that of Dropmore. The facts are as follows:—

"This araucaria, with four others, was brought to Kew in 1796, and kept in a greenhouse.

"In 1808 it was planted out in a poor sandy soil, and being supposed to be tender, was enclosed in a wooden house for many months in the year, in consequence of which its growth was checked, and it was rendered so weak that it was almost killed in 1838.

"It was not till the late Director took office in 1840 that the house was abandoned, good soil given to it, and other means taken (which have been sedulously repeated ever since) to encourage its growth.

"It is now a striking object 30 feet high and 90 in girth of the branches; and if not nearly so handsome an object as the Dropmore araucaria, this is partly due to the fact that the Dropmore tree was planted out at once, in a soil and situation as admirably adapted to araucarias as those of Kew are naturally unsuited to them; and partly to the fact, probably unknown to Prof. Owen, that there are two very distinct forms of this species, a conical, and a round-headed, of which the Dropmore specimen belongs to one, and the Kew specimen to the other.

"Of the other four plants, one is that now at Dropmore; a second was killed by cold at Kew early in the century; the third was given to Sir Joseph Banks at Spring Grove; and the fourth at a later period, to Prince Albert, and taken to Windsor.

"In the contrast drawn between the herbarium establishments at the British Museum and at Kew, it is stated that the staff of the former consists of three officers, with aggregate salaries of 850*l*., and 'that their time is exclusively given to the duties for which they are paid;' whereas the aggregate salaries of the three herbarium officers at Kew is 750*l*., and that one is Professor of Botany in University College, and another a lecturer at a London Medical School.

"I am surprised that Prof. Owen should be unaware that one of his own three officers is botanist to the Royal Agricultural Society, and another a lecturer at a London Medical School, and editor of a valuable botanical journal.

"Nor does Prof. Owen in his comparison take into consideration that the Kew herbarium is open from 8.30 A.M. till 5 P.M. in winter, and 6 P.M. in summer, whereas the British Museum herbarium is open only from 10 to 4 in winter, and 10 to 5 in summer; as also that the Kew officers have not only the keep of the largest and most frequented herbarium in the world, but of a very large library, and have the duty of naming all the plants throughout the gardens and museums, together with many other duties that do not fall upon the British Museum officers.

"The fact is, that the exigencies of this establishment require that the herbarium should be open during that long period, but the officers are not required to be in attendance, and at their work, for more than seven hours daily throughout the year.

"Those seven hours (and to their honour be it said, often many more) are devoted exclusively to the duties of their respective offices.

"That the officers both of the British Museum and of Kew should be chosen to conduct the very brief professional and other duties which they perform elsewhere (at their own time), is both honourable to themselves, and in many ways advantageous to the establishments with which they are officially connected, always assuming that these vocations do not interfere with their working hours at Kew, and at the British Museum, or with their powers of work during those hours.

"The statement that there are at Kew 'a special curator of the museum, &c., and an assistant at 315*l*. per annum,' is an error.

"There is but one curator for the three museums, and his salary is 120*l*., rising to 150*l*., without a house or any other advantage; he has no assistant, and never had one.

"The last of Prof. Owen's statements to which I shall allude are the following, which I quote *verbatim*:—

"'Dr. Hooker has been enabled to publish, or aid in the publication of, 130 volumes on botanical subjects. . . .

"'To the extent or proportion in which the Director's time has been diverted from the immediate aims of the Royal Gardens to this foundation of his scientific fame, the proportion of his salary of 800*l*. per annum must also be placed to his credit of the superaddition of the dead plants to the Botanical Department under the Board of Works, competing with the Botanical Department under the Trustees of the British Museum.'

"The first statement in this extract has no foundation in fact; it would ill befit me to notice the insinuation contained in the last.

"(Signed)

"JOS. D. HOOKER, Director

Royal Gardens, Kew, Aug. 6, 1872"

THE NEW RHINOCEROS

THE acquisition of a living Rhinoceros belonging to a species hitherto unknown to science, is certainly a remarkable event, and one that may well give comfort to those who may have supposed that the field of zoological discovery is worked out. If so large a beast has hitherto escaped the observation of naturalists, how many smaller animals must there still remain for the zoological explorer. But the truth is that we know less about some of these very bulky animals than those of more moderate dimensions, as their very size renders the collection and preparation of specimens of them more difficult. The importation of such monsters in a living state is a still more serious undertaking, and it is only within the last few years that the Zoological Gardens of Europe have become wealthy and enterprising enough to find funds for such expensive luxuries.

The animal of which we are now speaking, was originally captured near Chittagong, at the northernmost extremity of the Bay of Bengal, in January 1868, by some officers engaged in the supply of elephants for the Indian army. Some natives came into the station, and reported that a rhinoceros had fallen into a quicksand, at a place about sixteen hours' journey to the south, and had been unable to extricate itself. They had pulled it out by ropes attached to its neck, and had bound it between two trees, but were fearful of its breaking loose. Captain Hood and Mr. H. W. Wickes accordingly started with eight elephants, and brought the rhinoceros into Chittagong, where she was kept in a stockaded enclosure, "having a good bath excavated in the ground, and a comfortable shed attached to it." Here "Begum," as she was named, remained for nearly four years. Various negociations were entered into between the Zoological Society of London and the capturers, for her

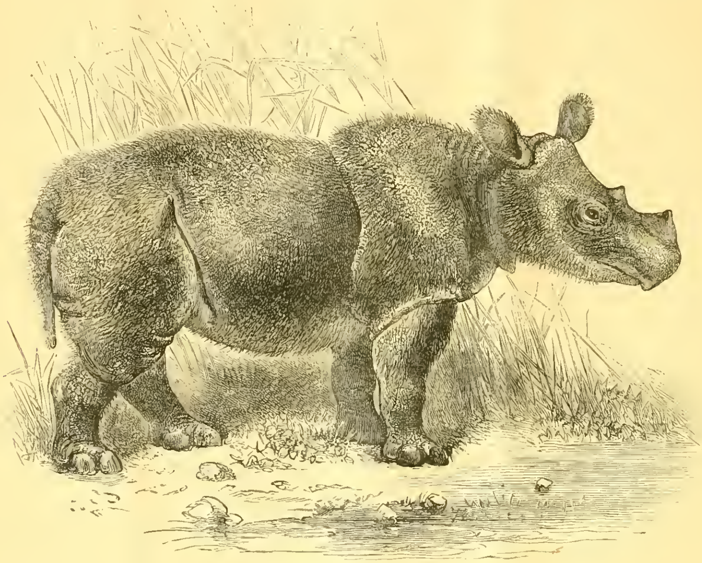

FIG. 1.—SUMATRAN RHINOCEROS

removal to this country, but these never came to any definite result. Besides the difficulty of arranging terms at such a distance apart, there seemed to be some question about the true ownership of the animal, which created additional embarrassment in the transaction. At length in the autumn of 1871, Mr. William Jamrach, the well-known dealer in living animals, being personally in Calcutta, was able to conduct the negociations to a successful result, and on his return to England, in February last, brought the animal with him. Upon her arrival "Begum" was immediately purchased by the Zoological Society, to whom, it was understood, the first offer was to be made, for the sum of 1,250*l*.

During the transit through Calcutta, this rhinoceros was examined by Dr. John Anderson, the Curator of the Indian Museum in that city. Dr. Anderson, thinking it possible that the animal might not live to reach England, had some figures of it made by a native artist, and drew up some notes on its external characters, which he communicated to the Zoological Society of London. In these notes, which have been published by the Zoological Society in their Proceedings (P. Z. S., 1872, p. 129), Dr. Anderson supposes the animal to be a Sumatran Rhinoceros (*Rhinoceros sumatrensis* of Cuvier), but comments upon several points in which it seemed to differ from former descriptions of that species, and upon its occurrence so far north of the hitherto known range of that species. When the rhinoceros arrived in London it was likewise referred to *Rhinoceros sumatrensis*—that being the only known Asiatic species of Rhinoceros with two horns, and was entered under this name in the Zoological Society's register of accessions, and is so spoken of in the new edition of the "Garden Guide." It is likewise mentioned and figured under this name in an article on Rhinoceroses, published in this journal for the 28th of March last. The cut there given is

now reproduced (see Fig. 2), in order to give an opportunity of comparing it with the figure (Fig. 1) of the true *R. sumatrensis.*

In July last Mr. William Jamrach received a female two-horned rhinoceros from Singapore, which is said to have been captured in a pitfall near Malacca, and placed it on deposit in the Zoological Society's Gardens. On comparing it with the female previously received from Chittagong, it became at once apparent that the two animals belonged to distinct, though nearly allied, species. The Malaccan animal, although undoubtedly adult, is much smaller—nearly as much as one third—than that from Chittagong. The fringe of long hairs on the posterior rim of the naked ears, which is very conspicuous in the Chittagong animal, is not present in the Malaccan example, in which, however, the whole interior of the ears is filled with short hairs. The whole body of the Malaccan animal is covered with coarse granulations, which are hardly apparent in that from Chittagong. The tail of the Malaccan animal is shorter and nearly naked; in that from Chittagong it is longer and tufted at the extremity. The head of the former animal is much narrower than that of the latter, as is particularly apparent when the distance between the ears of each is examined from a front view, and there can be no doubt that the skulls of the two animals, whenever they can be compared, will exhibit marked differences in size and structure.

Under these circumstances the Council of the Zoological Society thought it would be advisable to add the second animal also to their living collection, and accordingly agreed to purchase it of Mr. Jamrach for the sum of 600*l*. Unfortunately it did not live long in the Society's gardens.

Upon reference to authorities upon the Sumatran Rhinoceros, which was first described by Mr. William Bell in the Philosophical Transactions of the Royal Society for 1793, and afterwards by Sir Stamford Raffles in this country and by Cuvier and other writers in France, it became evident that the Malaccan animal was the true *Rhinoceros sumatrensis* of authors. This would be presumably the case, because the Fauna of the Britsh settlement of Malacca is nearly identical with that of the adjacent island of Sumatra. The Chittagong animal, its northern representative, is therefore proposed to be called the Hairy-eared Rhinoceros (*Rhinoceros lasiotis*), from its peculiar ear-fringe of long hairs, which has been already spoken of. How far the Sumatran Rhinoceros extends north along the Malayan peninsula is not yet ascertained, because, although Two-horned Rhinoceroses are known to occur in several intermediate localities, it is uncertain to which of the two allied species they belong. The range of *R. lasiotis* is likewise quite a matter of uncertainty at present, the animal being utterly unknown except from the individual in the Zoological Society's Gardens. But it is probable that it extends into Assam, where there are reports of the occurrence of a Two-horned species of Rhinoceros.

FIG. 2.—HAIRY-EARED RHINOCEROS *

Besides the two Rhinoceroses just spoken of, two other specimens of Asiatic Two-horned Rhinoceroses have been imported alive into Europe since the commencement of the present year. One of these was purchased by an agent of one of the American travelling menageries, and exported to New York; the other is now in the gardens of the Zoological Society of Hamburgh. Both these animals are said to have been received from Singapore, and to resemble exactly the Malaccan animal in London. Of the second a figure and description have been published in a Hamburgh journal (*Der Reform*), which shows that the animal is certainly the true *R. sumatrensis.*

* It should be stated that this figure is drawn on a smaller scale than that of the Sumatran Rhinoceros, the latter being really the smaller animal.—ED.

By the addition of these two animals to their Menagerie the Zoological Society have now been able to exhibit side by side specimens of four (out of the six certainly known) living species of Rhinoceros—a wonderful advance, when we consider that a very few years ago the Indian *Rhinoceros unicornis* was alone known in Europe in a living state. The two species remaining to be obtained are the Javan Rhinoceros (*Rhinoceros sondaicus*), a smaller representative of the One-horned Indian, and the White Rhinoceros of Africa (*Rhinoceros simus*). It need hardly be added that any correspondents of NATURE who may be able to assist in supplying these desiderata will not only be conferring a benefit on science, but will be liberally dealt with by the Council of the Society. P. L. S.

RECENT FALLS OF METEORITES IN FRANCE AND ITALY

THE French Academy of Sciences has recently received several important and interesting accounts of the fall of two or three meteoric masses in France and Italy. On the 23rd of July, about half-past five on a still afternoon, with a perfectly clear sky and a bright sun, a

violent report, followed by a rumbling noise, was heard in the commune of Lancé, canton of St. Arnaud (Loir-et-Cher). On the following day it was ascertained that the noise had been heard over a wide area of country, and had caused much uneasiness; and a letter arrived from a landowner of Lile-Bouchard, announcing that he had seen a "fiery lance" shooting across the sky in a direction from S.W. to N.E. with great swiftness. Whilst on its way its point appeared to split, giving rise to two meteors, which continued their way parallel to each other for some distance. Another observer south of Tours had also seen them, and described them as having the shape of a bottle, and being of an orange colour. M. De Tastes, who communicated the first account to the Academy, on proceeding to St. Arnaud, was fortunate enough to learn that one of these meteorites had been seen to fall near Lancé, and he was also successful in finding it. Its weight was 47 kilogrammes (about 103 lbs.), and it had penetrated to a depth of 1·40 metres (about 5 ft. 9 in.). On being removed, it broke into three pieces. Of the second meteorite nothing was heard for some time, but it was ultimately found at a place called Pont-Loisel, about 12 kilometres ($7\frac{1}{2}$ miles) to the south-west of the place where the other had fallen; and an account of it is given to the Academy by M. Daubrée. It is of exactly the same mineralogical character as the one first found, thus showing it originally belonged to it, but its weight is only 250 grammes, and it had only penetrated to the depth of about half a metre. On ascertaining the course of the meteorite, it was found that this, the smallest portion, had fallen first, and that the larger one had continued its course for some distance farther. In this respect it resembled the meteorite which fell on March 14, 1864, near Orgueil (Tarn-et-Garonne), in which the smallest portion, weighing about 15 grammes, first fell, and then the heavier one, weighing 40 grammes.

M. Daubrée has recently analysed the meteorite, and his results are somewhat remarkable. The largest piece is of an unequal spheroidal shape, with a rounded surface; it is covered all over with a crust, probably caused by the incandescence and superficial fusion. In appearance the fracture is black, and almost basaltic looking, showing a globular structure and numerous small spheroidal grains. Here and there small metallic grains are to be seen, yellow in colour, like iron bisulphide, these and other metallic-looking grains showing much better when the surface is polished. Its specific gravity was 3·80. Treated with water, a very small quantity of chloride of sodium dissolved out, and M. Daubrée remarks that this is not the first time that this salt has been found in meteorites; and he brings forward evidence to show that it could not have been derived from the soil in which the meteorite was buried, but that it must have formed part of it when it fell. No traces of any salts of potash, nor of any sulphates or hyposulphates could be found. Dissolved in nitric acid, a silicate was found, which was proved to consist chiefly of magnesium and protoxide of iron, and there was an undissolved residue, part of which was colourless, the remainder dark black. By means of spectrum analysis, copper was thought to be recognised; but calcium, barium, and strontium were shown to be absent. No carbon was found; but, as usual, cobalt and nickel accompanied the iron. The following is the complete analysis:—

Free iron combined with nickel and cobalt			7·81
Iron and other metals combined with sulphur		9·09	14·28
Sulphur combined		5·19	
Silicate	Silica	17·20	42·42
	Magnesia	13·84	
	Iron protoxide	11·33	
	Manganese protoxide	0·05	
Part unattacked by acid			33·44
Sodium chloride			0·12
Water			1·24
		Total	99·31

In its general appearance this meteorite resembled that which fell July 11, 1868, at Ornans (Doubs), but differs from it in the absence of free iron oxide. Other characters distinguish it from the black meteorites of Rutlam (East Indies) and that of Tadjera, near Sétif (Algeria).

Several meteorites have also lately been seen in Italy, which have excited considerable attention. One on the evening of the 8th of August, at about eight minutes past 11, was seen at Rome, and also at Velletri, Naples, and Palermo. A more interesting one than this was seen near Rome, at about 5.15 mean time, on the morning of the 31st of August, of which Padre Secchi has communicated a long account to the Academy. At about 5.15 in the early morning on that day a globe of fire, well marked and a little red in colour, appeared on the horizon towards the S.S.W., proceeding towards the N.N.E. Its progress was at first slow, but this gradually increased, and it left behind it a luminous train like a cloud lit up by the sun. When it had reached its highest point, E.N.E. from Rome, it suddenly expanded and took the shape of a cone having its base rounded in front; it brightened up greatly and finally disappeared. Three or four minutes after its disappearance a tremendous detonation was heard, which caused, in many places, houses and glass to rattle. This explosion was dull, different to thunder, and resembling more the explosion of a mine, and was followed by a rolling sound like file-firing. This noise was heard by Padre Secchi himself, but he did not see the globe of fire. The vapour-like residue left by the meteorite was at first in the shape of a long straight line, but it soon enlarged, and turned about like some great serpent until it disappeared about ten or fifteen minutes afterwards.

This meteor was also seen a long way from Rome, at Viterbo and at Veroli, but the noise of the explosion in each place was equally strong, and caused houses and glass to rattle. A small piece of the meteorite which fell near him was picked up by a curé soon after the explosion at Affile, near to Subiaco, where the ball of fire and the noise of the explosion were well seen and heard. The fragment has been recognised as a piece of a very ferruginous meteorite, very hard, and covered over with a crust. It is also said that at Orvinio "black stones" have been picked up. But this is not all. A well-instructed farmer had assured me, says Padre Secchi, that the same morning at 3.30, being at Casale S. Lorenzo, near to Porto d'Anzio, whilst he was waiting for his men, he saw out at sea, at an elevation of about 30° or 40°, a mass of fire or light like a fire, of a round form, apparently fixed, and which could not be confounded either with a lighthouse or any fire at sea. The position of this fire was exactly the same as that from which the meteorite afterwards appeared, and which he saw very distinctly in the heavens at 5.15, when he was so much struck with the coincidence of direction that he judged it to be the same mass of fire which had then reached the earth. The size of the meteorite at its first appearance and at the moment of explosion is represented as little less than the diameter of the moon. The extreme distances at which it was seen are 150 kilometres (93 miles) apart.

Another meteorite was seen at Subiaco on August 6, at four in the morning; and another near Ascoli on the 18th of September.

J. P. E.

DARDANELLES AND BOSPHORUS UNDER-CURRENT

It will be in the recollection of such of your readers as have followed the discussion on Ocean Currents, that I ventured nearly two years ago* to predict the existence of an Under-current of dense Ægean water into the Black Sea, "on the double ground of *a priori* and *a posteriori* necessity;"—that is, I affirmed it to be a necessary result of the excess of Specific Gravity in the water

* Proceedings of Royal Society, Dec. 8, 1870, § 123.

of the Ægean above that of the Euxine; whilst, I argued, if the salt continually passing out of the Black Sea by the surface-current were not thus replaced, the continual excessive influx of River water would, in time, wash the whole of the salt out of its basin.

My position was assailed by Captain Spratt, who affirmed (1) that his own experiments in the Dardanelles had shown the existence of still water beneath twenty fathoms; and (2) that the return of salt to the Black Sea was effected by a *surface* in-current during the winter, when the rivers are low, and when the wind sets *from* the Ægean along the Dardanelles, the Sea of Marmora, and the Bosphorus.

On an examination of Captain Spratt's experiments, however, I came to the conclusion that, when rightly interpreted, their results bore out *my* view of the case; and, as I stated in my letters of Nov. 14, 1871, my interpretation of them had the sanction of three eminent Naval Surveyors. Captain Spratt maintained that because a surface-buoy from which a "current-drag" was suspended at a depth beneath twenty fathoms *remains stationary*, the waters in which the "drag" hangs must also be *motionless*. To me, on the other hand, it appeared indisputable that if the surface-buoy is floating in a *current* which puts a strong strain on the suspending line, that strain would draw the "current-drag" through *still* water; so that the stationary condition of its suspending buoy can only be accounted for on the supposition that the action of the surface-current on it is *neutralised by some pressure in the opposite direction*, which can be nothing else than that of an under-current *meeting* the "current-drag."

The question is discussed in an Appendix to the forthcoming Report of my last year's work in the *Shearwater*, of which the following (written on board of her a year ago) is an extract:—

"Now since, according to Captain Spratt, this stationary condition of the 'current-drag' was shown at all depths below forty fathoms in the Sea of Marmora (even down to 400 fathoms), and at all depths below twenty fathoms in the Dardanelles, it seems an irresistible conclusion that whilst there is a rapid superficial *out*-current, running in the Dardanelles at the rate of $2\frac{1}{4}$ miles per hour, there is a deeper *under*-current from twenty fathoms to the bottom, running more slowly *in*-wards from the Ægean into the Sea of Marmora through the Dardanelles, and thence, it may be presumed, through the Bosphorus, into the Black Sea. And this conclusion finds complete confirmation in the results of a comparison between the respective Densities and rates of movement of the Dardanelles water at different depths, as observed by Captain Spratt himself. For whilst the progressive decrease in the movement of the 'current-buoy,' from $2\frac{1}{4}$ knots at the surface to almost nothing at twenty fathoms, indicates (as just now shown) first a cessation of all movement in the stratum in which the 'current-drag' hangs, and then a reversal in the direction of the current as the lower depth is approached,—the Density increased from 1,020 at the surface to 1,028 at twenty fathoms, and 1,029 at forty fathoms; the surface-water thus corresponding with that of the Sea of Marmora, whilst the water of the entire stratum from twenty fathoms to the bottom was equal in density to that of the Mediterranean. I hold, then, that the existence of an Under-current of dense Mediterranean water through the Dardanelles into the Sea of Marmora, is incontestably proved by the very experiments and observations which have been adduced by Captain Spratt as demonstrating the unsoundness of the Under-current doctrine."

Having understood that the *Shearwater*, on the completion of the Survey of the Gulf of Suez, would proceed to the Dardanelles, I requested the Hydrographer to direct that the question of the Under-current should be thoroughly examined; and he issued instructions accordingly.

I yesterday learned through the *Levant Herald*:—(1) that the existence of a strong Under-current has been placed beyond all question, a boat having been carried along by the "current-drag" suspended from it, *in opposition to the surface-current*: (2) that the rate of this Under-current is estimated as greater than the speed of the *Shearwater's* steam-launch; and (3) that it runs at a depth of twenty fathoms,—precisely that at which my interpretation of Captain Spratt's experiments has led me to predicate its existence.

I venture to think that this verification of my prediction will be regarded as a confirmation of the general Physical Theory of Under-currents on which it was based; and it is now for those who oppose that Theory to show by what other force than the difference in the *weight* of the Ægean and the Black Sea columns, consequent upon their great difference in Specific Gravity, the Dardanelles Under-current can be sustained.

WILLIAM B. CARPENTER

NOTES

MR. C. MELDRUM writes from Mauritius that he has been looking into the subject of the West Indian hurricanes, and he believes that they show a periodicity of frequency corresponding nearly with that of sun-spots. So far as he has yet examined the subject, the maximum of cyclone frequency is a year or two after that of sun-spots. It was so ten years ago, and is so again probably, the mean cyclone frequency occurring in 1862, and this year, 1872, being the most marked for hurricanes since. We greatly regret to hear that Mr. Meldrum is suffering severely from illness brought on by over-work. It will scarcely be credited that the only allowance made to him by the Government for an assistant is 50*l*. per annum!

WE learn from the *Gardener's Chronicle* that M. Milne-Edwards has undertaken a task for which all naturalists owe him thanks. The archives of the Museum of Natural History in the Jardin des Plantes contain a collection of 6,000 volumes and more than 1,500 manuscripts, which are almost entirely unknown to the scientific world; for nearly 60 years the dust that lay upon them has never been disturbed. In 1803 it was proposed to create a special department for these and other works and documents, but the idea was abandoned, and since that time the collection has remained huddled away in a corner, on account of space being wanting in the library of the museum. M. Milne Edwards has determined that such a state of things shall not be perpetuated, and has arranged that the collection shall be carefully examined, catalogued, and placed at the disposition of the scientific world. The manuscripts include a considerable number by Buffon, Cuvier, and Daubenton; there is a series of 24 pen-and-ink drawings by the last-named naturalist, representing the various types of Merino sheep, and exhibiting great artistic ability, and many albums filled with drawings of plants and flowers. It is proposed to add the books to the library of the museum, but there is so little space to be disposed of there, that it is expected the MSS. will be transferred to the great National Library, in the Rue Richelieu.

SIR DAVID BAXTER, who endowed in his life-time a Chair of Engineering at the University of Edinburgh, has by his will left the munificent gift of 40,000*l*. for the general purposes of the University.

THE death is announced, on the 16th inst. at Torquay, at the age of 75, of Lady Hooker, widow of Sir W. J. Hooker, K.H., formerly Director of the Royal Gardens, Kew.

MR. RAY LANKESTER, M.A., Fellow of Exeter College, Oxford, writes to correct the statement in our University Intelligence last week, that he has been appointed Deputy to the Linacre

Professor of Anatomy and Physiology in that University. He is merely delivering a course of lectures at the request of the Linacre Professor, which the Professor has hitherto been in the habit of delivering himself.

By a majority of two to one the managers have decided to remit the question of the admission of lady medical students to the practice of the Edinburgh Royal Infirmary to a committee, to report "whether, and to what extent, it is practicable to give instruction to females within the wards of the Infirmary." The minority desired that arrangements should at once be made for the instruction of lady students. *Apropos* of this subject, a moiety of the 1,000*l*. recently promised by Mr. Walter Thomson to the funds of the Committee for securing a complete Medical Education of Women in Edinburgh has been forwarded to the Executive Committee; (1) in payment of expenses that have to be incurred in prosecuting the claim of women to the highest medical education obtainable in the University of Edinburgh and elsewhere; and (2) in assisting or encouraging lady students who have been subjected to extra charges by the obstacles interposed in Edinburgh.

A new University is to be opened on November 1, at Klausenburg, the capital of Transylvania.

Mr. Thomas Howard, of the King and Queen Iron Works, Rotherhithe, who was for 37 years an Associate of the Institute of Civil Engineers, has bequeathed to it the sum of 500*l*., free of legacy duty, which sum he has, by will, directed "to be invested, and the interest thereof to be applied in such manner and under such conditions and instructions as the Council of the said Institution may think most expedient, for the purpose of presenting, periodically, a prize or medal to the author of a treatise on any of the uses or properties of iron, or to the inventor of some new and valuable process relating thereto, such author or inventor being a member, graduate, or associate of the said institution."

The following are among the publishers' announcements for the coming season:—By Mr. Murray:—The Expression of the Emotions in Man and Animals, by Charles Darwin, F.R.S. (with photographic and other illustrations); Records of the Rocks, a series of Notes on the Geology, Natural History, and Antiquities of North and South Wales, Siluria, Devon, and Cornwall, by the Rev. W. S. Symonds, F.G.S. (with illustrations); Travels in the Eastern Caucasus, on the Caspian and Black Seas, especially in Daghestan, by Lieut.-Gen. Sir Arthur Cunynghame, K.C.B. (with map and illustrations); The Geography of India, Ancient and Modern, an Elementary Manual for Students and General Readers, by Col. Yule, C.B. (with maps and woodcuts); The Longevity of Man, its Facts and its Fiction, including Observations on the more Remarkable Instances, and Hints for Testing Reputed Cases, by William J. Thoms, F.S.A.; Metallurgy of Gold, Silver, and Mercury, by John Percy, M.D., F.R.S., Lecturer on Metallurgy at the Royal School of Mines (with illustrations); The Geological Evidences of the Antiquity of Man, by Sir Charles Lyell, Bart., F.R.S., 4th edition revised; Metallurgy of Fuel, Wood, Coal, Copper, Zinc, &c.; also, Metallurgy of Iron and Steel, by John Percy, M.D., F.R.S., Lecturer on Metallurgy at the Government School of Mines (new and revised editions, with illustrations, 2 vols.); Siluria: a History of the Oldest Rocks in the British Isles and other Countries, by Sir R. I. Murchison, F.R.S. (5th and cheaper edition, with maps, plates, and woodcuts). By Messrs. Macmillan:—The Forces of Nature, a Popular Introduction to the Study of Physical Phenomena, by Amédée Guillemin, translated from the French by Mrs. Norman Lockyer, and edited, with Additions and Notes, by J. Norman Lockyer, F.R.S. (illustrated by 11 coloured plates, and 450 woodcuts); Papers on Electrostatics and Magnetism, by Prof. Sir W. Thomson, F.R.S.; The Depths of the Sea: An Account of Investigations conducted on board H.M.'s Ships *Lightning* and *Porcupine* in the Years 1868-9, under the Scientific Direction of W. B. Carpenter, M.D., F.R.S., J. Gwyn Jeffreys, F.R.S., and Wyville Thomson, LL.D., F.R.S., edited by Dr. Wyville Thomson (with illustrations). By Messrs. L. Reeve and Co.:—Lahore to Yarkand, Incidents and Natural History of the Expedition of 1870, by Dr. Henderson; On Harvesting Ants and Trap-door Spiders, by J. T. Moggridge, F.L.S.; Vol. 2 of the English Edition of Prof. Baillon's Natural History of Plants; and the Fifth Part of Hanley and Theobald's Conchologia Indica. By Messrs. Blackwood and Sons:—A Manual of Palæontology for the use of Students, by H. Alleyne Nicholson, M.D., D. Sc. Professor of Natural History and Botany, University College, Toronto (with 400 engravings); Advanced Text-Book of Botany for the Use of Students, by Robert Brown, M.A., Lecturer on Botany under the Science and Art Department of the Committee of the Privy Council on Education. By Messrs. A. and C. Black:—School Manual of Zoology, by Andrew Wilson (with illustrations; New Edition of Jukes' Scotch Manual of Geology, edited by Alfred J. Browne; New Edition of Elements of Mineralogy, by James Nicol, Professor of Natural History in the University of Aberdeen. By Messrs. H. S. King and Co.:—The Forms of Water in Rain and Rivers, Ice and Glaciers, by John Tyndall, LL.D., F.R.S. (with 32 illustrations); Physics and Politics, by Walter Bagehot, being vols. 1 and 2 of the International Scientific Series. By Messrs. Lockwood and Co.:—A rudimentary Treatise on Coal and Coal mining, by Warington W. Smyth, M.A.; Weale's Dictionary of Terms, new and enlarged edition, edited by Robert Hunt, F.G.S.; Waterworks for the Supply of Cities and Towns, with a description of the Principal Geological Formations of England as influencing Supplies of Water, by Samuel Hughes, new edit.; Projection, Orthographic, Topographic, and Perspective, giving the various Modes of Delineating Solid Forms by Constructions on a Single Plane Surface, by J. F. Heather, M.A.; A First Book of Mining and Quarrying, with the Sciences connected therewith, for use in Primary Schools and Self-Instruction, by J. H. Collins, F.G.S.; Places and Facts in Physical and Political Geography, for the use of Candidates in Public and Private Examinations, by the Rev. Edgar H. Rand; a Course of Analytical Chemistry, specially prepared for Universities and Science and Art Departments, Advanced and Honours Examinations, by W. W. Pink. By Messrs. S. Low, Son and Co.:—The Arctic Regions, illustrated with Photographs, taken on an Art Expedition to Greenland, by Wm. Bradford; with descriptive Narrative by the Artist; in 1 vol. royal broadside, 25 inches by 20 inches, bound in morocco; The Atmosphere, by Camille Flammarion, translated under the superintendence and revision of James Glaisher (with numerous woodcut illustrations and 10 beautiful chromo-lithographs). By Mr. Maclehose:—A Class-Book of Qualitative Chemical Analysis, by John Ferguson, M.A. By Trübner and Co.:—Mythical Zoology, or the Legends of Animals, by Angelo de Gubernatis, Professor of Sanskrit and Comparative Literature in the Instituto di Studii Superiori e di Perfezionamento, at Florence (2 vols.); A Practical Treatise on Pure Fertilisers, and the Chemical Conversion of Rock Guano, Marlstones, Coprolites, and the Crude Phosphates of Lime and Alumina generally, into various valuable Products, by Campbell Morfit, M.D., F.G.S. (with 28 Illustrative Plates or Construction Plans, drawn to Scale Measurements); Human Physiology, the Basis of Sanitary and Social Science, by T. L. Nichols, M.D. (with illustrations).

Prof. Galloway, of the Royal College of Science, Dublin, has two works nearly ready for the press:—"How the Natural Sciences are Taught, and how they ought to be Taught; with a Scheme for rendering more efficient the Government Science Schools;" and "A Manual of Applied Analysis."

THE first meeting for the season of the Victoria Institute took place on Friday last, when a number of new members were elected, the Society being stated to be greatly on the increase. The first paper to be read during the coming session will be by Mr. Charles Brooke, F.R.S., on Force and Energy.

THE Geologists' Association will hold its first meeting for the season on Friday evening, Nov. 1, when Dr. Hyde Clarke will read a paper on the Influence of Geological Reasoning on other Branches of Knowledge.

AMONG the courses of University Lectures and other means of scientific instruction announced to be given at Harvard University, Cambridge, U.S.A., during the present session, are the following:—On General Entomology, by Prof. Hagen—Mondays, Wednesdays, and Fridays, at the Museum of Zoology. Geological Excursions, by Prof. Shaler, on Saturdays—about eighteen during the year. On the Structure and Affinities of the Brachiopoda, by Prof. E. S. Morse—Mondays and Wednesdays, in Roylston Hall. On General Ornithology, by Mr. J. A. Allen—Wednesdays, at the Museum of Zoology.

THE following is the programme of papers to be read at the Winter Session, 1872-73, of the Glasgow Society of Field Naturalists:—On the present tendencies of Science, by J. Allan, Oct. 15.—On the Distribution of Plants, by D. Gregorson, Oct. 29.—A Life History of *Nematus saliceti*, together with some account of its Parasites, by P. Cameron, jun., Nov. 12.—On Spiders, by S. M'Donald, Nov. 26.—On Zoophytes, by W. D. Benson, Dec. 10.—On the Exotic Plants of Clydesdale, by R. M'Kay, Dec. 24.—On the Definition of Species, by Alex. Watt, Jan. 7, 1873.—Notes of Observations on Marine Zoology, by John Harvie, Jan. 21.—Notes of Observations with the Microscope, by G. Barlas, Feb. 4.—Botanical Gleanings from the Rubbish Heaps of the City, by G. Horne, Feb. 18.—On the Cynipidæ of the Glasgow District, by P. Cameron, jun., March 4.

A SERIES of short lectures is about to be delivered at the Ipswich Museum by the Curator, Mr. J. E. Taylor, and other gentlemen, illustrative of the objects in the museum. They will be held on Friday evenings throughout the winter, and admission will be free.

THE first of Abbé Moigno's long-contemplated *Salles du Progrès* was inaugurated on Tuesday evening, Oct. 15, at 30, Rue du Faubourg Saint Honoré, by a distinguished assembly, including M. Otto Struve, the Russian Astronomer. The praiseworthy object of the Abbé in establishing these assemblies is to popularise Science by means of lectures, exhibitions, conversaziones, &c., in which the instructive is combined with the entertaining. On Tuesday he detailed the programme which he intended carrying out at future meetings, and those present were entertained by the performance of some pieces of music. This last rather novel feature in scientific assemblies forms a regular part of the Abbé's programme. One or more pieces from the works of great masters of music will be performed at each meeting.

THE British Association Meeting at Brighton has already begun to bear fruit in that town. A desire has been aroused among several of the inhabitants to know more of Natural Science, and a course of science lectures in the Dome, chiefly to working men, has been projected. But the ladies have taken the initiative, and the germ of a Ladies' Educational Association has already been planted. Prof. W. F. Barrett has been invited to give the first course of lectures on Experimental Physics. The introductory lecture on the "Study of Natural Knowledge," was given last Friday afternoon, when, in spite of the wet, upwards of 50 ladies assembled. Miss Goulty, of 2, Sussex Square, Brighton, to whom it is right to add the effort is mainly due, has permitted the use of her spacious schoolrooms for these lectures. The second lecture on "Magnetism" will be given to-morrow (Friday) afternoon.

SIEBOLD'S NEW RESEARCHES IN PARTHENOGENESIS *

II.

SIEBOLD'S experiments extended over four years, and although some hundreds of nests were more or less observed, only thirty-seven—but these amply sufficient—gave the answer to his questions, passing successfully through all the stages above noted. Firstly, they furnished a virgin colony in a nest absolutely free from eggs and larvæ—except a few advanced larvæ purposely left in some nests and noted down—which colony laid eggs; secondly, these eggs produced without exception (some few eggs not developing) males.

The method of recording which was used must be mentioned to give a notion of the accuracy of the observations. A series of plans of each nest was kept, each cell being represented and its contents at different dates. Successive plans were used for recording the successive changes in the number of cells of the nest, and in their contents at different periods of the observations. Signs jotted down in the plan cells indicate such facts as these—*e.g.*, the cell contains a "parthenogenetic egg," or "a second parthenogenetic egg which was laid after a first one had disappeared," or "a larva sprung from the queen," or "a parthenogenetic male larva," &c., &c. A second record was kept, and is given for twenty-two cases, in which the following facts were noted:—Number of the nest, date it was made moveable, number of cells at that time, day of emergence of first worker-female, date of destruction of queen, eggs, and grubs, number of larvæ and pupæ left undestroyed at this date, date of first laying of parthenogenetic eggs, date of first emergence of parthenogenetic larvæ, date of first emergence of drones born from queens' eggs (these were null in most cases, and were always so late as not to affect the experiments by possibly impregnating the worker-female), number of the same, number of cells observed when the experimental conditions were established, date and duration of the experiment, maximum number of female workers employed in the affairs of the nest, number of larvæ, pupæ, and wasps of the parthenogenetic brood found at the conclusion of the experiment. After the account of the artificially obtained results, two cases are recorded in which Siebold found a parthenogenetic colony naturally established by the same accident which had destroyed their queen and comb.

Before concluding this chapter of his book, Siebold makes the very important observation that the facts observed in the parthenogenesis of Polistes are in opposition to the view maintained by Leydig, viz., that the sexual differentiation of the egg is independent of its fertilisation, and that the evolution of the male sex is due to diminution of nutrition and warmth. Bessels has already, in opposition to Landois, shown that this is not the case in the bee. If it were true for Polistes, the eggs laid in the early year, when it is cold, and when there is only the queen to attend to the larvæ, should produce drones. On the contrary, they produce females, and the drones appear precisely at the time when warmth and nourishment are most abundant.

Siebold concludes, therefore, that (1) the eggs bring with them from the ovary the capacity of differentiating themselves as males, and (2) of developing themselves, independently of male influence into male individuals; (3) but the same eggs can be changed in these properties by the influence of the male sperm elements, and proceed to develop as female individuals.

The second chapter, very short, is on Parthenogenesis in *Vespa holsatica*, which was inferred to occur from the observation of a naturally-produced queenless colony, the larvæ in the cells of which were all male.

The third chapter is on Parthenogenesis in *Nematus ventricosus*, the larva of which is known as the Gooseberry-caterpillar. Since three or more generations of these leaf-wasps occur in the season, they furnished abundant material, and the old supposition of parthenogenesis first put out as regards them by Robert Thorn, in the *Gardener's Magazine*, 1820, is shown by Siebold to be justified by carefully conditioned experiment. Some valuable observations on the anatomy of the generative organs, and on the curious increase in the size of the egg after it is laid, are given. The parthenogenetically produced progeny are in this case also male. The results of the *Nematus* experiments were not ready for publication until after the issue of the present work, and we

* "Beiträge zur Parthenogenesis der Arthropoden." Von C. Th. E. von Siebold, Professor der Zoologie und Vergleichenden Anatomie in München. (Leipzig: Engelmann, 1871.)

have received, through the kindness of Dr. Dohrn, a copy of the Sitzungsberichte of the Munich Academy of November 4, 1871, in which they are fully given. It appears that though an occasional female appeared among the male broods produced by unfertilised females, this was, in every case where it happened, fully accounted for by the accidental access of a fertilised female, or some such misadventure, duly noted in the records kept of the observations.

Of the fourth and fifth chapters, treating of Parthenogenesis in the Lepidoptera, *Psyche Helix*, *Solenobia triquetrella* and *lichenella*, we have not space to speak in detail. The same intimate inquiry, and the same very necessary prodigality in the amount of material subjected to experiment, which we noted above as to Polistes, characterise Prof. Siebold's treatment of these cases. The parthenogenesis in these cases produces female broods, and though the male of *Psyche Helix* has been discovered since Siebold's former researches on this moth, his conclusion is by no means invalidated, for the males are excessively rare. They were first discovered by Claus, of Marburg, who has indicated characters by which future observers may distinguish the sex of the caterpillars. Out of many hundreds of broods reared by Siebold, taken in various places, ranging from the Baltic to the plains of Lombardy, only once did he obtain males. There appear to be thus broods which are entirely female, and broods which are of mixed sexes. The conditions under which the male sex makes its appearance are not yet ascertained. It is exceedingly desirable that those who may be fortunate enough to come across a mixed brood, should make experiments to ascertain if all the eggs which are fertilised produce males. The females of the purely female broods are completely developed in every respect, having perfect copulatory organs, and the egg is furnished with a micropyle; therefore, as Siebold maintains, they must not be called pseud-ova. It should be mentioned that the inquiries necessary to establish the identity of the species, and the distinctive characters with regard to these little moths, have occupied a great deal of our author's time and attention, and are here recorded. In regard both to Psyche and Solenobia examination with the microscope was employed to determine the absence of male elements from the *receptaculum seminis;* and we have moreover an account of the structure of the ovaries. In relation to this matter, Professor Siebold takes the opportunity of replying to some criticisms of his former work by M. Plateau, who appears to have made little of the arguments based on the proof thus obtained of virginity, without knowing the real extent and nature of Siebold's studies, having, in fact, only read of them in an imperfect abstract. It appears also that M. Plateau took "ein einziger Fundort" to mean "un naturaliste collecteur," an amusing mistake to which our attention is drawn in a note, p. 155. We may briefly mention here with regard to Solenobia, that it appears that *S. lichenella* is only the female brood of *S. pineti*, of which males and females regularly occur. No structural difference appears to exist between the two kinds of females, but the former, on escaping from the chrysalis-sac, at once proceed to lay eggs, which produce invariably females; whilst the latter wait for copulation, and if that be withheld, die, and dry up without laying their eggs. These insects offer most promising material for further researches on the conditions attending the differentiation of sex.

We now come to the sixth and last chapter, on "the Parthenogenetic Reproduction in Apus and allied Crustacea." Already, in 1856, Siebold had stated his supposition that *Apus cancriformis*, *Limnadia gigas*, and *Polyphemus oculus*, in which species no males had been observed, presented examples of true parthenogenesis, and were not to be regarded as bud-producing "nurses," in a so-called alternation of generations. Leuckart subsequently expressed the same opinion with regard to the reproduction, independent of males, observed in *Daphnia*, *Apus*, and *Limnadia*. Ever since that period Siebold has continually kept an eye upon Apus. In 1858 the males of Apus were discovered by Kozubowski, and Siebold received specimens from various localities. He thus learned to distinguish with perfect facility the two sexes, and was enabled now to convince himself that, as with the Lepidoptera above spoken of, so with Apus, broods occur which are entirely destitute of males, and go on reproducing parthenogenetically, whilst other broods occur in which both sexes are present. The number of Apus of two species—*Apus cancriformis* and *Apus productus*—examined by Siebold, amounts actually to some thousands. He received quantities taken from various ponds in middle Europe (Apus occurs in shallow pools which dry up during parts of the year, and it can be taken in immense quantity), and had the opportunity of studying one pond—that at Gossberg, near Munich, with minuteness, from the year 1864 to the year 1869 inclusive, besides casual examinations of the same pond in 1857 and 1858. Time after time, taking several hundreds of the Apus from the pond, he never found a single male amongst them. On one occasion he had the whole contents of the little pond removed with the greatest care, so as to feel sure that he had obtained every Apus present. He received on this occasion 5,796 specimens of Apus, *every one of which being carefully examined* proved to be female. At the same time 2,576 specimens of Branchipus were obtained from the pond, which were, as usual, of both sexes. In those cases where ponds afforded both males and females of Apus, it is remarkable that the proportion of the sexes was very variable. The highest proportion of males appears to be in a case recorded by Sir John Lubbock, who found thirty-three male and thirty-nine female *Apus productus* in a pond near Rouen, whilst among 193 specimens of *Apus cancriformis*, from a locality near Krakow, only one male occurred. What is most important about this variation in the proportion of males to females is that in two or three localities, furnishing mixed generations of Apus, from which he has received, year after year, numbers of specimens, Siebold has observed an apparent constantly-augmenting disproportion of males to females, and he is led to the supposition that in these cases the males will at last cease altogether, and thus a female generation be produced which will continue to reproduce itself parthenogenetically, as in the Gossberg and a great number of other ponds. This is, however, by no means proved; and we have no idea at present as to how the males may make their appearance again, or what are the conditions affecting their development and extinction. It occurred to Siebold that an objection might be urged against parthenogenesis in Apus, in that, although he examined consecutive generations and found them always female, he could not be sure that males had not been present before he took his specimens, and had not died and decomposed after having fertilised the females. To meet such an objection, he firstly made himself thoroughly acquainted with the male generative organs and the spermatozoa, and secondly with the ovaries and their development. He found the spermatozoa to be motionless like those of other Crustacea, and he never succeeded in detecting any of them in the female genitalia amongst the specimens belonging to supposed female generations. But he equally failed to find spermatozoa or a receptacle for them in the female genitalia of the specimens of mixed generations, and therefore no conclusion could be drawn from the observation. The structure and development of the ovum, however, made this observation decisive, since it was found that an egg-shell forms round the ovum in the uterus, and, in the absence of a micropyle, fertilisation, if it takes place at all, must be accomplished before this shell is hardened. A further proof of another kind was obtained by experiment. Having removed eggs from females, which certainly at the time contained no spermatozoa, Siebold placed them in a small tank, and from these obtained Apus-embryos. Others were reared to maturity from eggs taken in the pond.

The relative size of male and female is a question about which there is some interest; differences which have been observed seem to depend on this, that Apus continues growing as long as the pond in which it lives does not dry up, and hence the eggs which hatch soonest give the largest-sized progeny. In his tabular statements Siebold gives measurements of the specimens examined by him at different times from various localities.

A few words must be said here upon the very extraordinary history of the ovum of Apus made out by Siebold, the structures being identical, whether the female examined belonged to a parthenogenetic or digenetic brood. The essential female organs of reproduction in Apus may be roughly described as two large tubes placed on either side the alimentary canal, opening externally at the posterior end, and giving off towards the other end primary and secondary branches. On the ends of these short secondary branches are situated the egg follicles. Four cells appear in each egg follicle in a very early stage of its development, and one of these takes on more rapid growth—becoming the egg-cell—whilst the others disappear as deutoplasmogen or vitellogenous cells; the egg then acquires some size and a red colour, and has a visible germinal vesicle. But such eggs are much smaller than the eggs observable in the main stem of the ovarian tube, and this appears to be the very startling explanation. The eggs escape from their

follicles as a matter of course, and pass along the canal leading from it to a primary branch of the ovarian tube, and there two and sometimes three of these eggs *fuse into one mass*, around which a shell is secreted, and which thus forms the actual egg—really a threefold egg; and from such a wonderfully formed egg only one embryo develops. Unfortunately we are not told what becomes of the germinal vesicles; according to the drawings they seem to disappear at this stage. We know of the development in the tunicate *Pyrosoma* of five embryos from one egg, here we have the converse case of one embryo developing from three eggs. Siebold appears to have convinced himself that the fusion is a normal thing, and not due to any pressure or osmotic action taking place during the microscopical examination. The structure of the ovary of Apus is figured in a plate.

As to the other crustaceans named, which are *Artemia salina* and *Limnadia Hermanni*, the occurrence of parthenogenetic broods is inferred from the descriptions of other writers whose works are criticised at some length, and also from examination of specimens. It seems not impossible from an observation of Zenker that in *Artemia salina* parthenogenetic alternate with digenetic broods. In the beginning of the year 1851 this observer found three males among one hundred females, later in July the same pond furnished thousands of females, but not one male.

In conclusion, Prof. Siebold, whilst adopting Leuckart's term "Arrenotoky," to designate the phenomenon of the parthenogenetic production of male offspring, as seen in the Hymenoptera, proposes the parallel term, "Thelytoky," for the pathenogenetic production of female offspring as demonstrated now conclusively in some Lepidoptera and Crustacea. It seems to us that a third term should also be available for the case of mixed offspring (that is of two sexes) such as "Amphotoky;" and the terms need not be limited to parthenogenetic cases. In his concluding remarks, whilst repeating the expression of his conviction that parthenogenesis will be found more and more to be of frequent and fixed occurrence in various classes of animals, Siebold alludes with caution to the list of cases in which parthenogenesis is stated to occur, given by Gerstaecker in Bronn's "Classen und Ordnungen des Thierreichs." Gerstaecker rightly enough distinguishes cases in which parthenogenesis has been observed as an accidental and rare exception, and those in which it has a definitely recurring place. Siebold considers (and after the great pains he has himself expended on the cases recorded in this book, he is fully warranted in so doing) that many of the examples put forward by Gerstaecker require a more careful testing, and he offers some remarks on parthenogenesis in the gall-flies, and in the silkworm moth. Finally, he alludes to cases among Vertebrates in which indications of a power of development in the egg, independent of the male element, have been observed. The most remarkable of these is that quoted by Leuckart in his work already cited, which Siebold omits here, but has done justice to in the short supplementary paper read at the Munich Academy since the publication of this book. In 1844 Prof. Bischoff found ova in the uterus of an unimpregnated sow, which exhibited segmentation of the yelk, some into two and four, and others into sixteen and twenty divisions. Other cases here given are as follows:—In the oviduct of a three-year-old rabbit, thoroughly separated pathologically from the uterus, Prof. v. Hensen of Kiel found ova in various stages of yelk-division, and some of their cells had even advanced into a branched condition. Dr. Oellacher of Innsbruck has observed stages of yelk-division in unfertilised hen's eggs. In fishes, in 1859, Agassiz observed yelk-division occurring in the eggs of Gadidæ, whilst yet in the ovary, and considered it to be due to impregnation, even stating that he had seen certain fishes place themselves in such a position as to favour this supposed intra-ovarian fertilisation. Burnett has since investigated the case, and concludes that the yelk-division is independent of fertilisation, a supposition which is rendered in every way probable from other researches on the fish egg; but, curiously enough, Dr. Burnett thinks these eggs should be regarded as "germs," and not as "true eggs," an opinion to which Siebold, of course, is completely opposed, and which, in invertebrate cases, has been shown to be untenable.

Siebold does not allude to those cases of ovarian cysts found occasionally in the unfertilised human female, and containing hair and teeth—a phenomenon which we should be glad to see further discussed and investigated, since, as far as we can remember, the origin of the contents of such cysts from irregularly developing ova is probable. The eel is suggested as a possible parthenogenetic vertebrate. It is a very strange fact that we are still ignorant of the ripe eggs and embryos as well as of the males of the eel, even as in the time of Aristotle. With the following words of that greatest naturalist, addressing them to those who still refuse to accept the existence of Parthenogenesis, Siebold ends his book:—"More belief must be given to observation than to theory, and this last is only worthy of belief when leading to the same result as experience."

E. RAY LANKESTER

ON SOME NEW POINTS IN THE MOUNTING OF ASTRONOMICAL TELESCOPES *

THE very great inconvenience attendant upon the use of the ordinary position circle of a micrometer divided on a metallic limb, and the necessity of having small lamps hung on to the micrometer for producing that very useful character of illumination of the wires known as the "dark field," has induced me to introduce some modifications in this (to the observer at least) very important part of an equatorial instrument.

These modifications have already been applied with success, and for the first time (as far as I am aware) to a 7-inch refracting telescope now in course of erection at the Observatory of the Royal Artillery Institute, Woolwich; and I have (in consequence of this success) been ordered to adapt them to the Great Equatorials now in course of construction for the Royal Observatory, Edinburgh, and the Observatory of the Lord Lindsay, Aberdeen.†

The rack and pinion tube carrying the eye piece or micrometer revolves freely in the casting which forms the lower end of the telescope tube, and carries a brass plate (all cast in one piece), on which is cemented a flat ring of plate glass, muffed on back, and in front varnished with an opaque varnish. Through this varnish the divisions are cut, so that on being illuminated from behind, the divisions appear bright upon a black ground. The vernier is similarly treated, and the whole of this circle, being covered with a cap, with a glazed window only sufficiently large to expose the vernier and about 15° of the circle, is protected from possible injury and is read most conveniently through this window, being illuminated by a beam of light constantly directed upon it from a lamp hanging on end of the declination axis, as will be afterwards explained.

Between the fixed casting which forms the end of the telescope tube and that which revolves in it is another metallic circle cut into 360 teeth on edge, and with 90 holes drilled accurately on face: into the teeth on edge is geared a screw which is mounted on fixed casting, one revolution of which is of course equal to an angular movement of 1°.

In the other (outer) moveable brass circle is mounted a steel pin working up and down in a small cylinder; this pin, being pressed down by a small spiral spring, enters into one or other of the 90 holes in the intermediate circle, and thus clamps the whole eye-end to the intermediate circle, in which condition a slow motion is obtained by the endless screw. When it is desired to move the eye-end through a large angle, the rack and pinion tube is grasped by the hand, and in doing so the hand almost necessarily grasps also a small steel trigger which lifts the steel pin out of the hole, frees the moveable circle, and allows it to be placed in any angular position. When the desired position is approximated, and the trigger relieved, the pin drops into the nearest hole, and the endless screw is then used for final setting.

The diagram will I think explain the various matters of illumination.‡

From a lamp hanging upon the end of the declination axis is sent a beam of slightly divergent light through this axis, which is hollow; this slightly divergent beam is utilised for six different purposes, three portions of it being reflected out in different directions to illuminate portions of the declination circle, of which one is for a long reader for setting from eye-end, and the other two for micrometer microscopes subdividing the 10′ division of circle into single 1″ arc.

None of these are shown in diagram, but the other three purposes for which the light is utilised, viz., for position circle,

* Paper read before the British Association at Brighton in Section A, Aug. 20, by Howard Grubb, C.E., F.R.A.S.

† The breech-piece and position circle of the Woolwich Equatorial were here produced

‡ The original diagram showed all three illuminations, and of different colours. Here it has been thought better to show the dark field by itself, and the bright field and position circle illuminations in a separate diagram.

bright field illumination, and dark field illumination of micrometer, are shown.

The position circle illumination is very simple (see Fig. 1), a single reflector R, attached to the inside of the tube directs a constant beam of light on the back of the glass circle at P.

The bright field illumination is effected by a very small central reflector, R′, which sends the light directly into the field of the micrometer.

This method is, I believe, now generally considered to give the best results, and has, as far as I am aware, but one disadvantage, viz., that the arm which supports the small mirror produces a little diffraction, and consequently deterioration of definition.

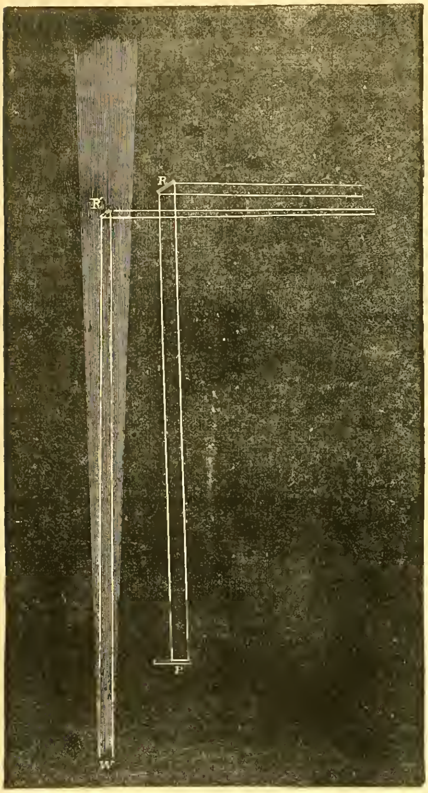

Fig. 1

This objection I have in some measure reduced by making the arm and mirror removeable at pleasure by pulling or releasing a string, so that while actually observing, it can be removed and replaced instantaneously.

In devising the dark field illumination, I started on the hypothesis that there were two essential points to keep in view, viz., that the lines should be illuminated on both sides (not one), and that the angle at which the light should be thrown upon the wires should be very great, so that the blackness of the field as seen through the eye-piece should not be injured.

I found that the best result is obtained by placing four prisms of total reflection round the field of the micrometer, just behind the wires, and of such an angle that the light thrown upon them should be reflected upon the wires at an angle such as is shown in the diagram Fig. 2, where W is the position of the wires in the focus of the objective.

In order that this scheme of illumination should be carried out effectually from the light of a single lamp hanging on the declination axis, it is necessary that a certain annular portion of the micrometer which embraces these prisms should be constantly illuminated from this lamp, and this is effected in the following way: a portion of the slightly divergent beam of light, shown in Fig. 2, proceeding from the lamp on the declination axis, is passed through a very low power convex lens, *l*, which renders the beam slightly convergent.

This is not necessary, but a mere matter of convenience, as it reduces the necessary size of the reflector and lens afterwards re-

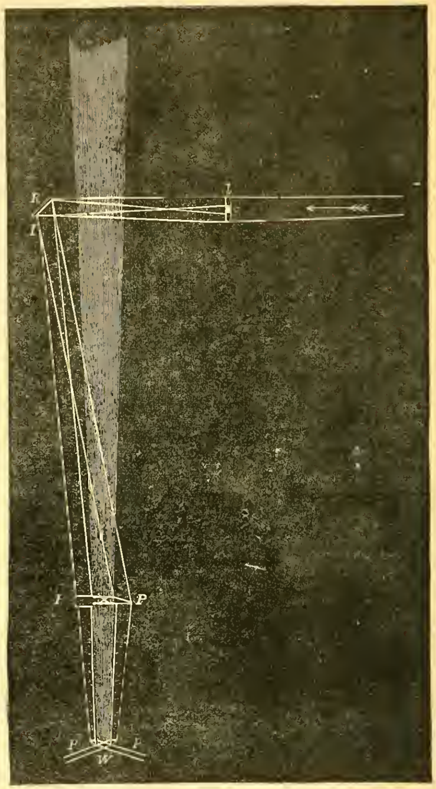

Fig. 2

quired. The light is now taken up by a reflector, R, within the tube, and directed towards the eye-end at such an angle that it crosses the axis of the telescope just at the inner end of the eye-piece tubes, X; hence it is passed through a piece of glass of a peculiar shape, P P, which I call, for want of a better name, an annular prism lens. This piece of glass has a hole cut in it large enough to admit the whole pencil of light from the object glass.

The use of this annular prism lens is twofold:—

1st. It has to alter the direction of the beam of light before diagonally thrown across the tube, RX, to that parallel to the axis of the telescope; and

2nd. It is necessary that it should have a slightly converging effect to reduce the size of the illuminated circle it produces.

This arrangement so far performs perfectly in all but one particular. It throws a strong beam of light constantly upon the four prisms $p p$, and illuminates the lines well; but although no direct light can enter into the field from the mirror placed so far out of the cone of rays from the objective, still the light thrown against the side of the eye-piece tube is sufficient to completely destroy the effect of this illumination. The difficulty, however, has been completely removed in this way :—

I should first mention that the eye-piece or micrometer tube is made double, an outer parallel tube and an inner taper one, and it is between these two that it is required that the light should be brought to the four prisms or micrometers, any light shining into the inner tube doing mischief by injuring the blackness of the field.

On the lens used to give a slight convergence to the light is placed a circular opaque disc, O, of a certain size easily ascertained. A lens, I, of a suitable focus being then placed near the reflector, an image is formed of that opaque disc just over the eye-piece tube at X, and of such a size, when properly adjusted, that no light can possibly enter the inner tube.

Thus, while not a single ray of light can by any possibility enter the inner tube, a flood of light is sent down between the inner and outer tubes, and directed upon the four prisms in whatever angular position they may be.

It only remains to say that both the intensity and colour of the light for both characters of the illumination are under complete control of the observer while actually observing.

One other matter is perhaps worthy of note.

The want of a convenient method of mapping nebulæ or faint stars by a reticulated diaphragm of bright lines in the field of view has long been felt, and the various methods of using diamond scratches on glass or illuminated lines are subject to objection, and troublesome to manage. A simple method of using an image of such a diaphragm instead of the actual diaphragm itself here suggests itself.

Referring to the portion of the rays used for bright field Illumination, and shown in Fig. 1, suppose the small diagonal mirror, R′, to be replaced by an equally small prism having such a convex power that it forms an image of any object at the end of the declination axis exactly in the same plane as the image formed by the objective—then any kind of reticulated diaphragm of bright lines on dark ground can be placed on the end of the declination axis which would have a suitably prepared carrier for them, and their image would be seen in the field of the telescope of any colour and any intensity desired.

SCIENTIFIC SERIALS

THE *Scottish Naturalist* for July is rich in articles of interest, mostly brief, and chiefly relating to Entomology and Ornithology. Many deserve notice, but we have been especially interested in one on the nest of *Formica rufa* and its inhabitants by the editor, Dr. Buchanan White.

IN the *Journal of Botany* for August, Dr. Trimen describes and draws the genuine *Ranunculus chærophyllos* Linn. which has been detected in Jersey, but was not heretofore known as a native of Britain. Dr. Hance describes a new species of Iris, *I. tomiolopha*. The Rev. J. M. Crombie contributes some notes on the Lichens in Sowerby's Herbarium.—In the September number, Dr. Hance describes another new species belonging to the Bignoniaceæ, *Spathodea cauda-felina*. Mr. T. R. A. Briggs contributes Notes respecting some Plymouth plants, and Dr. A. Ernst Notes on a small collection of Alpine plants from the summit of Naiguta in the mountains of Caracas.—The first article in the October number is Mr. Hayne's paper, read at the Brighton meeting of the British Association on the Flora of Moab. Mr. J. G. Baker, who has paid great attention to the Liliaceæ, has a monograph of the two genera *Dasylirion* and *Beaucarnea*. Another British Association paper, Mr. Hemsley's Summary Analysis of the Phanerogamic and Fern Flora of Sussex, is reprinted. The Rev. E. O'Meara contributes a continuation of his recent researches in the Diatomaceæ; and the Rev. J. M. Crombie, a description of a new erratic British *Parmelia*. Mr. Leo Grindon forwards a suggestive paper on the non-occurrence near Manchester of certain common British plants.

THE last part of the *Proceedings of the Swedish Academy of Sciences* for 1871 (Öfversigt af Kongl. Veterskaps-Akademiens Förhandlingar, Arg. 28, No. 7), opens with a notice by Prof. Lilljeborg of the occurrence of a South European species of Bleak (*Leucaspius delineatus*, Heckel) at Landskrona in Scania.—The same author has also a notice of the occurrence of *Limnadia gigas* (Hermann) in Sweden, which will prove of considerable interest to the student of Crustacea, as in it he gives a very detailed description, illustrated with good figures, of the structure of this curious species, and also gives a list of the other species of Phyllopoda, six in number, which inhabit Scandinavia. Prof. Lilljeborg is inclined to identify this species with the *Monoculus lenticularis* of Linnæus.—Prof. Nordenskiöld publishes a short paper, containing a table, on the fixed and variable atomic volumes of simple bodies.—The Swedish expedition to Greenland of the year 1870 originates two papers, namely, a valuable essay on the Phanerogamic flora of Disco Bay and Auleitsivik Fjord by Prof. S. Berggren; and a series of calculations of geographical positions worked out by M. E. Jäderin.—M. L. K. Daa discusses the origin and meaning of the name of Grumant applied by the Russians to Spitzbergen, and cited as an evidence of the independent discovery of that inhospitable land by the Russians; M. Daa states that Spitzbergen was named East Greenland by its earliest English and Dutch visitants, and he maintains that "Grumant" is merely a corruption of "Grönland."—Mr. H. D. J. Wallengren publishes a Contribution to the knowledge of the Lepidopterous fauna of the island of St. Bartholomew in the West Indies. He gives a list of 34 species belonging to various families from the Rhopalocera to the Crambidæ, with remarks on their characters and distribution. Three species are described as new, namely, *Graphiphora bartholemica*, *Micra Stålii*, and *Palthis Walkeri*.—M. L. J. Igelström notices the discovery of sandstone *in situ* in the Gefleborg district.

SOCIETIES AND ACADEMIES

PHILADELPHIA

Academy of Natural Sciences, April 9.—Prof. Leidy directed attention to some fossils upon which he made the following observations :—Several teeth and jaw fragments from the Loup Fork of the Niobrara River, Nebraska, obtained by Prof. Hayden, appear to indicate a large species of Felis, not previously described. The most characteristic specimen consists of an upper sectorial molar about as large as that of the Bengal tiger, and consequently much too large for either of the largest American cats, the panther and the jaguar. It is as much too small to have pertained to the American lion, *Felis atrox*, for its breadth is but slightly greater than that contained in the lower jaw, from which the latter was described. Breadth of the crown of the tooth is $15\frac{1}{2}$ lines; its thickness in front 8 lines. The measurements in the corresponding teeth of a Bengal tiger are, 16 lines in breadth, and $7\frac{1}{2}$ lines in thickness in front. The form of the fossil tooth is the same as in the other feline species. The extinct species may be named *Felis augustus*. A distal extremity of a humerus, from the Niobrara River, about the size and construction of the corresponding part in the Bengal tiger, may belong to this species. Another fossil, consisting of a detached body of a vertebra, apparently indicates an extinct reptile allied to *Plesiosaurus* and *Discosaurus*. The specimen, recently received from Prof. Hayden, was obtained in 1870, on Henry's Fork of Green River, Wyoming. It is free from attached matrix, and was the only specimen pertaining to the animal which was found. It probably belonged to a formation of earlier date than that of the same locality, which has yielded other fossils previously described. The vertebra is from the base of the tail, and is much shorter in relation to its other dimensions than in *Plesiosaurus* or *Discosaurus*. The extremities are concave, and encircled near the margin of the articular surfaces with a narrow groove. Posteriorly there are two larger articular facets, as widely separated as the bone would permit, for the junction of a chevron. Anteriorly there are no marks of chevron attachment. The roots of strong transverse processes or diapophyses project from the sides of the body just above the middle. The neural arch was completely co-ossified with the body, leaving no trace of its earlier separation. The breadth of the body is 23 lines, its depth 19 lines, and its length 1 inch. Viewing the specimen as probably representing a genus different from those mentioned, I propose to name it with the species as *Oligosimus grandævus*. Another fossil is a remarkable specimen, obtained by Prof. Hayden in the "Black Foot Country" at the head of the Missouri River. It looks as if it had formed part of the dermal armour of some huge saurian or perhaps of an armadillo-like animal. It is imperfect, and looks as if it were half broken away. In its present state it is hemiovoid, about two inches in diameter, concave below and convex above, where it is

covered by about fifteen large mammillary bosses. Accompanying this specimen there is a distal phalanx, which may belong to the same animal. It is rather less than two inches long. The articular surface is transversely elliptical, $1\frac{1}{4}$ inch wide, and 11 lines deep, and feebly depressed, so as to indicate a moderate degree of mobility. The upper surface of the bone slopes to the end, and is transversely convex. The extremity is expanded at the borders. Beneath are several vascular perforations. Though the specimens are not sufficiently characteristic to determine positively whether they belong to a mammal or a reptile, or whether they even belong together to the same animal, the former one is so peculiar that I am disposed to regard it as representing a genus and species, which may be named *Tylosteus ornatus*.—Mr. Cope made the following remarks on a curious habit of a snake:—"I had for some time a specimen of *Cyclophis æstivus*, received from Fort Macon, N. Ca., through the kindness of Dr. Yarrow, living in a wardian case. The slender form of this snake, and its beautiful green and yellow colours, have led to the opinion that it is of arboreal or bush-loving habits. It never exhibited such in confinement, and instead of climbing over the caladia, ferns, &c., lived mostly underground. It had a curious habit of projecting its head and two or three inches of its body above the ground, and holding them for hours rigidly in a fixed attitude." In this position it resembled very closely a sprout or shoot of some green succulent plant, and might readily be mistaken for such by small animals.

PARIS

Academy of Sciences, October 7.—M. Faye, President. M. A. Trécul read a paper entitled "Observations on the various parts of the Flower of *Campanulaceæ*," and his long paper was followed by an account of some "new experiments intended to show that the germs of the ferment which produces wine come from the exterior of the skin of the grape," by M. Pasteur. The author prepared forty flasks with long necks, which were twisted and bent in the now so well known fashion first used by this chemist. Ten flasks were partly filled with grape-juice, and allowed to rest; ten others, also containing juice, had introduced into them a few drops of water, in which a small piece of grape-skin had been washed; the next ten had juice and water from the skin like the last, but were boiled; and the last ten contained juice and a few drops of the interior of a grape carefully extracted by means of a glass tube, without bruising the skin. The series containing the unboiled juice and grape-skin washings were soon full of mycelium and beer-yeast, and a few days after of *Mycoderma vini*, within forty-eight hours of the appearance of which they were in a state of violent fermentation. None other of the flasks were changed in the slightest degree, even after days; and the author states that they will remain unchanged for years. M. Fremy replied to this in a note on ferments, in which he states that M. Pasteur confounds ferments with the spores of mould. M. Fremy believes the ferment to be generated in the fermentable liquor, and that fermentation can also be started by mould spores by a secondary action, hence he considers that M. Pasteur has only proved that this latter kind of fermentation is produced by the grape-skin. M. Pasteur replied that he only intended to prove that the juice of the grape is not of itself alone capable of fermenting, and that neither the albuminous matters of the juice nor the parenchyma cells are developed into ferment cells by the action of atmospheric oxygen alone. At the request of M. Dumas, M. Pasteur then read an account of some "new facts serving to elucidate the theory of true fermentation." M. Fremy again criticised the paper, and after a reply from M. Pasteur, the subject dropped. M. A. Trécul then read a note confirming several of M. Pasteur's observations, and was followed by M. Faye with a note on a memoir of Mr. Clerk Maxwell, "On the stability of the Saturnian Rings."—A note from M. Otto Struve, "On the exactness which should be attributed to the constant Coefficient of Aberration determined at the Pulkowa Observatory," was then read, and next came "Researches on Crystalline Dissociation" (continuation), by MM. P. A. Favre and C. A. Valson. This paper, containing a great number of numerical results, was followed by "Studies on the Echinodermata," by M. S. Lovén, and by a paper on the structure of heterogeneous vegetables, by M. Th. Lestiboudois.—M. de Caligny then read a note on the effects of the communication of a lateral movement to a stream of water traversing a reservoir, and on the sand-banks which thence result. This was an account of some experiments made by the author. He finds that banks are deposited almost parallel to the stream.—M. Chevreul then read a note relating to a work on colour, by M. P. Havrez, which he presented to the Academy; and M. Dumas presented a pamphlet by M. de Jacobi, entitled "On the galvanic deposition of iron by a powerful electro-magnetic solenoid." The author hoped by these means to deposit permanently magnetic iron, but failed; the deposit, however, was composed of agglomerations of crystals, whilst iron deposited in the ordinary way is smooth and amorphous.—M. J. M. Gaugain then presented his second memoir on the induction currents produced in M. Gramme's machine, which was referred to the Physical Section.—A note on the efficacy of lightning conductors, by M. W. de Fonvielle, was sent to the commission on that subject. A note from M. Laborde, on auroræ, storms, and waterspouts, was sent to the Physical Section, and the Aerostatic Commission received memoirs from M. Reynal and M. Babé and a letter from M. Braconnier, all on aërial navigation.—A note from Raoult de Couesquelon on a "New System of Masked Batteries" was sent to the Commission on Military Art, and two notes from M. Duclaux, two from M. Cornu, and an article from the Journal *La Gironde* by M. Laliman, all on *Phylloxera*, were sent to that Commission.—M. de Saint-Venant then presented a note from M. J. Boussinesq on "Lines of Summit (*faîte*) and Thalweg," which was followed by a note from M. Béchamp "On the action of borax on fermentation." The author demonstrates that the boric acid of the borax is not the cause of the peculiar action of this body, as that acid does not produce the effects of borax. Hydric sodic carbonate, however, acts in a strictly analogous way; hence the author decides that it is the sodium present in the borax which determines its action. —A note from M. E. Monier "On the determination of the amount of vegetable matters in contaminated potable waters" then followed. The author uses a method now abandoned by all the best analysts of water in this country, namely, titration with potassic permanganate.—M. E. Gouriet then read a paper "On certain exterior characters which distinguish the different sexes of the River Craw-fish (*Astacus fluviatilis*)." The author finds the following differences:—If the length of the animal be taken as 100, then the antennæ in the male are 67·83, and in the female 57·18. The weight of the animal being 100, the great claws are in the male 27·81, in the female 12·92; moreover, the female abdomen is much more developed than that of the male —A note from M. Brown "On the relations between electricity and mephitic emanations" closed the session.

THURSDAY, OCTOBER 31, 1872

THE GREAT CIRCUMNAVIGATING EXPLORING EXPEDITION

PREPARATIONS for the expedition which is about to be despatched by the Admiralty for the purpose of dredging, sounding, and otherwise scientifically investigating, the deep sea, have been for some months past in active progress, and are now rapidly approaching completion. The vessel set apart for the purpose is H.M.S. *Challenger*, a main-deck corvette of 2,306 tons, now lying at Sheerness. Her commander is Capt. G. S. Nares, R.N., well known as the author of a valuable work on seamanship, greatly in use in the Royal Navy. Capt. Nares has seen a great deal of active service, including exploration in the Arctic regions, and he has left the charge of the Survey in the Gulf of Suez for the purpose of taking charge of the present expedition. Second in command is Commander J. P. Maclear, R.N., son of Sir Thomas Maclear, late Astronomer Royal at the Cape of Good Hope, who has also seen a great deal of service in various parts of the world, and whose name is familiar to our readers from his having taken part in the Eclipse Expedition to Spain, and also in that to Ceylon. Commander Maclear will undertake the magnetic observations, which will form part of the work of the Expedition. The other naval officers are—1st Lieut., Pelham Aldrich; 2nd Lieut., Arthur C. Bromley; 3rd Lieut., George R. Bethell; Navigating Lieut., Alfred E. Tizard; Sub-Lieutenants, H. C. Sloggett and Lord George Campbell; Pay-master, R. R. Richards; Chief Engineer, James H. Ferguson.

On the scientific staff of the Expedition, the following have received appointments from the Admiralty, bearing date Oct. 1872:—Prof. Wyville Thomson, F.R.S., &c., Director of the Scientific Staff. Under him the following have been appointed:—Mr. J. J. Wild of Zurich, who will accompany Prof. Wyville Thomson as private secretary. (Mr. Wild was for some time private secretary to the Abbé Moigno, and is an accomplished artist); Mr. J. Y. Buchanan, M.A., Edinburgh, Chemist to the Expedition. (Mr. Buchanan has been until now Senior Assistant in the Chemical Laboratory of Edinburgh University, and has had the advantage of pursuing the study of his subject in Germany, at Leipsig and elsewhere); Mr. H. N. Moseley, M.A., Oxon, Naturalist (Mr. Moseley is a pupil of Prof. Rolleston, and has been enabled, by a Radcliffe Travelling Fellowship, to study biology further at Vienna and Leipsig: he was a member of the late Eclipse Expedition to Ceylon); Dr. Von Willemoes Suhm, Naturalist (Dr. Von Willemoes Suhm, who has been some time Assistant to Prof. Von Siebold, of Munich, is a distinguished naturalist, and is well known from his papers in Siebold and Kölliker's "Archiv" on Annelids); Mr. John Murray, of Edinburgh University, Naturalist (Mr. Murray, a Canadian by birth, has had great experience in taxidermy and the collection and preservation of Vertebrata generally, has travelled in Canada, and has also been far into high latitudes on a whaling cruise). Prof. Wyville Thomson will of course devote all his time not consumed by the superintendence of the scientific investigations in their various branches, preparations of reports, &c., to zoological work.

Of the three Naturalists, Dr. Von Willmoes Suhm and Mr. Moseley will undertake especially the Invertebrata procured during the expedition, whilst Mr. Murray will direct his attention principally to the Vertebrata. Mr. Moseley will also undertake botanical collection whenever an opportunity presents itself of landing in interesting localities, and all the scientific staff will give to this branch of biological investigation as much of their time as possible. Algæ, &c., obtained by dredging and otherwise at sea, will also be entrusted to Mr. Moseley. An experienced photographer, a noncommissioned officer of Engineers, forms one of the party. The expedition is under the immediate direction of the hydrographic department of the Admiralty.

The Admiralty authorities having applied to the Royal Society for advice in the conduction of the expedition, a committee of the Society was formed for the purpose of considering the subject, and counselling the Admiralty in the matter. The Committee consists of the President and Officers of the Royal Society, with Dr. Carpenter, Dr. Frankland, Dr. Hooker, Prof. Huxley, the Hydrographer of the Admiralty, Mr. Gwyn Jeffreys, Mr. Siemens, Sir William Thomson, Prof. Wyville Thomson, Dr. Williamson, and Mr. Alfred R. Wallace, and has the power of adding to its number.

The *Challenger* has had her timbers put in thorough repair, and has been specially fitted out for the work for which she is intended. She has an auxiliary screw, with engines of 400-horse power (nominal), and carries about one month's coal. She carries two cutters, a steam pinnace, a South Sea whaling or surf boat, a jolly boat, two gigs, and a dingy. Stages have been erected amidships, from which the dredges will be worked, and immediately aft of the stages is the steam winding-in apparatus. Prof. Wyville Thomson has been several times down to the ship to give directions for the special arrangements for scientific work. The fore magazine is prepared for the stowage of the large quantity of spirits which will be required for the preservation of natural history specimens, and of the many thousand stoppered bottles which will contain them. A chemical laboratory and naturalist's workroom have been fitted up in the afterpart of the vessel; and spirit is laid on to the workroom by means of a pipe leading from a metal cistern placed in the nettings. Several hundred miles of best whaling line have been prepared at Chatham for the *Challenger*, for dredging, and she carries about forty dredges. Amongst the stores are traps of various forms, harpoons, a harpoon gun, and fishing tackle of all kinds, including trawls, trammels, a seine, shrimp-nets, fish-traps, and lobster-pots. From the latter, used in deep water, great results are expected; and it is not improbable that living specimens of Nautilus may thus be procured. Prof. Wyville Thomson is now superintending the construction, in Edinburgh, of the various forms of apparatus required for physical research. Several beautiful instruments of this nature have been devised by Mr. Buchanan; and notably a new deep-sea pressure-gauge, and an instrument for bringing up samples of water from the bottom, which is provided with two taps which are closed by the contact of the apparatus with

the bottom, and a safety-valve to allow of the expansion consequent on decrease of pressure as the apparatus is hauled up. A hydraulic machine will be carried on board, capable of testing the accuracy of all the physical apparatus, thermometers, pressure-gauges, &c., from time to time, in a chamber in which a pressure of three tons on the square inch can be obtained. The attempt will be made to use piano wire for sounding, after Sir William Thomson's method. A small aquarium has been devised by Mr. Moseley, which will be used for the study of the development of interesting animals. Except in absolutely calm weather it will be entirely closed, and a constant stream of water will be passed through it from a reservoir by means of finely perforated roses made—at the suggestion of Mr. Lloyd, of the Crystal Palace—of vulcanite. The route to be followed by the *Challenger* is not yet definitely fixed, and is still under the consideration of the Admiralty, who will be guided very much in the matter by the advice of the Royal Society Committee; but it will be very nearly as follows:—

The vessel, which is at present at Sheerness, will probably go round to Portsmouth about the middle of November, and sail from thence in the beginning of December for Gibraltar, the first haul of the dredge being made in the Bay of Biscay, if the weather should chance to be favourable. From Gibraltar she will proceed to Madeira, thence to St. Thomas, the Bahamas, Bermuda, the Azores; from thence to Bahia, touching at Fernando Norohna; then across to the Cape of Good Hope, and, after a stay in that neighbourhood, southwards to the Crozetts and Marion Islands and Kerguelens Land. A run southwards will then be made as far as possible to the ice, and the course thence be made to Sydney. New Zealand, the Campbell and Auckland groups, Torres Straits, New Guinea, and New Ireland will then be visited. A long cruise of perhaps a year will then be made amongst the Pacific islands; thence the expedition, passing between Borneo and Celebes, and visiting Luzon and its neighbourhood, will proceed to Japan, where a stay of two or three months is expected. Thence northward to Kamskatka, whence a run will be made northwards through Behring's Straits, and then through the Aleutian Islands, southward to Vancouver's Island, and so through the deep eastern region of the Pacific by Easter Island, and possibly by the Galapagos Archipelago to the Horn, and thence home. The voyage is expected to take about three and a half years.

It is difficult to over-estimate the immense benefit which science must derive from an expedition such as this. Apart from the results of intense interest which may be expected from the deep-sea work, the principal object of the expedition, and which must go far to elucidate a subject on which our knowledge is at present of the most imperfect description, abundant opportunity will offer for the accurate investigation of the animal and vegetable life of many highly interesting and yet imperfectly known or totally unexplored regions. The investigation of the floras of such islands as Fernando Norohna and the Marion and Crozett groups cannot fail to yield most instructive results; and it is needless to speak of the intense interest which centres in New Guinea.

No expedition has ever started under such favourable auspices as the present for yielding valuable scientific results, and great praise is due to the Government for the very liberal and thorough manner in which all arrangements have been carried out.

FIGUIER'S VEGETABLE WORLD

The Vegetable World: being a History of Plants, with their structure and peculiar properties. Adapted from the work of Louis Figuier. New and Revised Edition, with 473 Illustrations. (London: Cassell, Petter, and Galpin.)

NOTWITHSTANDING its ambitious title, this is, on the whole, a satisfactory book. If, however, in dependence on the title, it is ordered in the expectation of finding anything that will replace Lindley's "Vegetable Kingdom," or Baillon's "Histoire des Plantes"—at least, what this latter will be when finished, if it ever is finished—the purchaser will be disappointed. We have here a repetition of the old plan of attempting to compress into one small octavo volume an account of the Morphology, Physiology, Classification, and Geographical Distribution of plants. As far as can be, as we have said, the execution is good; some parts are even exceptionally well done; the defects are those of the plan. The style of Figuier's original work, florid and Gallic to excess, is entirely unsuited to the English reader; the "adapter" has used his pruning-knife with judicious severity, and has produced a book that may fill a useful place in popularising the study of botany, and leading the way to fuller and more special treatises.

The first part of the work, "Organography and Physiology," treats of the structure and different forms of the various organs in a systematic manner, and yet with a fresher style than is usual in text-books. It is, moreover, a relief to find that the majority of the illustrations, which are excellent throughout, are not those which have wearied the eye in many a familiar book. The details of terminology are relieved by information on many interesting points which we do not find in ordinary text-books. Thus in the very early pages we have an account of Knight's and Dutrochet's experiments with vertical and horizontal wheels to determine the effect which gravitation exercises in determining the downward tendency of the roots. Further on is a description and drawing of Hales' apparatus for measuring the force of ascending sap, by which he claims to have determined that the force which impels the sap in the vine is five times as great as that which impels the blood through the large arteries of the horse.

The portion devoted to the "Phenomena of Fertilisation and Germination" is full, and about the best in the book, the illustrations being especially superior to those found in most other works of a similar character. The cut here reproduced (Fig. 2) represents the very curious arrangement by which the fertilisation of *Vallisneria spiralis*, a favourite water plant in aquaria, is effected. The female flowers are borne on long spiral stalks which uncoil when the flower is ready to open, so as to allow it to float on the surface of the water. The male flowers, on the contrary, have very short stalks which are entirely submerged, but detach themselves when mature, rising to the surface,

and then only discharge their pollen in the immediate proximity of the female flower ; after which the stalk of the female flower again coils up, and carries it down to the bottom of the water, where the seed ripens.

The second part, on "Classification of Plants," is occupied with a brief description of the various systems adopted at different stages of botanical knowledge, with short biographies and portraits of the most distinguished botanists, from Tournefort to Robert Brown.

The third part is devoted to the "Systematic Arrangement of Plants," commencing from the lowest and proceeding to the highest forms. The account of the different orders of flowerless plants is the best with which we are acquainted in any elementary work, and will give the beginner an excellent outline of the immense variety of structure and physiological phenomena to be found among the lower forms of vegetable life. We find a good description of the different modes of reproduction in the

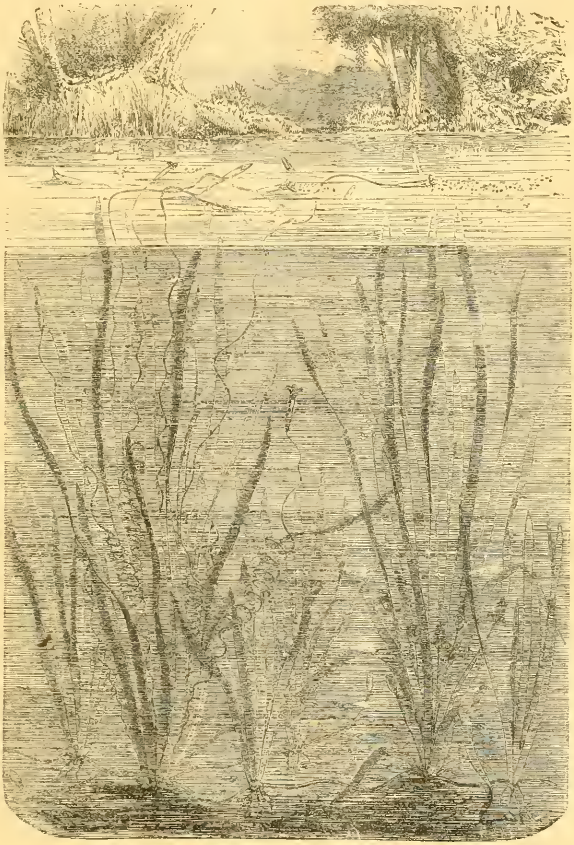

FIG. 2.—*Vallisneria spiralis*

Algæ, which are often so enveloped in technical terms as to be barely intelligible to the student. The illustrations also are excellent, as is the case throughout this section. Those here given of the early stages in the life of a fern taken from Thuret (Figs. 3—7), are such as have been heretofore unknown to English text-books. This section is, in fact, altogether thoroughly satisfactory.

More exception may be taken to the portion which treats of flowering plants, especially to the continued use, notwithstanding its defects acknowledged by the author, of the unsatisfactory system of classification adopted by Lindley in his "Vegetable Kingdom." The retention at the present day of such classes as the Rhizogens and Dictyogens as of the same value as Monocotyledons and Dicotyledons, is altogether indefensible. An equally serious defect is the very inadequate amount of attention given to the Gymnogens, and to the elucidation of the peculiarities of their structure which seem to form a con-

necting link between flowering and flowerless plants. It seems to us a mistake to attempt in an introductory

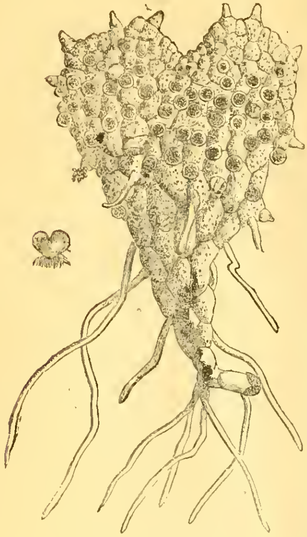

FIG. 3.—Prothallium of *Scolopendrium*, with Antheridia (magnified)

text-book even an outline of the characters of the natural orders of flowering plants ;' but if this were necessary to

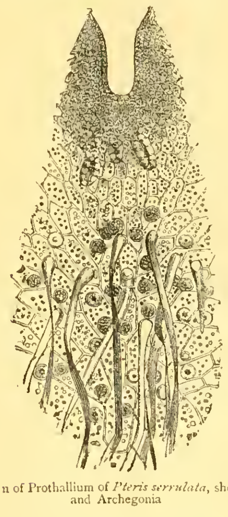

FIG. 4.—Portion of Prothallium of *Pteris serrulata*, showing Antheridia and Archegonia

the plan, this portion should have been completely re-arranged, to make it conform to the present state of botanical science. The chief advantage of the systematic portion of a course of botanical lectures is that it gives the teacher the opportunity of demonstrating the value in

FIG. 5.—Antheridia (magnified)

classification of certain peculiarities of structure, by placing side by side species belonging to the same and to allied natural orders, in a manner better calculated to arrest the

FIG. 6.—Antherozoids

attention of the student than if presented to him in any other way. This advantage, however, is not gained by the introduction of a section devoted to the details of classification into a text-book.

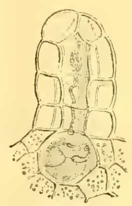

FIG. 7.—Isolated Archegonium, showing the action of the Antherozoids upon the Embryonal Cell

The fourth part of the work, on the "Geographical Distribution of Plants," though too brief, is interesting, and contains much valuable information in a small space.

Altogether, this English version of Figuier's "Vegetable World" is a good book to place in the hands of an intelligent student who is desirous of learning something of the laws which govern plant life. A. W. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Ocean Currents

IF Mr. Laughton will take the trouble to read my previous Reports with attention, he will find that I have based no *argument* upon my "trough" experiment, which I have used merely as an *illustration*. The argument in favour of the *vertical* Oceanic Circulation which I advocate rests upon the *facts* of Deep Sea Tem-

perature. In my forthcoming Report, these facts (including many which have not been hitherto published) are discussed, in connection with the Temperatures of Inland Seas; and if Mr. Laughton will frame a better hypothesis for the explanation of them than that of the Thermal Circulation first advanced by Pouillet, and latterly accepted by Herschel and Sir William Thomson, I will gladly accept it.

Mr. Laughton will also find that I am not ignorant of the geographical facts he mentions respecting the *horizontal* or *superficial* movements of the Ocean. But he must be well aware that a current may be flowing in one direction *on* the surface, and a tidal or other movement in a contrary direction *at a small depth* beneath it. A very careful observer told me a few days since that at a time when the *surface*-current in the Dardanelles, urged on by a south-westerly wind, was blowing *inwards*, he had distinctly seen the movement of the water *at a short distance beneath the surface* to be *outwards*—this being indicated by the direction of the water-weeds. Below this, again, as the researches of the *Shearwater* have shown, there is a deep under-current *inwards*.

In confirmation of this last statement, my friend Mr. Redhouse, who resided many years at Constantinople as Translator to the Embassy, has informed me that the existence of the deep under-current in the Bosphorus has long been perfectly well known to the native fishermen of Constantinople, as well as to European residents who amuse themselves with the sport.

WILLIAM B. CARPENTER

University of London, Oct. 29

London University Examinations

PROF. W. G. ADAMS, in order to controvert my statement that mechanical and natural philosophy have little to do with medicine, enters into theories with regard to the production of animal heat which I must leave him to settle with his colleague, the Professor of Physiology in King's College. As he insinuates a doubt as to my own acquaintance with the thermometer and its uses, on my own behalf I may venture to say that not only did Professors Graham and Brande require a knowledge of this and kindred matters of candidates for the Matriculation and First M.B. Examinations of the University of London, but that years before Mr. Adams was connected with King's College, I was rather a "swell" at natural philosophy and chemistry under the late Dr. Miller's tuition.

Mr. Adam's temperature must, I fear, have been abnormally high, or his barometer of propriety correspondingly low, when he penned the paragraph relating to the report of the sub-committee, and endeavoured to gain support for his views by suppressing the latter half of the quotation. The sentence really stands as follows: "The preliminary scientific examination has tended to give prominence to theoretical and scientific knowledge *at the expense of a sound practical acquaintance with medicine, surgery, midwifery*," &c.; but by the omission of the words in italics Mr. Adams makes the report (contrary to its whole tenor) support his view that "it is in consequence of such knowledge that medical science has advanced with such rapid strides." The illustration of the application of a cupping-glass is not a very happy one, for cupping has for years been notoriously a purely mechanical art entrusted to medically-unqualified men, who could in no sense claim a knowledge of natural philosophy.

In conclusion, may I say that the Senate of the University of London at its session of the 23rd inst., took action in the matter to which I have called attention, and appointed a committee to consider it; and may I express a hope that, should Mr. Adams be really ill, he may not be unfortunate enough to fall into the hands of one of his own medical philosophers?

Cavendish Place CHRISTOPHER HEATH

Can the Stature be in any way affected by the Will?

IT is written that "no man by taking thought can add one cubit unto his stature;" but if there be any truth in the following extract from Babbage's "Passages in the Life of a Philosopher," it appears that man can, at all events, voluntarily deduct nearly an equivalent amount from his height.

At the opening of chapter xviii. of the work just cited, Mr. Babbage makes the following statement respecting the celebrated thief-taker Vidocq, with whom he had an interview:—"He had a very remarkable power, which he was so good as to exhibit to me. It consisted in altering his height to about an inch and a half less than his ordinary height. He threw over his shoulders a cloak, in which he walked round the room. It did not touch the floor in any part, and was, I should say, about an inch and a half above it. He then altered his height, and took the same walk. The cloak then touched the floor, and lay upon it in some part or other during the whole walk. He then stood still, and altered his height alternately several times to about the same amount.

"I inquired whether the altered height, if sustained for several hours, produced fatigue. He replied that it did not, and that he had often used it during a whole day without any additional fatigue. He remarked that he had found this gift very useful as a disguise. I asked whether any medical man had examined the question, but it did not appear that any satisfactory explanation had been arrived at."

Now if this had been the statement of an unscientific person, or one whose powers of observation were presumably untrained, it might be put aside unheeded; but coming, as it does, from one very unlikely to jump to conclusions, it seems to merit some degree of attention.

This, then, being granted, the question arises, how can we account anatomically for this shortening in height? Of this the solution does not appear to be very clear. The only way in which an individual could alter his height would be either by adopting a stoop of his neck and shoulders, or by bending his knees, and flexing his thighs upon his pelvis, or, lastly, by actually shortening his vertebral column.

The two first methods may be disregarded, as they would be pretty evident, even if a cloak were worn, and, if employed by Vidocq, would scarcely have aroused the curiosity and wonder of Mr. Babbage. The last only, namely, a voluntary shortening of the vertebral column, remains then to be considered.

Now, there seems to be a general impression, both among doctors and the laity so-called—though it is difficult to discover any definite and concrete expression of it in the text-books—that, by virtue of the compressibility of the intervertebral fibro-cartilaginous discs, the stature of a man when he goes to bed is shorter than when he gets out of it, the amount of shortening varying, I suppose, according as the individual dangles a cane in the "Row," or is employed somewhat more actively as a "fellowship porter" at the docks.

Granting, then, that there may be some passive, involuntary shortening of the vertebral column to the extent of an inch or an inch and a half* after the application of a weight to its summit for the duration of some hours, how does a voluntary shortening come to be brought about? Since fibrous and cartilaginous structures are not directly acted upon by the will through peripheral nerves, such action must be produced through the medium of muscles; and here we come to the crux, what are the muscles which could be employed in shortening the vertebral column? Hæmally, the only likely muscle in the cervico-dorsal region is the vertical portion of the *longus colli*, which passes from the bodies of cervical vertebræ Nos. 2, 3, 4, to the bodies of the three lower cervical and three upper dorsal vertebræ; and in the dorso-lumbar region there is the *psoas magnus*, which takes origin from all the lumbar and the last dorsal vertebræ, but which, unless the femur (where it is inserted) were fixed, could hardly affect the vertebral column, while neurally there are the numerous dorsal muscles of complex arrangement, such as the *quadratus lumborum*, *sacro-lumbalis*, *longissimus dorsi*, &c.

There seems to be, however, nothing in the arrangement of such muscles as would satisfactorily account for a voluntary shortening and elongation, or rather, restoration to the normal length; of the vertebral column, though it is possible that in some individual cases there may be some special endowment of innervation and co-ordination of muscle which permits of such action,

* Philippus Pieper, in an inaugural thesis, "De Viribus Corporis Human Mechanicis," Berolini, 1821, states, with regard to the elasticity of the vertebral column (p. 5), that in a man of middle height who had been carrying weights the difference at the end of the day was only 11‴. In the last edition of Druitt's "Surgeon's Vade-Mecum" it is stated (p. 341) that "the intervertebral substance is compressible to such an extent that an adult man of middle stature loses about an inch of his height after having been in the erect position during the day. Since the united thickness of the intervertebral substances in an adult man is about 3·875 inches we see that they lose nearly one-fourth by compression, which they do not recover till after some hours of rest." Among works which I have consulted in vain upon this point are, Borelli, "De Motu Animalium," and "De Vi Percussionis" (Lugdun. Batav. 1686), Giraud-Teulon's "Principes de Mécanique Animale" (Paris, 1858); Henle's "Bänderlehe;" and the "Traité de la Mécanique des Organes de la Locomotion," by G. and E. Weber, in tom. ii. of the "Encyclopédie Anatomique." W. and E. Weber's "Mechanik der Menschlichen Gewerkzeuge" (Göttingen, 1836), is unfortunately in none of the large libraries to which I have access,

just as it might permit of the wagging of the ears, or of the scalp movements, which may be occasionally witnessed in those gifted with such accomplishments.

It is in the hope, then, that some one who has studied anatomy from a mechanical stand-point may throw some light upon this somewhat obscure matter, that I have asked a question which, I trust, my be one not unworthy of the consideration of "philosophical" anatomists.

New University Club, Oct. 16 J. C. G.

Magnetic Storm Oct. 14—18

On the 14th of this month a magnetic storm commenced at 10.20 P.M., and lasted until 11 P.M. of the 18th. It was as remarkable for the extent as for the duration of the disturbances. The only lull in the storm was during the afternoon of the 16th.

The general character of the perturbations was the same throughout, consisting mostly of long movements of the needle to and fro on either side of the mean position. There was a very striking coincidence between the curves of the 15th, 16th, 17th, and 18th during the morning hours, the maximum westerly deviation having been attained at about 6 A.M. on each successive day. During the afternoon of the 17th, the greatest movement of the declination needle towards the west was equal to that of the previous morning, whilst the oscillations towards the north were greater than on the other days of the storm. The movements of the vertical-force magnet were frequently too great to be recorded on the photographic paper, and this magnet was several times thrown off its balance. The horizontal-force magnet was more violently disturbed at the very commencement of the storm than at any subsequent period.

The remarkable coincidences that are now being discovered between these magnetic disturbances and other important natural phenomena render it useful to draw attention to those changes in the magnetic force of the earth which present any feature particularly worthy of notice. The storm I am now referring to is on several accounts the most important that has occurred since 1867, and it is to be hoped that some practical spectroscopist has had favourable weather during these few days, as a magnificent array of solar prominences may not improbably have rewarded his interesting labours.

Stonyhurst Observatory, Oct. 23 S. J. Perry

Circular Rainbow

Being, in company with a friend, Mr. Hall, on the east peak of the Berceau (3,640 ft.) on the 25th inst., a circular rainbow was visible at 2.30 P.M. upon the upper surface of light white clouds that drifted from S. up the rocky valley which was E. of where we stood—though the true wind was W. and moderate. The sky was almost of the richly dark Italian blue, across which a few clouds (cirrus) slowly passed.

When first seen the diameter of the outside of the circle was 10°, but it increased gradually up to 15°. The colours of the "bow," which was somewhat less than 1° in width,—were the same as in the common rainbow, and very vivid. When we were a few yards apart, each saw only his own figure within the circle, large and well defined, so that the movement of an arm became visible. Before long the shadow of the mountain on which we stood invaded the lower portion of the circle, depriving it of its colour, but not always destroying its continuity;—and my figure remained complete even where the continuity was destroyed. Light clouds passed across the sun, causing a partial, rarely a complete, disappearance of this most beautiful phenomenon, which we watched with great interest for twenty-six minutes—how long it had existed before 2.30 I know not.

M. Moggridge

Earth Currents and Sun-spots

In the last number of Nature there appears a letter from Mr. W. H. Preece respecting the recent occurrence of electric storms of considerable intensity; and in connection with this interesting subject it may be worth while relating that the solar spots have lately (that is to say, during the last few weeks) been larger than usual. One of them attained great proportions, and was distinctly visible to the unassisted eye (on October 15) through a fog which partially obscured the sun's intense light. On the date mentioned this spot had completed about one-half of its transit across the solar disc, and it is remarkable that on the same day the electric storms attained their maximum, and "the interruptions to business were serious," as remarked by your correspondent. The spot referred to was not so large as several which appeared during the two preceding years, but exceeded in magnitude any of those which have come under my observation during the present year. It disappeared from the sun's western edge on about the 21st of October; but just previously to this the spot had been considerably smaller, and showed indications of dissolution. The spots now visible on the solar surface are not very conspicuous; there are, however, two visible of the larger class—one of these is situated in the north-east quadrant, and the other in the south-east quadrant, and they are situate at about the same distances from the limb. Between these spots there were yesterday two small ones perceptible running parallel with the equator.

Bristol, Oct. 28 William F. Denning

Measurement of Faint Spectra

May I suggest, as a supplement to Mr. Capron's clever arrangement for spectral measurement, a method which I have found useful with faint spectra. It is that a part of the slit should remain fixed, while the upper or lower half, or the middle only, should be movable. In this way two images of the spectrum are formed, one of which may be made to move over the other like a vernier; and thus any line may serve as an index, when, from want of light, it would be impossible to see the brass points. We obtain in this way many of the advantages of Zöllner's reversion spectroscope.

With such an arrangement, and with an embossing edge attached by a spring to the movable slit, so as to register on a card when pressed, I have succeeded in making several tolerable measurements of the faint auroral bands, which it was difficult to perform by direct comparison. It is, of course, necessary to have at least one line of known position in the field.

Merrifield on the Deviation of the Compass

Will you kindly pardon my again troubling you with an explanation?

Last week, seeing what I considered a harsh review of my little book, in Nature for Oct. 17, I, in the midst of my work and the heat of the moment, penned a reply to my reviewer, without thinking more of the matter. To-day, whilst giving a lesson on the subject to a pupil, I saw my error; and I beg to plead guilty to that "looseness" which has led to inaccuracy in the passage quoted from page 52. Instead of "deviation" I meant, and should therefore have said, "Vertical iron shows the same indirect magnetic force," &c., and to my class I have always used these words. I now tender my apology to my reviewer for my hasty letter, and beg to thank him for pointing out this "looseness and inaccuracy." I trust you will make this letter as public as my last. John Merrifield

Rainfall in Bombay

As it may interest some of the readers of Nature to know the amount of rain which fell on one occasion during the heavy monsoon rains which recently occurred at Bombay, and which I regret to see in your Notes had so disastrous an effect upon the library of the Asiatic Society, I quote the following from a letter which I have just received from my friend Mr. C. Chambers, F.R.S., Director of the Colaba Observatory, dated 10th Sept., 1872.

"Just a week ago we were treated to 7·20 inches of rain in two hours, which is nearly twice as heavy as I have known before, *i.e.*, had personal experience of."

In order that we m y form some idea of the enormous amount of the downpour, we must imagine the whole rain which has fallen in this neighbourhood since June 8, to have been concentrated in the time named; or, perhaps, better still, to suppose that the heaviest part of the shower which fell about half-past twelve, on the 3rd inst., and lasted for seven minutes, had continued for two hours.

Mr. Chambers was some time ago much troubled by the

presence of foreign matter, apparently dust, in the interior of his magnetic instruments. He now writes:—"In NATURE, vol. vi. p. 286, Fig. 2, is a thing very like the organic functions I speak of as being seen on the knife edge and plane of the vertical force magnetograph. I have described it as looking like the 'interlacing tea leaf stalks,' doubtless it was beginnings of life."

Can any of your readers state if it is probable that such objects are to be found in the place he names.

Kew Observatory, Oct. 23 G. MATHUS WHIPPLE

THE APPEAL FOR SKELETONS OF WILD ANIMALS

I AM glad to see that Mr. Moseley has started the question of the acquisition of skeletons of wild animals, a subject which has hitherto been too much neglected by those who have charge of museums. Mr. Moseley might have put his case more strongly than he has done; for not only are the two museums he mentions destitute of skeletons of the wild specimens of the larger *Felidæ*, but, so far as I know, no European museum possesses more than skulls. Possibly there may be an entire skeleton in the very rich museum of Leyden, but there are none in the British Museum, nor at Paris, nor Vienna, so far as I have been able to examine those collections. We are better off at Cambridge, for we not only have a considerable series of skulls of tigers, leopards, and the so-called "maneless" lion of Guzerat, but a fine skeleton of a Puma (*Felis concolor*) sent home from Florida in excellent condition by one of that much-abused class, "sportsmen."

There is, however, a subject even more important than the acquisition of foreign animals, namely, the collection of a good series of skeletons of different ages and sexes of all the European mammals. This is no easy matter, even in the case of the commoner species. We have only lately succeeded in acquiring an adult skeleton of the Red Deer (*Cervus elaphus*); but the one we have obtained (through the kindness of Mr. Balfour, of Trinity College) is an adult Royal stag, so fine as to be worth waiting any length of time for. Again, how many museums possess a skeleton of the brown bear of Europe, or the lynx, or the glutton, or the wolf, or even really good skeletons of such comparatively common animals as the badger, the otter, and the numerous small *Viverridæ*? And yet the bones of these occur more frequently in turbaries than do those of the extinct *Felidæ* in caves, while they are certain to become extinct from the pressure of civilisation and the consequent restriction of their range, far sooner even than those large animals which are directly persecuted, as tigers are in India.

I find it easier almost to get skeletons sent from abroad than to have them collected in England. Any gentleman who unites with love of sport a knowledge of natural history—no uncommon combination—will often send home considerable collections, and take great trouble to procure the different animals that he has been asked to look for. Such a collection we have just received from Lord Walsingham (of Trinity College), formed by him in North-west America. It includes complete skeletons of *Ovis montana*, *Antilocapra americana* (Pronghorn), white-tailed stag, mule deer, black bear, beaver, martin, besides a series of separate skulls. Last year we got an *Otaria* from San Francisco, one of the herd which the intelligent citizens of that capital are wise enough to preserve, and a musk-ox from the German North-Polar Expedition. In short, there are few animals that may not be acquired by energy and perseverance; and travellers in distant countries are fond of showing that they have not forgotten their old university; but it is infinitely more difficult to induce gentlemen, or their keepers, in England or Scotland, to collect the wild animals that still linger in their preserves; and this is the direction in which I venture to think an effort should be made.

The "directions for preparing skeletons" given by Mr. Moseley are excellent. Allow me to make one or two additions to them. It is most important to note the sex of each animal, with the locality in which it was taken and the date of its capture. I do not recommend the soaking of the carcase in water after the muscles have been removed. It loosens the ligaments, and makes the after-process of drying more difficult—a process which is difficult enough in Europe, especially in mountainous districts. Moreover, it is difficult to find a suitable place to do it in abroad. I find the colour of the bones not seriously affected by the non-extraction of the blood. The skeleton may be packed up before it is quite dry if sawdust be substituted for hay or straw. Pine sawdust is especially good for this purpose. It is very fine, dry, and slightly antiseptic.

Museum, Cambridge, Oct. 24 J. W. CLARK

THE ZOOLOGICAL STATION AT NAPLES

SINCE the last notice given in NATURE,* the building is almost finished, and all endeavours are now concentrated upon the arrangements of the interior. Two more months, and the fifty-three tanks of the public aquarium will be ready to be filled with the clear and limpid water of the Mediterranean.

The upper story receives still more attention. My plan of letting the tables having met with great applause from all sides, has worked some changes in the general arrangements of the rooms. The room previously intended for the library has been added to the great laboratory, which now measures 40 ft. in length, 25 ft. in breadth, and 24 ft. in height. It has three great arched windows 20 ft. high and 10 ft. broad, to the north, and three smaller ones looking into the small light-court in the centre of the building. The former three windows will give light to six microscopic tables, whilst the three smaller windows will yield enough light to three tables fitted up for common anatomical work. In the centre of the laboratory a wooden stand will be placed, 27 ft. in length and 8 ft. in breadth, and having three stories. This stand will bear tanks of different sizes—the lowest story the heaviest, the upper the smallest. The latter will be moveable, so as to allow close inspection on the working table. Each of them will receive a small current of sea water, and will have its own outlet, so as to isolate completely its contents from the neighbouring tanks. There will be plenty of room for some sixty or eighty tanks. The water running out of them is collected, and runs down into the tanks of the public aquarium. Four doors unite the laboratory to the three adjacent smaller rooms, which are provided each with a working table and with tanks, whilst the fourth door leads to a corridor and to the staircase. A gallery all round the walls of the laboratory, at the height of fourteen feet, will furnish room for the library. Two small staircases unite it to the floor of the laboratory, and four narrow doors to four adjacent small rooms, of which two may be used as reading-rooms for making notes, &c. It will be absolutely forbidden to take any book out of the building.

On the same floor as this great morphological laboratory, the physiological one is to be found; indeed the door which opens to the corridor leads also immediately to the room destined for this purpose. Its length is 20 ft. by 14 ft.; it has several glass doors to the west, opening upon an ante-room as wide as the room itself, and which, in case of need, can easily be transformed into a laboratory, thus enlarging the physiological laboratory to double its present size; it has a separate tube, with a constant supply of sea-water, and a table for microscopic work. Prof. du Bois-Reymond has promised to assist in arranging instruments and apparatus for experimental use.

* See NATURE, Vol. v. p. 437.

Besides these laboratories, there are rooms with windows and glass doors, all capable of being transformed, when necessary, into laboratories, for every room has its tube with sea-water. But as it is most likely that by-and-by extensive collections will be formed, to assist in working out a most accurate and detailed fauna of the Bay, or even of the Tuscan Sea, these rooms, especially a large one on the south side, will at first be left empty.

Downstairs there is another small apartment on the north side, destined for a botanical laboratory. It has one large and two smaller windows, thus allowing four microscopical tables to be furnished, three of which will be let, whilst the fourth belongs to the botanist of the station, who is to be engaged next winter. In the basement two series of store-tanks will be placed, into which all the animals will be put immediately after being caught by the fishing and dredging expeditions, which will be sent out every day, weather permitting.

The library of the station has received many valuable presents. Thus Prof. Allman, Mr. Darwin, Prof. Flower, Mr. Gosse, Prof. Huxley, Mr. Gwyn Jeffreys, Sir John Lubbock, and Prof. Owen, have promised or sent their biological works; and German publishers, such as Georg Reimer of Berlin, and Braumüller of Vienna, have joined Engelmann, Vieweg, and Fischer, in offering all their biological publications. A catalogue is being prepared, containing a complete list of the actual state of the station library.

By the kindness of Mr. Gwyn Jeffreys, dredges have been procured of the best pattern, such as that experienced zoologist recommended; boats have been built for special dredging purposes, and everything also is being prepared to render the station as efficient as possible.

We hope in our next article to give some information as to the relations, into which the new institute has entered with governments and learned bodies. Here we may still be allowed to point out, that since the foundation of the Naples station has been taken earnestly into hand, similar endeavours have been made both in Austria and France. In both countries the Government has been asked to establish Zoological Laboratories on the coast. We have still to wait the results of such demands.

Naples, Oct. 24 ANTON DOHRN

VESTIGES OF GLACIAL ACTION IN NORTH-EASTERN ANATOLIA

In a paper dated some months back* I gave an abridged notice of some traces of ice-action, referable to the so-called epoch, in the central plateau of Asia-Minor. A journey undertaken this summer through the north-eastern districts of the peninsula has enabled me to observe several other phenomena of the same class, and to determine in some measure the extent and degree in which that prolonged depression of temperature affected this region.

My route traversed an extensive but rarely visited tract of country, that, namely, of the great Chorok, or Harpagus river-valley from Beyboort to Artween, and the mountain lands that extend beyond that valley east and north up to the frontier of Russian Georgia, returning by the Black Sea coast. The space thus explored extends from long. 40° to 44° E., and from lat. 40° to 42° N.

The valley of the Chorok river, for a distance of about 120 miles—that is, from the neighbourhood of Beyboort to that of the town of Artween—runs almost parallel with the sea-coast in an E.N.E. direction, and is separated from the basin of the Euxine by a lofty chain of mountains, the higher peaks of which reach an altitude of 11,000 feet above the sea-level, and even more. The whole long and narrow strip of land bears the name of Lazistan, or country of the Lazes, a Mingrelian tribe, mentioned by Strabo as tenanting the same region in his time.

* See NATURE, vol. v. p. 444

Near Artween, long. 42,° the valley turns sharp to the north, and finds its way through a narrow and precipitous cleft to the sea.

The southern side is determined by the highlands which form the watershed between the tributaries of the Black Sea and those of the Persian Gulf; but farther east the same range, deflecting somewhat to the north, unites with the prolongation of the Lazistan mountains, and acts as watershed not only to the already-mentioned streams, but also to those of the Caspian, which it separates from the two other fluvial systems. Farther on the Russo-Georgian frontier follows its eastern slope.

Returning to the Chorok valley—one might almost call it trench—I may as well notice that its height above sea-level at Beyboort is about 5,000 feet, and at Artween only 1,000 feet, whence the extreme rapidity of the river, suitably named the Harpagus, may be inferred. The geological character of the mountain chains on either side is extremely varied. Cretaceous and Jurassic strata have in both been extensively superimposed on the plutonic rocks that frequently pierce through and form the higher ranges; volcanic formations, less ordinary in the southern chain, are of frequent recurrence in the northern. Indeed the Lazistan mountains, where they dip into the sea, are almost wholly volcanic in structure. Large tracts of a metamorphic character also occur, but more on the northern than on the southern side.

Roads, in a European sense of the word, throughout all these districts, there are none; even a tolerable horse-track is only an occasional luxury. Hence my entire tour was performed partly on horseback at walking pace, partly on foot; so that I had full opportunity for the most leisurely observation. My route first followed the southern side of the Chorok valley for about seventy miles, then the northern for about fifty more, after which I traversed the eastern highlands to the Russian frontier, a distance of about 160 miles, then turned north till I reached the Black Sea coast, along which I returned.

And having now given these summary indications, which the nature of the country, scarcely ever visited by Europeans, and in general very little known, seemed to make necessary, I will now proceed to the account of the principal phenomena referable to the glacial period.

While travelling at an altitude varying from 3,000 to 7,600 feet according to the exigencies of the route along the southern side of the valley—that is, on the northern slope of the Euphrates watershed—I crossed three large moraines, two of them descending from the slopes of Charmeli Dagh, a lofty granite ridge, streaked with snow all through the year. Their lower extremity was at about 5,000 feet above sea-level, their upper origin attaining nearly 8,000 feet. The mountain sides here are Jurassic or limestone; but the broad streams of angular blocks that follow their depressions were almost exclusively granite of the same kind as that which forms the mountain wall above. Where, however, the general altitude of the chain does not exceed 7,000 feet, as is occasionally the case, no moraines are to be observed, though large angular boulders are not uncommon on the broad ledges. The upper mountain lines are invariably rounded, and, as it were, smoothed off; the sides marked with scooped depressions much too wide for their depth to be attributable to torrent action; low down in the valley the slopes terminate in rifted precipices.

That the epoch to which these moraines belong was posterior to that of the volcanic action which, though long since extinct at the surface, has left so many traces along the north-eastern coast of Asia-Minor, was rendered in one instance sufficiently evident by the constituents of a broad stone-ridge which I crossed near the highest point of the mountain chain, a little to the east of Erzeroom.

Here, at an elevation reaching to upwards of 7,000 feet, the ordinary Jurassic strata were interrupted by a volcanic outbreak of several miles in extent, like a huge patch of

black lava and scoriæ extending far up the mountain side, where traces of a large crater were still observable. Above, to a height of full 9,000 feet, towered the granite peaks, and here, reaching down towards the valley, a wide moraine traversed the road. It was mainly composed of volcanic fragments, though mixed with blocks of granite; and must consequently have been formed at a time when the volcano had not only existed, but had also ceased its action.

To assure myself of the true character of the phenomenon, I quitted the path and rode up and along the stone-stream to a considerable distance, till in fact my horse could no longer make his footing sure; and I had fully convinced myself that the moraine was the result of glacial action alone, not of torrents or weather action referable to more recent times.

Not far on I had to traverse the pass called Keskeem Boughaz, or, the entrance of Keskeem; this latter being the name given to the district on either side of the lower Chorok valley. The road here reaches an altitude of 8,200 feet; yet is far overtopped by the granite range of Tortoom, even now streaked with perpetual snow, to the south. Here again I observed a large moraine, winding down from the upper ridge; while the first plateau of Keskeem, about 7,400 feet above sea-level, into which I next descended, was strewn capriciously with large granite boulders, many ten or more feet in diameter. Another volcanic tract succeeds, where the path winds along a valley hemmed in by gigantic cliffs of black lava, dashed with blood-red porphyritic stains. From this point my track followed a level too low to permit of expecting or of finding any further glacial traces in this region.

Summing up the observations made during this stage of my journey, I come to the conclusion that the ice-cap of the north-easterly Anatolian watershed, in post-pliocene times, must have reached downwards, on the northern side of the range at least, to about 7,000 feet above the present sea level; while some of the glaciers issuing from it descended to about 4,500 feet of the same measurement. In what degree the sea-level of the entire eastern portion of the peninsula has changed—it would seem since the epoch referred to—I shall speak further on.

Two phenomena only remain to be noticed;—one, the absence of all organic traces, whether marine or otherwise, in these rocks and strata; an absence which I have heard remarked on by the few natives capable of observing these things; another, the frequent presence, in the moraine or glacial belt, of scratched and striated rocks, especially granite.

Crossing the river, now at its shallowest in the summer season, but still containing, at a distance of a hundred miles from its mouth, as large a body of water as the Thames during high tide at Richmond bridge, my path led to Artween, the chief village-centre of these regions, along the north-western side of the valley; that is, along the inner slope of the coast range. These Lazistan mountains form a very lofty, but comparatively narrow ridge, of great steepness, and ill adapted to the formation of glaciers; and besides they must have been, even in the glacial epoch, exposed to the comparatively mild atmosphere of the great sea, now represented by the Black Sea and the Caspian only, but which then covered so large a portion of what is now Russia.

Here, however, I again found evident traces of the same cold period, but written in different characters. Not moraines indeed, nor the other analogous appearances indicated in the more inland district, but signs of alternating snows and thaws, of weather-change and water-action on a scale much vaster than is possible in the existing condition of climate, even were the most rigorous winter, such as now is, to be succeeded by the warmest summer. Wide and deep clefts, the work of torrents, yet flowing, but dwindled to comparative insignificance; great sweeps of shattered rock fragments down slopes inaccessible from their steepness, due to frosts of a severity unknown at this day, followed by corresponding thaw; and every mark of climatic disintegration, much beyond, though in kind similar to, that which these crags now undergo. And lastly the water level of the Chorok itself, judging by the eroded shelves and like indications left here and there in the cliffs along its shores, must have been from fifteen to twenty feet above its actual level; a circumstance which can scarcely be attributed to other causes than the melting of great supplies of ice and snow; since there is no reason whatever to suppose that any considerable diminution in the forest growth around has taken place from the earliest to the present times.

That there really was such a difference between the glacial conditions of the Lazistan, or coast mountains, and those of the inland watershed in the epoch alluded to, is in a measure confirmed by their actual state. For though the Lazistan peaks considerably surpass in height those of the southern chain, being some of them above 11,000 feet in elevation, whereas the others average from 9,000 to 10,000 only, yet snow lies all summer through on the latter, much more abundantly than on the former; while on the other hand the annual quantity of rain and snow that in the winter months of the year fails on the Lazistan mountains is at least the double of what is apportioned to the southern or Armenian chain. A depression of 15° to 20° centigrade in the average temperature of the year, would now to a certainty cover the latter with glaciers, while it would furrow the former with torrents of the first magnitude.

Leaving the Chorook valley, my road—or track, to speak more properly, for road in our sense of the word there was none—led north-east up to the great water-shed already often mentioned, and which here, turning northwards also, separates from each other not the Black Sea and Persian Gulf river systems only, but a third also, that of the Caspian. For about forty miles my journey, though passing through a district abounding in other geological phenomena of great interest, yet supplied me with none of the class to which these notes specially refer, for the reason that it lay wholly along valleys and through ravines often below 4,000 feet in sea elevation, and never exceeding that height. But at the Karanlik Dagh, or Mountain of Darkness, so called either from the black and dense fir forests that clothe its sides, or from the thick mists that hang for months along its middle slopes, and at a point as nearly as possible opposite the extreme north-eastern angle of the Black Sea, here about fifty miles distant in a direct line, I began at last the ascent of the main ridge, the backbone of the land. While slowly climbing the limestone ledges of the mountain, and at the height of 6,400 feet, I here once more found athwart my way a colossal moraine, formed of worn granite blocks and partly overgrown with forest, descending from an overtopping height, which I afterwards ascertained to be about 8,000 feet. But before we reached it I traversed an intervening ledge, 7,300 feet above the sea, composed of granite rocks, worn and marked with unequivocal ice action, though now wholly bare of snow. A valley divided this ridge from the highest of all, that called Penek, up which a difficult track, called the "Egri Yokoosh" or "crooked ascent"—and it well deserved its name—brought us at last, landing us on a cold, undulating granite plateau of 9,000 to 9,500 feet in elevation. Here and there its depressions were scooped out into deep little oval lakes, full all summer through of clear blue water, and looking the very memorials of vanished ice; while the gently sloping sides of the plateau itself were strewn with boulders of every size and shape, but all granite, seemingly brought there from the higher peaks of the Penek chain, about five miles off. Nor did these boulders cease to occur, sometimes in greater abundance, sometimes less, till we reached the great basin of Ardahan, near the sources of the Kur, or Cyrus river, here a slender stream,

on its way to join the Araxes, and enter with it the Caspian Sea.

The height of the Ardahan plain is 6,500 feet; it is, but for a very gentle easterly slope, an absolute water-like level; the bottom of this lake basin, for such it certainly was, consists of deep alluvial soil, mixed with detritus and large boulders; the sides are all rounded and smoothed off in gentle slopes, and bear every mark of having been long ice-covered. They are of various altitudes, but all alike. I climbed one of the lateral plateaus, at the north-eastern corner of the plain, till I had reached 2,000 feet above the Kur stream; boulders everywhere.

These plateaus stretch east to the Russo-Georgian frontier, about twenty-five miles distant. They contain many notable lakes, some of which I visited; that called Childer, in particular, is about ten miles in extreme length by eight in breadth. Its surface is 6,700 feet above the sea, and it is encased in mounded hills, like those already described. The natives declare its depth to be unfathomable, and, somewhat inconsistently, affirm that a submerged city exists below. But a clever Beg, or Chief of the neighbourhood, a friend of mine, had the curiosity to sail across it in every direction, sounding the bottom, and assured me that its greatest depth, near the northern extremity, did not exceed twenty-two fathoms, while he added, laughing, that of the buried city his line had discovered for him no trace. Karzach lake, not far off, a square-shaped sheet of water about four miles in extent each way, seems to be stilll shallower; while Tch Lake, as it is called, close by which my road passed, is now a mere marsh, though of considerable dimensions. Like the other two it has left, however, on its banks the marks of having been once much deeper and wider than at present. The plateau on which these lakes are situated continues, with alternate elevations and depressions, but always bearing the features already described, for about thirty miles to the north, till, having reached its greatest altitude in Kel Dagh, a mountain about 11,000 feet high, it begins to descend step by step to the plains of Georgia and the Black Sea. From this point its whole character changes, rifts, abrupt precipices, and narrow gorges taking the place of the rounded undulating outlines it bore farther inland. Nor is any further trace of boulders or moraines to be seen, at least below an elevation of nearly 8,000 feet.

It is to be remarked that this entire range, like the central Anatolian watershed, is almost uniform in its geological composition; Jurassic on its lower slopes; granite above. One only exception here occurs, and that is along the deep and rapidly descending chasm through which the torrent Kur finds its way; a chasm traversing the plateau in its greater width, from the basin of Ardahan to the Russian frontier. Its sides, and the rock in its neighbourhood to, in some places, a considerable extent, are volcanic.

My return route, from the Russian frontier near the well-known river Phasis, now the Rion, to Trebizond, lay along the coast; thus affording me excellent opportunities for studying on the northern or sea-side the same Lazistan mountain-chain, which I had already, in some measure, examined on its mainland or inner slope. Rarely stratified, its formations are most often volcanic, or metamorphic, gneiss and shale, with granite above. But if the inner and sheltered side had shown, as I have already noticed, no direct trace of glacial action, still less could I expect to discover any such on the outer or sea slope. However this generalisation was interrupted by one remarkable exception.

High up in the Lazistan mountains, about half way between Trebizond and Batoom, is perched the almost inaccessible district of Hamshun, a highland region tenanted by a colony of wholly different origin from the Mingrelian population around them, namely Armenian, though now all professing, not over-zealously, the Mahometan system. How or when they came there, no record tells. This district I resolved to visit; and three days of such breakneck scramble as even Turkish mountain-tracks had never before afforded me, brought me into the very centre of Hamshun.

Here, at the modest height of 6,900 feet above the sea, I stood on a granite-strewn plateau, thinly green with grass, sheltered from the sea by a tolerably lofty series ot peaks on the N.W.; and backed to the S.E. by the tremendous jagged cliffs, blackish granite dashed with white snow streaks, else naked in all their savageness, but known by the uncouth names of Onoot Dagh, Alti Parmak Dagh, Jamookh Dagh; and, towering over all in startling resemblance to the Alpine Matterhorn, only more fantastic if possible, in its precipitous isolation of peak, Verehembek Dagh, rising full 12,500 feet above the sea, from which it is visible at a distance of about a hundred miles; a natural and unmistakeable beacon to the sailor. The plateau itself was about forty miles in length; and irregular in breadth; its surface too mounded, and often jotted over with boulders. But just as my track led near under the base of Verehembek, at an altitude of 8,300 feet, it crossed a large broad moraine, descending from the higher slope, and having its base in a broad bare valley not far below; thus indicating that here too, at the highest and widest part of the Lazistan chain, perpetual ice had once existed in sufficient quantity to furnish at least one glacier. But, if warrantable conclusions can be drawn from a single instance, the limited ice-cap of the Hamshun highlands extended no farther down than 8,500 feet at most, perhaps 9,000; thus differing by a line of one to two thousand feet from the glacial covering of the inland range.

What correctness there may be in this as in my other conjectures, I, of course, cannot well estimate: but I have now recorded the chief phenomena of this nature noted by me in these regions; it is for those more versed in such matters than myself to read their meaning aright.

Of the volcanic phenomena in the Lazistan or coast-chain, I shall say nothing here; that subject requiring, from its very copiousness, to be treated apart. But there is one fact connected with it worth noticing, as a corollary to what I have written; though a mere notice is all that can be given it for the present. It is, the elevation or depression of the south-east of the Black Sea coast.

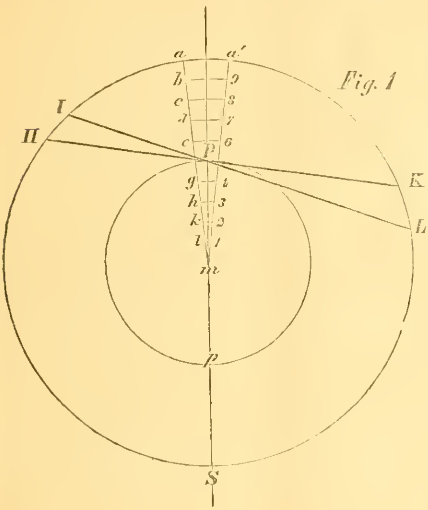
In a former paper I remember having remarked that, judging by the actual position of an old river bar, as also by the height of certain cavernous excavations in the neighbouring cliffs, I am inclined to think that the coast near Trebizond itself has been raised to an elevation of about twelve, perhaps fifteen feet in post-glacial times. Having now ridden along the entire shore up to the mouth of the Phasis, I remark that the traces of similar uprising during, certainly not earlier than, the same period, as written on cliffs now a considerable way inland, on estuaries evidently prolonged, and on crags, still as before, coming sheer down into the sea, but wave-marked higher up than the possibility of the most violent storm could now effect; all these would seem to indicate that the same rising has been continued along the entire easterly line of coast, though not to an equal degree; the greatest elevation appearing to have taken place exactly at the south-eastern angle of the Euxine, near Batoom, from which point east and north it would gradually have diminished. West of Trebizond again it distinctly,—if traces of the kind mentioned be not misleading,—diminishes; till at, and to some distance west of Cape Jason it not only ceases, but is exchanged for a depression of the coast several feet. eight or ten seemingly, below its former level. Farther west again a slight rise would appear to have taken place; but allowance must be made for the effects of currents, which are very strong all along the coast.

Trebizond, Oct. 3 W. GIFFORD PALGRAVE

THE SOURCE OF SOLAR ENERGY

ALL incandescent bodies shrink rapidly if permitted to radiate freely, the rate being nearly proportional to the degree of incandescence. The enormous temperature maintained at the surface of the sun must therefore produce rapid shrinking, although we do not know the rate by actual observation. We know, however, what amount of mechanical energy the sun parts with in a given time, and we know the size and the specific gravity of the solar mass.

Demonstration is not needed to prove that motion of the particles within a spherical body towards the centre caused by attraction, develops a certain amount of mechanical energy resulting in the generation of heat within the mass. Nor is it necessary to show that the fixed relation between heat and energy enables us to determine the extent of contraction produced by gravitation, during cooling, if we can ascertain the amount of heat radiated in a given time by a sphere of known size and specific gravity. With reference to the sun, the elements thus specified are of the following magnitudes:—Heat radiated per minute, 312,000 thermal units from one square foot of surface; diameter, 852,584 miles; specific gravity, 0·250 compared



to that of the earth, or $5{\cdot}50 \times 0{\cdot}250 = 1{\cdot}37$ of water. Hence assuming that the mass is homogeneous, the weight of one cubic foot of the matter composing the sun will be $62{\cdot}5 \times 1{\cdot}37 = 85{\cdot}6$ pounds. It will be seen presently that, in case the sun's mass is not homogeneous, the want of homogeneity will not materially affect the question of attraction and the resulting energy. At first sight it would appear that no probable amount of contraction of the sun could develop by gravitation towards the centre an amount of dynamic energy of $312,000 \times 772 = 240,864,000$ foot-pounds per *minute* for each square foot of the solar surface. Yet, so vast is the mass contained in a spherical pyramid, the base of which is one square foot and whose length is equal to the sun's radius, that a very small longitudinal contraction suffices to develop by gravitation towards the sun's centre the stated enormous dynamic energy. It will be readily understood that the energy developed by the shrinking of a spherical pyramid, the sides of which are sectors of the great circle of the sun, will represent accurately the energy produced by the shrinking of the entire mass. And, in view of the great dimensions of the sun and the formidable array of figures involved in the computation of the energy exerted within the entire sphere, the advantage of considering only the mass covered by a single square foot of the solar surface will be evident. Let *I K S*, Fig. 1, represent the great circle of the sun, *a m a'* the spherical pyramid referred to, and Fig. 2 the said pyramid drawn to a larger scale, its axis being divided into ten equal parts. It is proposed to ascertain what extent of longitudinal contraction of the spherical pyramid *a m a'* is necessary to produce an amount of dynamic energy corresponding with that developed by the radiation from one square foot of the solar surface in a given time. The investigation will be somewhat facilitated if we compute the amount of energy developed by a definite contraction of the sun's radius, say one foot. Let us therefore suppose that *a a'*, the distance of which is $\frac{852,584}{2} \times 5,280 = 2,250,821,760$

Fig. 2

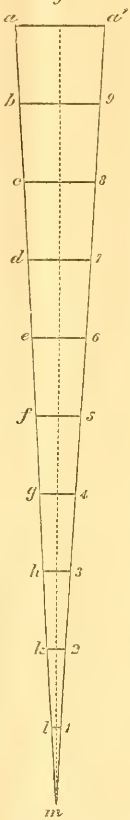


Fig. 3

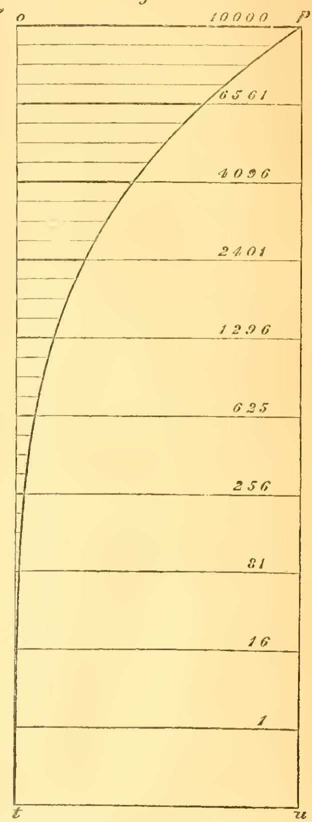

feet from *m*, has fallen through a space of one foot, the intermediate points *b*, *c*, *d*, &c., participating proportionably in the fall. Assuming that the solar mass remains homogeneous during the contraction, it follows from Newton's demonstration ("Principia," lib. i. prop. lxxiii.) that since a particle just within the circumference of the sphere at *a* is ten times farther from the centre *m* than a particle at *l*, the former will be attracted towards *m* with ten times greater force than the latter. It will be readily perceived that, for a given movement towards the centre, the quantity of matter put in motion at *a* will be greater than at *l*, in the ratio of the squares of *a a'* and *l* 1, or 100 : 1. Hence, in accordance with the demonstration referred to, a given radial depth of the solar mass at *a* will exert a force towards *m*

$10 \times 100 = 1,000$ times greater than an equal radial depth at l. But, in computing the dynamic energy developed by the shrinking of the sun, it must be borne in mind that a particle at a falls through a distance ten times greater than a particle at l. The length of the ordinates of the curve $p\,t$, Fig. 3, representing the ratio of dynamic energy developed at the respective distances from the sun's centre, has been calculated accordingly. A cursory examination of Fig. 2 can scarcely fail to lead to the conclusion that the mass composing the smaller sections of the spherical pyramid towards the centre of the sphere, will be attracted by the larger mass composing the sections towards the circumference. Newton has disposed of this question by a geometrical demonstration which, considering the form of the attracting mass, and the extreme complication arising from the varying direction and unequal magnitude of the attracting forces, may be regarded as one of the most elegant of his masterly demonstrations of important propositions and theorems. It will be evident on reflection that, unless it can be proved that a particle at P is not attracted by any portion of the mass contained within the outer spherical superfices $I\,K\,S$ and the interior spherical superfices $P\,p$, the mass composing the sections near the base of the spherical pyramid will exert the disturbing attraction before alluded to. Our demonstration of the energy produced by the attraction of the matter within the sun, during shrinking, falls to the ground, unless it can be shown that every particle composing the spherical pyramid is in perfect repose as regards the attraction exerted by exterior particles. The great geometer thus establishes that repose:—Let $H\,I\,K\,L$ be a spherical superfices, and P a corpuscle placed within.* Through P let there be drawn to this superfices the two lines $H\,K$, $I\,L$, intercepting very small arcs $H\,I$, $K\,L$; and because the triangles $H\,P\,I$, $L\,P\,K$ are homogeneous, those arcs will be proportional to the distances $H\,P$, $L\,P$; and every particle at $H\,I$ and $K\,L$ of the spherical superfices, terminated by right lines passing through P, will be in duplicate ratio of those distances. Therefore the forces of these particles exerted upon the body P are equal between themselves. For the forces are as the particles directly, and the squares of the distances inversely. And these two ratios compose the ratio of equality. The attractions, therefore, being made equally towards contrary parts, destroy each other. And, by a like reasoning, all the attractions through the whole spherical superfices are destroyed by contrary attractions. Therefore the body P will not be anyway impelled by those attractions.

Referring to Fig. 3, let us recollect that the ordinates of the curve $p\,t$ do not indicate the force exerted by mere attraction. As already stated, their length represents the dynamic energy developed at definite distances between the centre and the circumference of the sphere. The energy actually produced is represented by the superficies $o\,p\,t$, while the rectangle $o\,p\,u\,t$ represents the energy that would be called forth if the force exerted at every point of the axis of the spherical pyramid were the same as that exerted at $a\,a'$. Our space will not admit of introducing the calculations by which the energy represented by the ordinates of the curve $p\,t$ have been computed. It will be proper, however, to call attention to the fact that the energy exerted at each of the divisions of the base line $o\,t$ is definite; hence the length of the ordinates is exact. Calculations based on the data thus furnished show that the superficies $o\,p\,t$ is 0·20015 of the superficies $o\,p\,u\,t$.

We have before stated that the want of homogeneity of the solar mass will not materially affect the amount of energy developed by the gravitating force during the sun's shrinking. Referring to the several figures, it will be seen that the energy exerted at a point half way from m, viz., ordinate 5, is 0·0625, or $\frac{1}{16}$ of that exerted at $a\,a'$; and that the energy developed by the mass contained within the spherical pyramid $f\,m\,5$ amounts to only $\frac{1}{31}$ of that developed by the gravitation of the mass contained within the spherical pyramid $a\,m\,a'$. Now the volume of the spherical pyramid $f\,m\,5$ represents that of a sphere the diameter of which is one half of the sun, while the spherical pyramid $a\,m\,a'$ represents the volume of the entire solar mass. The energy resulting from the gravitation of the central spherical mass $P\,p$ being thus only $\frac{1}{31}$ of the energy exerted by the spherical mass $I\,K\,S$, it will be perceived that the degree of density of the matter towards the sun's centre will not materially affect the result of our calculations founded on perfect homogeneity.

We may now proceed to ascertain the amount of dynamic energy produced by the assumed shrinking of the axis of the spherical pyramid $a\,m\,a'$. Having already demonstrated that the said energy will be 0·20015 of that produced by the gravitation of a homogeneous mass, the section of which is one square foot extending from the surface to the centre, it only remains to determine the weight of one cubic foot at the surface of the sun. The specific gravity of the solar mass being 85·6 pounds per cubic foot, while the sun's attraction is 27·2 times greater than terrestrial attraction, the weight of one cubic foot at the solar surface will be $27·2 \times 85·6 = 2328·3$ pounds. Multiplying this weight by the sun's radius expressed in feet, we have, $2328·3 \times 2,250,821,000 = 5,240,633,000,000$, which product, multiplied by 0·20015, shows that the gravitating energy of the matter contained in the spherical pyramid, exerted during a longitudinal contraction of one foot, amounts to 1,048,912,000,000 foot pounds. Dividing this latter product by the solar energy per minute, already stated, we find that 4355 minutes, = 3·024 days will elapse before the energy produced by constant solar radiation equals the gravitating energy exerted during the shrinking of one foot of the solar radius. The length of one year, 365·25 days, being divided by 3·024, we learn that the annual shrinking of the sun's radius amounts to 120·7 feet. The foregoing figures prove that, notwithstanding this apparently great contraction, a period of 1864 years is necessary to diminish the sun's diameter $\frac{1}{10,000}$. It hardly requires explanation that this result is reached by dividing the sun's diameter by 10,000 times the stated annual shrinking.

Helmholtz, in accordance with Laplace's remarkable nebular hypothesis, asserts that the continuation of the original condensation of the matter composing the sun develops an amount of mechanical energy capable of generating sufficient heat to make good the present solar emission. According to his calculations, the sun's diameter will be reduced $\frac{1}{10000}$ in the course of 2,000 years. The practical data assumed by the eminent physicist being less accurate than those upon which our calculations are based, the discrepancy regarding time, 2,000 years against 1864 years, necessary to effect the stated shrinking of the sun's diameter, may be satisfactorily explained. It will be well to observe that the intensity of the radiant heat will not diminish with the diminished size of the sun. On the contrary, for a given area of the solar surface, the dynamic energy produced by a given rate of shrinking will be increased, since the mass remains the same, while the attraction is inversely proportional to the square of the distance from the centre. But the *rate* will diminish with the contraction of the sphere; hence a shrinking of $\frac{1}{10}$th of the sun's diameter, instead of occupying $1,000 \times 1864 = 1,864,000$ years, will require somewhat more than 2,000,000 years. At the end of that period the gravitating energy will continue to develop, as at present, an amount of dynamic energy represented by 312,000 thermal units per minute for each superficial foot; but the radiating surface, *i.e.*, the area of the solar disc, will have diminished in the ratio of 10^2 to 9^2.

The present maximum temperature produced by solar radiation on the ecliptic when the earth is in aphelion, being 67·2, while the intensity of radiant heat diminishes as the area of the radiating surface, it follows that, at the end of 2,000,000 years from the present time, the tropical solar intensity will be reduced to $\frac{9^2 \times 67·2}{10^2} = 54·4°$, unless Prof. Tyndall's opinion is correct, that the earth, in common with the other planets, must "creep in, age by age, towards the sun."* But the pace is no doubt so slow that our calculations will not be seriously affected; hence, applying the foregoing demonstrations to the past, it will be seen that the temperature called forth by solar radiation 2,000,000 years ago must have been, owing to the greater diameter of the sun at that period, about $\frac{11^2 \times 67·2}{10^2} = 81°$ within the tropics. Now we are justified in assuming that the increased evaporation of the sea, and the consequent humidity of the atmosphere, modified the stated solar intensity, calling forth the luxuriant flora of past ages, which geology has made us acquainted with. The computed diminution of solar intensity, $67° - 54° = 13°$, during the next 2,000,000 years will probably be deemed extravagant by those who do not bear in mind that the computation must be based on

* Sir Isaac Newton, in his demonstrations relating to spherical bodies, supposed these to be composed of an infinite number of spherical superficies the thickness of which he thus defines:—"By the superficies of which I here imagine the solids composed, I do not mean superficies purely mathematical, but orbs so extremely thin that their thickness is as nothing; that is, the evanescent orbs of which the sphere will at last consist, when the number of the orbs is increased, and their thickness diminished without end."

* See "Heat as a Mode of Motion," p. 499.

the assumption that a constant power is being exerted during the stated period capable of developing, as at present, the stupendous energy of 240 millions of foot-pounds in a single minute, for each square foot of the surface of a sphere whose diameter exceeds 850,000 miles. This inconceivable amount of work cannot be performed with a less expenditure than the motive energy developed by the fall of a mass equal to the mass contained in the sun, the weight of which is nearly a thousand times greater than the weight of all the planets of the system. Obviously a *continuous* development of such an amount of energy is physically impossible, since there is a *limit* to the distance through which the weight can fall. Now the foregoing demonstration enables us to determine the said limit, with sufficient exactness to prove that although the efficiency of the great motor, during the past, may be measured by hundreds of millions of years, its future efficiency will be of comparatively brief duration.

Statements relating to the permanency of solar heat, based on the assumption that no diminution has been observed during historic times, have no weight in view of our demonstration showing that a shrinking of $\frac{1}{10}$ of the sun's diameter can only reduce the intensity from 81° to 67°·2, difference = 13°·8, in the course of two millions of years. This period being 500 times longer than "historic times" say 4,000 years, it will be seen that the diminution of the temperature produced by solar radiation, has not exceeded $\frac{13 \cdot 8}{500} = 0 \cdot 027$, or $\frac{1}{37}$ deg. Fah. since the erection of the Pyramids.

It will be proper to observe, before concluding our brief investigation of the source of solar energy, that, the development of heat by the shrinking of the sun, however fully demonstrated, leaves the important question unanswered: how is the heat generated by gravitation within the mass transmitted to the surface? If the matter within the sun is a perfect conductor of heat—a very improbable supposition—that fact alone furnishes a satisfactory answer. Imperfect conductivity, on the other hand, calls for other means of transmitting the energy from within, to make good the enormous loss caused by the external radiation. Besides, the falling of the crust at the rate of ten feet per month, attended by increase of internal pressure, and probably ejection of gaseous matter, together with the disturbance occasioned by contraction at the surface, disclose a mechanism of startling perplexity. But the parting with 312,000 thermal units for each square foot of the solar surface, involving an expenditure of kinetic energy fully 240,000,000 foot-pounds per minute, cannot be made good in that brief space of time, unless the sun shrinks at the rate ascertained by our calculations.

The development of solar energy in accordance with the combustion hypothesis (lately resuscitated by M. E. Vicaire) merits no consideration, while careful investigation has proved the meteoric hypothesis to be untenable. It must be admitted, however, that the mechanical difficulties alluded to, especially those relating to the means of transmitting the heat to the surface of the sun, any temporary local derangement of which must be productive of dark spots for a time, are of such a nature that the absolute certainty of solar radiation may be questioned; nor is evidence wanting to show that the solar mechanism is liable to derangement. History informs us that the great luminary has, during several seasons, partially failed to perform its functions. Herschel states, in his "Outlines of Astronomy," that "in the annals of the year A.D. 536 the sun is said to have suffered a great diminution of light, which continued fourteen months. From October A.D. 626 to the following June a defalcation of light to the extent of one-half is recorded; and in A.D. 1547, during three days, the sun is said to have been so darkened that stars were seen in the day-time." Again, the glacial periods, the ascertained abrupt termination and recurrence of which puzzles the geologist, point to periodical derangement of the solar mechanism in past ages.

J. ERICSSON

EXTRAORDINARY WHIRLWIND IN IRELAND

IN a letter to the *Belfast News-Letter*, Mr. C. J. Webb describes an extraordinary whirlwind which occurred in the district around Randalstown, about six miles N.W. of Antrim, near the shores of Lough Neagh, on the 25th of August last. The same phenomenon was witnessed about an hour and a half earlier the same evening at Banbridge, about seven miles S.W. of Dromore. It was first seen near Randalstown about 5 P.M., between that place and Toome, moving rapidly up Lough Neagh from the south, and presenting the appearance of a defined column of spray and clouds, whirling round and round, and not many yards in breadth, while at its base the water was lashed into a circle of white foam. It was next heard of in the neighbourhood of Staffordstown, about a mile from the lake, where it partially unroofed two houses, and damaged any trees or crops which happened to be in its course. From this point it travelled in a straight line for Randalstown, about three miles distant. It passed across a field close to Mr. Webb's house, levelling eight haystacks, and carried a considerable part of the hay up into the air out of sight. The breadth of the storm could be accurately ascertained at this point, and must have extended about thirty yards, as stacks remained unruffled at either side, while those between were thrown down and carried away or scattered about. Everything it lapped up was whirled round and round, and carried upwards in the centre, while dense clouds seemed to be sucked down on the outside, and came close to the earth. Both before and after there was lightning and incessant peals of thunder; but there was no rain till some time afterwards. Mr. Webb next observed its track in a hollow, some three hundred yards further on, where it knocked down a haystack, and then plunged into a wood of fine old Irish oaks. Here it tore numerous branches and limbs from the trees, carrying some along with it, and throwing others to the ground. One noble tree in the centre of the wood seems to have been a peculiar mark for its vengeance, although it would have been completely protected from any ordinary storm, owing to its position. It next passed across a corner of Shane's Castle demesne. Some who were at a short distance from this point describe its approach as causing considerable alarm. It was accompanied by a wild rushing noise, and the crashing of the trees and branches could be heard becoming louder and louder as it advanced. It crossed the valley over the railway viaduct, close to Randalstown, fortunately avoiding the village. It here presented the appearance of a vast whirling column of leaves and branches, mingled with clouds which looked like smoke.

The railway station next suffered, innumerable slates and two and a half cwt. of lead being torn from the roof in an instant. A great part of the railings surrounding the gardens was torn up, and an iron bar one inch thick, belonging to the gate, was bent to an angle of sixty degrees. A small shed at the rear of the station was unroofed, rafters and slates being hurled to the ground. What will give some idea of the excessive pressure of the wind, is the fact that three boards of the flooring of the waiting-room were forced up, owing to the wind finding an entrance to a cellar underneath, though the only aperture was a round hole about one foot in diameter. All this was the work of a few moments. The storm then passed away, leaving comparative calm behind. It next crossed an adjacent bog, scattering the turf in all directions. The last place Mr. Webb heard of its having visited was a farm house about three miles from Randalstown, between Antrim and Ballymena. It would be interesting to ascertain whether it travelled across to the sea-coast.

NOTES

THE British Association Committee on Mathematical Tables, of which Prof. Cayley is the chairman, has determined to tabulate the Elliptic Functions, or more accurately, the Jacobian Theta Functions, which are the numerators and denominators of the former, and their logarithms. The tables, which are of double entry, will therefore give eight tabular results for each

8,100 arguments; besides certain other quantities, depending only on the modulus, that will be added. Forms have been printed, and the calculation has already been commenced. The Elliptic Integrals (the inverse forms to the Functions) were, as is well known, calculated by Legendre, and published in his "Traité des Fonctions Elliptiques, 1826." It is unquestionable that the Elliptic Functions are the most widely used transcendents in analysis that have not yet been tabulated, and it is believed that the tables will be found very generally useful in all the mathematical sciences. The great labour has no doubt alone prevented any previous attempt. The work proposed by the committee will, when completed, be most likely the largest piece of numerical computation, with general application throughout the whole of mathematics, that has been undertaken since the original calculation of the logarithms of numbers and trigonometrical functions of Briggs and Vlacq, 1620–1633.

DR. FREDERICK WELWITSCH, the well-known African explorer and botanist, died at his residence in London on Sunday, the 20th inst., in the 66th year of his age. A native of Carinthia, Dr. Welwitsch studied medicine at Vienna, and early devoted himself to botanical pursuits. When on a visit to Portugal, he was induced to take up his residence at Lisbon as Director of the Botanical Gardens there, and in 1853 was despatched by the Portuguese Government to Angola to investigate the natural history of that region, where he remained from 1853 to 1861. His collections of the vegetable productions of that country are unrivalled in extent and completeness, have established a new region in geographical botany, and have been copiously used in the compilation of the two volumes already published under the auspices of the authorities at Kew of the "Flora of Tropical Africa." Dr. Welwitsch was not himself an extensive writer, but the number of species new to science discovered by him and described by others is very large, among the most remarkable of which is one of the most extraordinary vegetable productions known, dedicated to him by Dr. Hooker, the *Welwitschia mirabilis*. He was also an accomplished zoologist, and his entomological collections are of great extent and value. It is understood that the British Museum will have the first option in the purchase of the most valuable part of his collections.

THE death on Monday, 21st inst., is announced of the physicist, M. Jacques Babinet, the academician, at the age of 78 years. He was elected to the Academy in 1840. Another member of the Academy, M. Puiseux, has also just died.

SIR JOHN LUBBOCK and Mr. Grant Duff are now travelling in Asia Minor; and it is expected they will bring home some very important and interesting information on the pre-historic remains of that region, an almost untried hunting-ground.

THE *Gardener's Chronicle* states that it is proposed that the sum of 48,000*l.* shall be included by the French Government in the Budget of 1873 for the commencement of the entire rebuilding of the museums and conservatories of the *Jardin des Plantes*, a move which has been long in contemplation. In addition, the vote for civil buildings for 1873 includes a sum of 8,000*l.* for the construction of laboratories of chemistry and zoology in the Museum for the *Ecole des Hautes Etudes*, and for the completion of the reptile house.

THE Board of Trinity College, Dublin, has elected Dr. Benjamin M'Dowell to the Professorship of Anatomy and Surgery, and has resolved to found a new Professorship of Comparative Anatomy, endowed with 100*l.* a year and a portion of the fees for dissections. The professor will have to deliver eighteen lectures each year.

THE Swiney Lectureship, which has just been vacated by Dr. Cobbold, will be filled up in February. It is a travelling Lectureship, open to Doctors of Medicine of Edinburgh University, and is tenable for five years.

THE statue to the memory of Sir Humphrey Davy has just been erected at Penzance, his native place. The statue, which cost 600*l.*, is a colossal one, and stands on a massive granite pedestal in front of the Post Office, and a few yards from the house in which the great chemist, philosopher, and inventor was born.

WE learn from the *Mechanics' Magazine* that a committee of the Derby and Chesterfield Institute of Engineers has been appointed to consider the possibility of erecting a memorial hall, to cost 20,000*l.* to 30,000*l.*, in memory of George Stephenson.

IN reference to Mr. J. R. Hind's letter to the *Times*, printed in its issue of Oct. 19th, on the subject of the probable existence of a planet revolving round the sun within the orbit of Mercury, we propose to revert to the subject as soon as Mr. Hind has further discussed the subject; as we learn that in consequence of errors in some of the calculations made by some who have previously inquired into the subject, a revision of some of the results announced in the letter in question is necessary.

AN admirable article has appeared in *Engineering*, under the heading, "Great Britain in Formâ Pauperis." The burden of the writer is the parsimonious, nay, even ungratefully insolent manner, in which the neighbourly request of Austria for a reciprocity of assistance (such as she and other nations afforded to England in 1851 and 1862) in the forthcoming Universal Exhibition at Vienna has been met by the Government and the Treasury. It appears, that whereas France, torn and bleeding at every pore, votes 60,000*l.*, her conqueror, Prussia, an equal sum, with a supplementary vote, Italy the same sum, Spain 1,200,000 reals, the minor states of Europe in proportion, even little Switzerland voting 16,000*l.*, Great Britain, wealthy and powerful, the ancient friend and ally of Austria, who has contributed to her exhibitions over 100,000*l.*, votes the noble, magnanimous sum of six thousand pounds sterling! We fully sympathise with the indignant comments of our contemporary at the lamentable parsimony for which our Government has made us responsible.

THE *Gardener's Magazine* announces its full adhesion to the views enunciated in our article on the potato disease, that it is in its origin cosmical, and probably connected with the great cycle indicated by the recurrence of sun-spots.

THE total number of entries at the various medical schools of London for the session just commenced is 1496, of which 476 are of new students, the former number being 21, and the latter 8 in excess of those last year. Guy's and University College Hospitals occupy the first place, each with 83 fresh entries. Westminster brings up the rear with 4.

THE prizes of the Charles Science and Art School, Plymouth, were distributed on Friday, Oct. 21, by Sir Massey Lopes, Bart. M.P., who spoke very encouragingly of the success of the schools.

MR. THOMAS WEBSTER, Q.C., F.R.S., will read a paper before the members and friends of the London Association of Foremen Engineers and Draughtsmen "On the Promotion of Practical Science and Technical Education by Museums of Inventions established and maintained by the Surplus of the Inventors' Fee Fund," at the meeting to be held on Saturday, the 2nd of November, at the City Terminus Hotel, Cannon Street, at 8.30 P.M.

THE Council of the Institution of Civil Engineers invite communications dealing in a complete and comprehensive manner with such subjects as (*a*) Account of the Progress of any Work in Civil Engineering, as far as absolutely executed—Smeaton's Narrative of the Building of the Eddystone Lighthouse may be taken as an example; (*b*) Descriptions of dis-

tinct classes of Engines and Machines of various kinds; (*c*) Practical Essays on Subjects allied to Engineering, as for instance, Metallurgy; and (*d*) Particulars of Experiments and Observations connected with Engineering Science and Practice. A list of thirty seven special subjects recommended for competition is appended. For approved original communications, the Council will be prepared to award the premiums arising out of special funds devoted for the purpose.

THE Crystal Palace Company's school of Art, Science, and Literature, has issued its prospectus for the thirteenth session, 1872-73, of classes for gentlemen, conducted by eminent professors and teachers.

THE following are the Science Lectures for the People to be given this winter at Manchester:—The first on Tuesday, Oct. 29, by Prof. Roscoe, F.R.S., On the Rainbow; and these other lectures will follow:—Prof. Geikie, F.R.S., On the Ice Age in Britain; Prof. Balfour Stewart, F.R.S., The Sun and the Earth; Prof. Clifford, On Atoms; Prof. Barrett, On Faraday's Electrical Discoveries; Dr. J. H. Gladstone, F.R.S., The Life of Faraday; Mr. William Pengelly, F.R.S., Prehistoric Man. The fee for each of these lectures, as before, is one penny! Many people will wish they lived in Manchester.

THE following lectures will be delivered in Gresham College, Basinghall Street, E.C., by E. Symes Thompson, M.D.; On Draughts, Friday, Nov. 8; On Mineral and Vegetable Tonics, Monday, Nov. 11; On Prescriptions, Tuesday, Nov. 12. The lectures are illustrated by diagrams and experiments, are free to the public, and commence each evening at seven o'clock.

THE following lectures are announced to be delivered in connection with the Torquay Natural History Society:—Introductory Address, by Dr. Wilks (President), Nov. 4. The Fertilisation of Flowers, by Dr. Wilks, Nov. 25. "Natural Selection," by Dr. Wilks, Dec. 2. Museums and Our Museum, by the Rev. T. R. R. Stebbing, M.A., Dec. 9. Fossils as characteristic of Strata, by J. E. Lee, F.G.S., F.S.A., Dec. 16. The Share of the Italians in the Progress of the Natural Sciences, by Signor Olivieri, Lit. and Phil. Doctor, Jan. 27, 1873. The Unity and Progress of Man, by J. B. Paige Browne, March 3. Monte Rosa—its Peaks, Valleys, and Glaciers, by Dr. Wilks, March 17. Teleology, by Rev. T. R. R. Stebbings, M.A., March 24. Curiosities of Natural History, by Dr. C. Paget Blake, April 7. Aerostation, by W. Froude, F.R.S., April 21.

IN addition to our announcements of last week, Mr Van Voorst announces as follows:—Mr. W. Saville Kent, of the British Museum, is engaged upon a new "Manual of the Infusoria:" the treatise will be devoted entirely to the Ciliate, Flagellate, and Suctorial Protozoa, to the exclusion of the Desmids, Diatoms, Rotifers, and other foreign organisms comprised under the above title by Ehrenberg, Pritchard, and other writers; the Rev. Thomas Hincks is preparing for publication "A History of British Polyzoa" with figures of all the species, uniform with his "Hydroid Zoophytes;" "The Birds of the Humber district," by John Cordeaux of Great Cotes, Ulceby, is in the press; a second edition, with new plates and additions, of "Falconry in the British Isles," by Capt. Salvin and Wm. Brodrick, is in preparation.

THE Zoological Society has just issued a revised list of the valuable animals now or lately living in the Society's Gardens. It contains a list of nearly 500 Mammalia, upwards of 1,000 Aves, and nearly 300 Reptilia, Batrachia, and Pisces, with their habitats and dates of acquisition, and is illustrated by 30 very well-executed woodcuts. As the list is published at the very low price of 2*s*., it ought to be in the hands of every one who is in the habit of using the Gardens.

PROF. MIGUEL COLMEIRO, director of the Botanic Garden at Madrid, announces the publication of the second edition of a "Treatise on the Elements of Botany, organographic, physiological, systematic, and geographical," in two vols,, with numerous illustrations. Prof. Colmeiro is the author of thirty separate papers on botanical subjects.

A SECOND edition is announced as in the press of Gardiner's "Flora of Forfarshire," edited by Mr. John Sadler, author of the "Flora of Edinburgh." Many important additions will be made to the original work, in which the editor will be assisted by resident botanists, and the author's valuable notes on the different species, and on various localities of special interest, will be retained.

JOHN HEYWOOD'S recently-published School Atlas is a marvel of cheapness. It contains twelve coloured maps about 10 in. by 8 in., of Europe, the two hemispheres, England and Wales, the British Isles (physical), Scotland, Ireland, Asia, Africa, North and South America, and Australia; and the price is Sixpence!

THE following we take from the *School Board Chronicle*:—"Some curious statistics have been published, establishing a suggestive comparison between the expenses of education and police supervision in the cities of St. Petersburg, Berlin, and Vienna. With regard to education, the expenses of the Russian capital are estimated at one per cent. of the total budget; Vienna stands as high as nine per cent.; and Berlin reaches thirty-one. Costs of philanthropic institutions are represented by the proportions of Berlin, twenty-two; Vienna, fifteen; and St. Petersburg, nine per cent. Of course, the ratio becomes inverted when we turn to the expenses of the police force. Here we find Prussia down for seventeen, Austria for twenty-one, and Russia for fifty-one (figures of comparison). Berlin employs one policeman for every 495 of its inhabitants, Vienna one for every 416, and St. Petersburg one for every 210. The practical teaching of these statistics is, that while Berlin pays twice as much for schools as for prisons and police, Vienna pays two and one-third times less, and St. Petersburg fifty times less."

THE same journal prints the following item of information:—"Reports concerning the four Prussian academies for the scientific pursuit of agricultural knowledge inform us that these institutions have been frequented during the past summer term by 173 students. Of these 65 were newly matriculated, and 10 unmatriculated. Classified according to their nationality there were 117 from Prussia, 13 from other German States, and 43 foreigners. In order of academic population Proskau stands first with 63 students; then comes Poppelsdorf, near Bonn, with 43; after that the institution at Berlin with 37; and last of all the Academy at Eldena with 30 students.

THE following, in reference to education in Greece, is again from the same journal:—"From 1835 to 1869, the number of students at the University of Athens had increased from 35 to 1,205; the number of gymnasia in Greece, which was 3 in 1835, had risen to 16 by the year 1866. During the same period of time the number of secondary schools had increased from 21 to 189, and that of the pupils frequenting them from 2,500 to 7,300; within 33 years, also (1833-66), the national elementary schools had increased from 17 to 1,070, and the scholars from 8,000 to 65,000. Among the secondary schools there were, in 1869, 6 institutions for girls, numbering 680 pupils. As a sorrowful set-off to such cheering news, it must be mentioned that there are still in Greece 240,000 children and youths who receive no education whatever; that is to say, more than three times the number of those who frequent the schools.

INTERNATIONAL METRIC COMMISSION

THE following methodical statement of the resolutions come to by the International Commission on Weights and Measures at its recent meeting at Paris was presented to the French Academy of Sciences by M. Tresca, one of the secretaries of the Commission.

I. *In reference to the Metre*

1. As a starting-point for carrying into effect an international measure, the Commission takes the metre of the Archives, in its present condition.

2. The Commission declares that, considering the actual condition of the platina measure of the Archives, it thinks the marked or line metre (*mètre à traits*) may be deduced from it with certainty. Nevertheless, this opinion of the Commission requires to be confirmed by the different processes of comparison which can be employed in this investigation.

3. The proportion (*équation*) of the International Metre will be deduced from the present length of the metre in the Archives, determined according to all the comparisons which have been made by means of the processes which the International Metric Commission will be in a condition to employ.

4. While deciding that the new International Metre ought to be a line-metre (*mètre à traits*), of which every country will receive an identical copy made at the same time as the universal prototype, the Commission will feel bound afterwards to construct a certain number of standards marked by projections (*étalons à bouts*) for those countries which desire them; and the proportions of such metres to the new prototype *à traits*, will also be determined under the care of the International Commission.

5. The International Metre will have the length of the metre at zero (centigrade).

6. There will be employed for the manufacture of the metres an alloy composed of 90 parts of platina and 10 of iridium, with a margin (*une tolérance*) of 2 to the 100, more or less.

7. In manufacturing the measures, the ingot must be formed by a single casting by means of the processes used in the working of the known metals. The number and form of these measures will be determined by the International Commission.

8. These measures will be annealed for many days, at the highest temperature—notwithstanding that they are never likely to be subjected to anything but the most feeble strains—before taking them to be compared with the standard instruments.

9. The bars of platina alloy upon which the line-metres are to be traced, will have a length of 102 centimetres, and their transverse section will be represented by the model described in a note of M. Tresca.

10. The bars intended for the construction of the projection metre measures (*à bouts*), will have a similar transverse section, but symmetrical in the vertical direction, conformably to the special figure which represents it; the nobs or projections (*bouts*) will then be wrought with a spherical surface of one metre radius.

11. During all the operations which the standard metres must undergo, they will be supported on the two rollers (*rouleaux*) indicated by General Baron de Wrede; but, for their preservation, they will be placed in a suitable case.

12. Each of the International Metres ought to be accompanied by two mercurial thermometers, isolated, and carefully compared with an air-thermometer; it is deemed necessary that these thermometers should be verified from time to time by means of the air-thermometer.

13. The method of M. Fizeau will be employed to determine the dilatation of the platina alloy used in the construction of the metres.

14. The prototypes will be submitted to the processes by means of which the coefficients of the absolute dilatation of the complete metres can be best determined. These measures will be separately made, at five different temperatures at least, between zero and 40° centigrade.

15. The comparison of the prototypes with each other ought to be made at, at least, three temperatures comprised between these same limits.

16. The Commission decides that two apparatus be constructed, the one with a longitudinal movement for tracing these metres, the other with a transverse movement for their comparison.

17. The comparisons will be made by immersing new standards in a liquid and in air; but the standard of the Archives must not be immersed in any liquid before the end of the operations.

18. The tracing of the line or traced metres (*à traits*), and their first comparison with the metre of the Archives, will be for the first effected by means of M. Fizeau's process.

19. For the determination of the proportions of the various standards, there will be employed moreover all the means of comparison already known and approved, according to circumstances, either by actually bringing the different forms into contact, or by the method of Messrs. Airy and Struve, or by that of MM. Stamkart and Steinheil.

20. The relations between the Archive metre and the new International traced metre, as well as the relations between the other traced standards and the International Metre, will be determined by comparing the results of all these observations.

21. Operations will be performed, on the other hand, by setting out from the International Metre for the construction of the standards with projections (*étalons à bouts*), which may be asked for by various states.

II. *In reference to the Kilogramme*

22. Considering that the simple relation established by the authors of the metric system between unity of weight and unity of volume is represented by the actual kilogramme in a manner sufficiently exact for the ordinary uses of industry, and even of science; considering also that the exact sciences have no real need of a simple numerical relation, but only of a determination as exact as possible of that relation; and considering the difficulties which would result from a change of the existing unity of metric weight, it is decided that the international kilogramme will be derived from the kilogramme of the Archives in its present condition.

23. The International Kilogramme ought to be decided by weighing in a vacuum.

24. The material of the International Kilogramme will be the same as that of the International Metre, viz.: an alloy of platinum and iridium, as stated in No. 6.

25. The material of the kilogramme will be founded and cast in a single cylinder, which will afterwards be subjected to furnace heat and mechanical operations, such as will give to its whole mass the necessary homogeneity.

26. The form of the International Kilogramme will be the same as that of the kilogramme of the Archives, viz., a cylinder whose depth is equal to its diameter, and whose corners may be easily rounded.

27. The determination of the weight of the cubic decimetre of water ought to be made under the direction of the International Commission.

28. The balances which will be used for weighing ought to be, not only those which may be placed for the present at the disposal of the Executive Committee by institutions and men of science who possess them, but also a new balance constructed according to conditions of the greatest exactness.

29. The volumes of all kilogrammes will be determined by the hydrostatic method; but the kilogramme of the Archives will neither be placed in water nor in a vacuum before the end of the operations.

30. To determine the weight of the new kilogramme, in comparison with that of the Archives, in a vacuum, two auxiliary kilogrammes will be made use of, as nearly as possible of the same weight and the same volume as that of the Archives, according to the method indicated by M. Stas. Each of the new kilogrammes ought also to be compared in air with the kilogramme of the Archives.

31. When the International Kilogramme is constructed, all others will be compared with it, in air and in vacuum, for the determination of their proportions.

32. For this purpose is employed the method of alteration and that of substitution, with a counterpoise of the same material.

33. The corrections for losses of weight in air will be effected by means of the most precise and least disputed data of science.

III. *In reference to the carrying out of the Commission's Decision*

34. The making of the new prototypes of the metre and the kilogramme, the tracing of the metres, the comparison of the new prototypes with those of the Archives, as well as the construction of the auxiliary apparatus necessary to these operations, are entrusted to the care of the French section, with the concurrence of the Permanent Committee, provided in the following article.

35. The Commission has chosen from its members a Permanent Committee, which will do duty till the next meeting of the Commission, with the following organisation and powers:—(*a*.) The Permanent Committee will be composed of twelve members, belonging to different countries. Five of these members

constitute a quorum : it will choose a president and secretary, and will meet as often as it deems necessary, but at least once a year. (*b.*) The Committee will direct and superintend the execution of the decisions of the International Commission, in reference to the comparison of the new metric prototypes with each other, as well as the construction of balances and other auxiliary apparatus necessary for these comparisons. (*c.*) The Permanent Committee will perform the work indicated in (*b*) with all appropriate means which may be at its disposal ; it will meet for the performance of its task at the International Bureau of Weights and Measures, the establishment of which will be recommended to the nations interested. (*d.*) When the new prototypes will be constructed and compared, the Permanent Committee will give a report of its work to the International Commission, which will sanction the prototypes before distributing them to the different countries.

36. The Commission suggests to Governments interested how great would be the utility of founding at Paris an International Institution of Weights and Measures, upon the following bases :—1st. The establishment would be international and declared neutral. 2nd. Its seat will be at Paris. 3rd. It would be founded and supported at the common cost of all the countries which adhere to the treaty that might be made between the interested states for the creation of the establishment. 4th. The establishment will depend upon the International Metric Commission, and will be placed under the superintendence of the Permanent Committee, who will choose the director. 5th. The International Bureau would serve the following purposes :—(*a.*) It will be at the disposal of the Permanent Committee for the comparisons which will serve as a basis for the verification of the new prototypes with which the Committee is charged. (*b.*) The preservation of the international prototypes, in accordance with the directions laid down by the International Commission. (*c.*) The periodical comparison of the international prototypes with the national standards and with the tests, as well as that of the standard thermometers, according to the rules laid down by the Commission. (*d.*) The construction and verification of the standards which other countries may require in future. (*e.*) The comparison of the new metric prototypes with the other fundamental standards employed in the different countries and in science. (*f.*) The comparison of standards and scales which may be sent for its verification, either by Governments or by scientific societies, or even by mechanicians and servants. (*g.*) The Bureau would execute all the works which the Commission or its Permanent Committee would require of it in the interest of metrology and the propagation of the metric system.

37. The Bureau of the Commission is required to apply to the French Government, and request it to be good enough to communicate diplomatically the views of the Commission concerning the foundation of an International Bureau of Weights and Measures to the Governments of all the countries represented in the Commission, and to invite these Governments to conclude a treaty to create harmoniously, and as soon as possible, such an International Bureau upon the bases proposed by the Commission.

IV. Concerning the means of Preserving the Standards and the Guarantee of their Invariability

38. The Commission is of opinion that the International Standard ought to be accompanied by four identical measures, maintained at a temperature as invariable as possible ; another identical measure ought to be preserved, for the sake of experiment, at an invariable temperature in vacuo ; it would take means to establish tests in quartz and beryl, to be compared at any time with the complete measure, in whole or by portions. (The other means are reserved.)

39. The Commission thinks that in the interest of geodesy the French Government should cause to be re-measured, at a convenient time, one of the new French bases.

All these resolutions were made by the Commission most harmoniously, and in a spirit of complete confraternity ; all the votes were nearly unanimous.

BIRTH OF CHEMISTRY

III.

Practical Chemistry of the Ancients.—Metallurgy ; gold, silver, electrum, copper, bronze, tin.

IN the preceding articles we have discussed such theories of the ancients as involve the conception of change of matter (notably the assumed transmutation of the elements), and which hence concern the early history of chemistry. Having done with theory, we have now to inquire to what extent the ancients were acquainted with practical chemistry, what metals or other elements were known to them, and what processes dependent upon chemical action. We do not, of course, use the term "practical chemistry" strictly in its present sense, because chemistry as a science was altogether unknown to the ancients. Some have indeed endeavoured to prove that the Egyptians must have been acquainted with the science, from the skill with which they used various metallic oxides for colouring glass ; but we have no proof of this. Neither Herodotus, nor Pliny, nor Vitruvius, indicates any knowledge of chemistry as a science among either Egyptians, Greeks, or Romans. Pliny, in his celebrated "Natural History," has laboriously amassed all the practical science and pseudo-science which the ancients possessed, and we find no mention of either chemistry or alchemy. At the same time it is impossible that the Egyptians and Sidonians can have attained their marvellous skill in the manufacture and colouring of glass, and in the extraction and working of metals, without the acquirement of a considerable amount of knowledge of the properties of matter, and of certain chemical changes. But this knowledge could never be worked up into a comprehensive system ; it resulted from the labour of artizans, and the gulf between the philosopher and the manipulator was both wide and deep. There could be no union of practice and theory. Between Herakleitos with his theory that fire is the primal element, the actuating force of the Universe, and the man who wrought metals never so deftly, who applied fire to the use and service of mankind, there was no sympathy, no reciprocal transference of ideas. To reason concerning the properties of matter with one's eyes shut was all very well, but to experiment with matter, to endeavour to determine the cause of such and such a change by experiment, was utterly unworthy of a philosopher. Anaxagoras is said to have made an experiment to prove that there is no vacuum. Aristotle found that a bladder of air weighed in air weighed more than the empty bladder (which, if the experiment be properly made, is by no means the case), and hence concluded that the air has weight. But these are solitary exceptions ; the way to study Nature, if she is to be studied at all, is, they maintained, to apply the pure, unaided intellect to the study, and to keep mind and matter as distinct as possible. From all this it resulted that your workers in metals and in curious arts, your makers of glass and pigments, kept their knowledge of matter to themselves, as secrets to be handed down from father to son.

Seven metals were known to the ancients, viz., gold, silver, copper, tin, iron, lead, and mercury. The first six are mentioned by Homer, and appear to have been known from remote antiquity, while mercury was not known till a later date ; it was, however, common in the first century B.C. The Greek word μεταλλον, whence *metallum* and *metal*, signifies *a mine*, hence it was applied to anything found in mines, notably metals ; μέταλλον is connected with μεταλλ'ω, "to search for diligently."

Gold has been valued from the earliest ages, on account of the peculiarity of its colour, its lustre, and its unalterability in air. The metal is invariably found in the native state, that is, uncombined with other substances, hence no metallurgical operation is necessary for its extraction. It is very often met with in surface deposits, and in early times was undoubtedly far more common in alluvium and the beds of rivers than now. It would thus be easily extracted by washing, and the grains could readily be fused together into a mass. Gold mines formerly existed in Ethiopia, in which the gold was found in a matrix of quartz, like much of the Australian gold of the present day. These mines were worked by the Egyptians, who employed large gangs of slaves for the purpose. The quartz was crushed, and the gold obtained from it by washing. We find representations of gold washings, and the subsequent fusion of the metal, on Egyptian tombs, at least as early as 2500 B.C., that is to say, about the time of Joseph in Hebrew history. The woodcut (Fig. 1) on the following page is given by Sir Gardner Wilkinson, and is taken from a tomb at Beni Hassan : it represents gold washing, and the fusion and weighing of the metal.

It is obvious that the process is only indicated, and not accurately or minutely portrayed. Another form of furnace is depicted below (Fig. 2), and a blowpipe somewhat different from that shown in Fig. 1. The raised portion of the furnace is doubtless for the purpose of concentrating the heat upon the crucible, on the principle of the reverberatory furnace.

Gold once obtained was soon made into ornaments ; very fine gold wire was used by the Egyptians for embroidery 3,300 years ago. Many of the Egyptian and Etruscan gold ornaments are

very beautiful; we may notice particularly the gold myrtle wreath found in an Etruscan tomb a few years ago. The Egyptians also used gold for inlaying, and it was beaten into leaf and used for gilding as early as 2000 B.C. In the Odyssey the gilding of the horns of an ox about to be sacrificed is mentioned.

Silver, like gold, is often found native, and from several of its ores the metal may be extracted by the action of heat alone. It has been known from the earliest ages, and was used chiefly for ornaments and embroidery. Gold was used for money before silver, which was first known as "white gold." The oldest silver Greek coin is a coin of Ægina, and was, perhaps, coined in the eighth century B.C. But the oldest coins in existence are the *electrum* staters of Lydia. Electrum consists of about three parts of gold to one of silver. Probably the metals were first found in nature thus alloyed, and as no method of separating them was then known, they were worked up together. Electrum was so called from its resemblance as regards colour to amber (ἤλεκτρον), which received its name from ἠλέκτωρ, the sun. It will be remembered incidentally that the science of Electricity was so called by Gilbert of Colchester, because the attractive force was first observed in amber. Amber is mentioned more than once by Homer. Electrum as a metal is first mentioned in the *Antigone* of Sophocles. It was found naturally alloyed, as in the pale gold of the Pactolus, which contains a good deal of silver; and was also made artificially. Probably all very pale gold was called electrum; Pliny states that gold containing a fifth part of silver is called electrum. In the British Museum there are many coins made of this alloy.

Copper was in use before iron. It is, as is well known, usual to denote various early ages by the substances then used for domestic implements. Thus we have the "age of stone," the "age of iron," &c. The stone age is followed by the age of copper, this by the age of bronze, and the age of bronze by the age of iron. Homer wrote in the age of copper; the shield of Achilles is made of gold, silver, tin, and copper; the arms and implements and utensils of his heroes are of copper. Mr. Gladstone has argued at some length that by chalcos (χαλκος) Homer meant copper, not bronze, as it is so often rendered. Chalcos is spoken of as a cheap and common metal, while tin was very scarce and rare; and it is scarcely probable that so many things, even down to the commoner utensils, could have contained ten or twelve per cent. of tin. Again, Mr. Gladstone points out that Homer speaks of chalcos as ερυθρος, red, a term that could not apply to bronze; and he goes so far as to say, "If chalcos be not copper, then copper is never mentioned in Homer" (*Juventus Mundi*, p. 530). At the same time we must remember that copper is very soft for cutting-instruments, and a small quantity of tin hardens it; some of the Greek bronzes only contain 1 per cent. of tin. Dr. Percy found in a bronze bowl of great antiquity from Nineveh, copper 99·51, tin ·63. Ancient nails have been found containing copper 97·75, tin 2·25; and Mr. Gladstone suggests that, as tin is sometimes found associated with copper in nature, this may account for their composition. Copper is sometimes found native, sometimes in the form of ores, from which the metal is easily extracted. It appears to have been both cheap and plentiful at an early date. Romulus is said to have coined copper; it was also used for money by the Egyptians. Great confusion exists among old writers regarding the words signifying bronze and copper: Pliny clearly did not understand the difference between copper and bronze. The words *æs* and χαλκός appear to have been applied indiscriminately both to copper and to alloys of copper containing a large proportion of that metal. Copper was alloyed with tin at such an early date, because copper is soft and is unsuitable for cutting-instruments, while the addition of tin hardens it. The fusing point of copper is between that of gold and silver, and is far below that of iron, while the fusing point of tin is only 446° F. Thus the two metals could be alloyed without any special metallurgical difficulties or the requirement of an inordinate temperature. Copper was first obtained by the Romans from Cyprus, where it was very plentiful; they called it *Æs Cyprium*, which became corrupted into *Cuprum*, from which we get our present chemical symbol for

FIG. 1.—Gold Washing: Fusion and Weighing of the Metal, from early Egyptian Tomb

copper, *Cu*. According to Solinus *æs* was found at Chalkis, in Eubœa, hence χαλκος, the Greek word for copper. We read of "ores of æs," and of brass and bronze being dug out of mines, whereas the term *brass* is applied by us to an alloy composed of copper and zinc, and *bronze* to an alloy of copper and tin. Zinc as a metal was unknown to the ancients, and brass appears to have been made in Pliny's time by heating together metallic copper, calamine (a native carbonate of zinc), and charcoal; the latter reduces the calamine, and the metallic zinc and copper then combine. According to Dr. Thomas Thomson, *aurichalchum*, or golden copper, was the proper name for brass. *Æs* is to be always translated copper or bronze, *not* brass, of which latter very little use appears to have been made. Among other alloys of copper, the ancients possessed the celebrated *Æs Corinthiacum*, which, according to Pliny, was formed accidentally during the burning of Corinth, by Mummius, B.C. 146. There were four varieties of this, one of which contained equal proportions of gold, silver, and copper; the others were most probably various admixtures of copper and tin. The commonest kind of ancient bronze contained in 100 parts, 88 parts of copper, and 12 parts of tin. Two specimens of bronze from Nineveh were found by Dr. Percy to contain respectively—

FIG. 2.—Furnace and Blow-pipe from Egyptian Tomb

	Bronze hook.	A small bell.
Copper	89·85	84·79
Tin	9·78	14·10
	99·63	98·89

The proportion of copper and tin (about 10 to 1) is, remarks Mr. Layard, the composition of our best modern bronze, while the increase of tin in the case of the bell proves that the Assyrians were well acquainted with the increase of sonorousness produced by changing the proportions of the metals. Modern bell metal contains about 80 parts of copper to 20 parts of tin. Sometimes a small quantity of lead was introduced by the ancients

into their bronzes. Thus, a certain bronze for statues was formed by fusing together 100 parts of copper, 10 parts of lead, and 5 parts of tin. In a very ancient bronze armlet (probably Phœnician) found in this country, and belonging to a period anterior to the Roman occupation, Prof. Church found—

Copper	86·49
Tin	6·76
Zinc	1·44
Lead	4·41
Oxygen and loss	·90
	100·00

Bronze was very much used in Egypt for vases, mirrors, arms, &c. These, according to Sir G. Wilkinson, usually contain from 80 to 85 per cent. of copper, with from 15 to 20 per cent. of tin. By the use of some acid substance, the surface was sometimes covered with a green or brown patina. Although the casting of the metals was not known in Greece in the time of Homer, bronze was probably cast in Egypt 2000 years B.C.

Several compounds of copper were used by the ancients, both the red and black oxide were obtained by heating copper to redness, and allowing it to cool in the air; they distinguished between the scales which fell off during cooling, and those which were caused to fall off afterwards by blows of a hammer. These oxides were principally used for colouring glass. Verdigris or acetate of copper was obtained as now by covering plates of copper with the refuse of grapes after the expression of the vine juice. Copper pyrites and a rude kind of sulphate of copper would appear from Pliny's obscure account to have also been known.

It follows from the above remarks concerning bronze, that tin, like copper, was known at a very early date. This is the more remarkable, because it has always been a comparatively scarce metal, and it was obtained from distant localities. Formerly it was almost entirely supplied by Spain and Britain. The Phœnicians, who were the earliest traders, obtained it first from India and Spain, and afterwards from Britain. The Greek name for tin, kassiteros (κασσιτέρος), was perhaps derived from the Insulæ Cassiterides, or Scilly Islands, from whence the Phœnicians asserted that they procured tin; but it has been suggested that in all probability they invented the story because they desired a monopoly of the metals, while in reality they procured all their tin from the mainland of Cornwall, where it has always abounded. Tin must have been very valuable, or the Phœnicians would not have traded so far for it. Homer evidently considers it of far greater value than copper. In the time of Pliny it was worth about eight shillings the pound. The metal was known in Egypt 2000 B.C. Pliny mentions that it was found in the form of small black grains in alluvial soils, from which it was obtained by washing; this account would agree with a description of the so-called *stream tin*, which is tin ore separated from the parent vein, and carried down by streams. It is an oxide of tin, and the metal is obtained from it by strong ignition with charcoal. Tin was used for tinning copper vessels, for making mirrors, and in the manufacture of bronze. In the Iliad the greaves of the armour of Achilles are made of tin, and it enters into the composition of the shield; it was also used for coating copper.

(*To be continued.*)

SCIENTIFIC SERIALS

THE *Bulletin de l'Académie Impériale des Sciences de St. Petersbourg*, xvii., No. 2, commences with a proposed new classification of the Balænoidea, by J. F. Brandt, with the view of including extinct forms recently met with in Central and Southern Europe, and in Central Asia. He bases it mainly on skeleton structure, with special reference to form of cranium. The next paper contains some algological studies by Christopher Gobi. He describes how moisture, with heat and light, acts on chlorophyll in the cells of Chroolepus, accumulating it at the periphery, and leaving a nucleus of red pigment at the centre. He also describes a new species of the plant, which he terms *Chroolepus uncinatus*. It is found on the maple, ash, and linden, and its chief characteristic is a hook-shaped zoosporangium with subsporangial cell at the end of a series of irregular cylindrical-shaped cells forming the stalk. The growth of the zoosporangia takes place only at night. This new species is most closely allied to the *C. umbrinus*. —C. J. Maximowicz gives a full description, in Latin, of certain plants in Japan and Mandshuria.—The last paper is by C. J. Maximowicz, on the influence of strange pollen on the form of fruit. He experimented with two very distinct species of lily, *L. davuricum* and *L. bulbiferum*, kept in a room warmed by sunlight. He fertilised the flower of each with pollen from the other, and the process was repeated in several individuals. When the capsules developed, each was found to have the form characteristic of the other plant. The form of the seeds in both was intermediate between those of the parents.

Annalen der Chemie und Pharmacie, No. 9, 1872.—The first article, by Dr. Schreder, describes a new product of styphnic acid, obtained by reaction of cyanide of potassium with the neutral potassa salt of the acid. He names it *Resorcin-Indophan*, and gives as its formula $C_9H_4N_4O_6$. It is soluble in water, but insoluble in alcohol and ether. The potassa, soda, and baryta salts of the substance are discussed.—In a paper on some combinations of vinyl, Dr. Baumann describes the action of sodium methylate on an excess of iodide and bromide of vinyl at ordinary temperature; experiments on the action of cyanides of potassium and of silver on bromide of vinyl; and the conversion of bromide and chloride of vinyl into isomeric bodies.—An essay on camphoric acid, by F. Weeden, contains an account of a new modification, called meso-camphoric acid, obtained by action of hydriodic and hydrochloric acid on dextro-camphoric acid; its formula is $C_{10}H_{16}O_4$. He also treats of substitution products of camphoric acid anhydride and of amido-camphoric acid.—A paper on "Carbazol," a substance prepared from coal-tar oil, is furnished by C. Graebe and C. Glaser; and Herr Graebe also communicates a note on "Vapour Densities of some Aromatic Compounds of High Boiling-point."

Poggendorff's Annalen der Physik und Chemie, No. 6, 1872.—This opens with a detailed account, by Dr. Rudolph Kœnig, of his various experiments with manometric flames. His apparatus is based on the effects of sound-waves upon a membrane presented to them, which, in its turn, affects a stream of gas flowing to a jet, causing the latter to dance. The jet is imaged on the mirror-covered sides of a revolving box, and its successive motions (caused by the sound and varying with it) appear from the reflection, which, through the box's motion, becomes a luminous line of images. Dr. Kœnig has successfully employed this method in the study of various acoustical effects—combinations of notes, vowel sounds, "overtones," interference, &c., and the varieties of flame-forms produced are fully shown by numerous drawings.—In the paper following, S. Lamansky describes a series of careful experiments on the heat spectra of the sun and the lime light. The absorption bands in the ultra red of the former had the same position, though the prisms were varied, those used being flint glass, bisulphide of carbon, and rock salt. The position and intensity of the heat maximum and the intensity of absorption were found to vary with the time of year and of day at which the observations were made. The heat spectrum of limelight is continuous, and its maximum further removed from the end of the visible spectrum than in the case of sunlight.—E. Hagenbach continues the account of his experiments on fluorescence of various substances; and H. Weber communicates a paper on the Heat Conductivity of Iron and of German Silver.—The serial also contains (of original articles) a short note from Prof. Clausius in reply to Prof. Tait's last communication; a description of an improved Holtz machine, by W. Musaeus; a note on the spectrum of aurora, by A. v. Oellingen; and one or two others not calling for special notice.

THE *Scottish Naturalist* for October opens with an article by Mr. J. Allen Hooker, on "The Study of Entomology," containing some very useful hints to young entomologists as to the direction in which their studies and observations can be most usefully turned, some of which are all but entirely neglected by collectors in this country. Mr. James Hardy then describes his new "Ragwort-seed Fly," *Anthomyia Jacobææ*; and Dr. Buchanan-White concludes his account of the nest of *Formica rufa* and its inhabitants. A number of items of information of especial interest to Scottish zoologists and botanists fill up the number. In both the last two numbers there are instalments of the "Insecta Scotica," the Lepidoptera of Scotland by Dr. Buchanan-White, and the Coleoptera of Scotland by Dr. D. Sharp.

SOCIETIES AND ACADEMIES

PHILADELPHIA

Academy of Natural Sciences, April 9.—Prof. E. D. Cope read a paper on "Intelligence in Monkeys." "I have two species of *Cebus* in my study, *C. capucinus* and a half-grown *C. apella*. The former displays the usual traits of monkey ingenuity. He is an admirable catcher, seldom missing anything, from a large brush to a grain, using two hands or one. His cage door is fastened by two hooks, and these are kept in their places by nails driven in behind them. He generally finds means sooner or later to draw out the nails, unhook the hooks, and get free. He then occupies himself in breaking up various objects, and examining their interior appearances, no doubt in search of food. To prevent his escape I fastened him by a leather strap to the slats of the cage, but he soon untied the knot, and then relieved himself of the strap by cutting and drawing out the threads which held the flap for the buckle. He then used the strap in a novel way. He was accustomed to catch his food (bread, potatoes, fruit, &c.) with his hands, when thrown to him. Sometimes the pieces fell short three or four feet. One day he seized his strap and began to throw it at the food, retaining his hold of one end. He took pretty correct aim, and finally drew the pieces to within reach of his hand. This performance he constantly repeats, hooking and pulling the articles to him in turns and loops of the strap. Sometimes he loses his hold of the strap. If the poker is handed to him, he uses that with some skill for the recovery of the strap. When this is drawn in, he secures his food as before. Here is an act of intelligence which must have been originated by some monkey, since no lower or ancestral type of mammals possess the hands necessary for its accomplishment. Whether originated by Jack, or by some ancestor of the forest who used vines for the same purpose, cannot be readily ascertained. After a punishment the animal would only exert himself in this way when watched; as soon as an eye was directed to him he would cease. In this he displayed distrust. He also usually exhibited the disposition to accumulate to be quite superior to hunger. Thus he always appropriated all the food within reach before beginning to eat. When different pieces were offered to him, he transferred the first to his hind feet to make room for more, then filled his mouth and hands, and concealed portions behind him. With a large piece in his hands, he would pick the hand of his master clean before using his own, which he was sure of."

PARIS

Academy of Sciences, October 14.—M. Faye, President. M. Tresca presented to the Academy the resolutions of the International Metrical Commision, which will be found in another column. — M. Yvon Villarceau then read a paper on the constant of aberration and the speed of light, considered in their connection with the absolute movement of translation of the solar system.—M. J. Bertrand presented observations on the last number of the "Journal für die reine und angewandte Mathematik," Berlin (Band 75, Erstes Heft); the observations consisted of a reply to Helmholtz's answer to the objections raised against his electro-dynamic theory.—M. Max Marie then read, "An extension of the Method of Cauchy to the study of Double Integrals, or theory of elementary contours in space."—A note from M. Ch. V. Zenger, on the action of conductors disposed symmetrically around an electroscope, followed. It was referred to the Commission on lightning conductors.—Some new documents from M. Buss relative to his governor for motive power engines were referred to MM. Tresca and Morin. A project for military aërostation, from M. J. Boué, and another for aerial navigation from M. H George, were referred to the Commission on Aërostation.—M. E. Guillier's proposed process for the destruction of *Phylloxera* by the use of a "mixture of the ashes of healthy vine wood, soot, river sand, washing water, essence of turpentine, and ammonia," M. Ajot's proposal for the same purpose, and M. Loarer's* note on the appearance on some exotic plants of certain insects believed to have come from transported *Phylloxera* eggs, were all referred to the *Phylloxera* Commission.—M. F. Massieu's note on the determination of the maximum tensions of vapours was then read, and was followed by a note from M. T. du Moncel on the action of carbon powder rammed down round the negative electrodes of carbon batteries. The author finds that coarse carbon powder thus used greatly diminishes the resistance in the battery.—This paper was followed by one from M.M. Schützenberger and Géradin, on a new process for the estimation of free oxygen.—M. A. Petit's note on "antifermentescible substances" followed. By the above name the author means bodies which prevent fermentation, he finds bichloride and binoxide of mercury the most powerful in this way.—M. E. J. Marey then read a note on the paces of horses studied by the graphic method. The author exhibited a number of traces obtained by an instrument which followed the muscular movements and traced them on paper.—Next came M. A. Sanson's paper entitled "Researches on the Fleeces of precocious Merinos."—M. Stan. Meunier then read a paper on the characters of the crust produced on terrestrial rocks by atmospheric agency, compared with the black outer crust of grey meteorites.—After which M. Chasles made some remarks on presenting a work entitled, "I'S. Offizio, Copernico e Galileo," &c., by M. Govi. He was followed by M. Larrey, who addressed the Academy on presenting the Report of the Director-General of the Medical Department of the English Army, for 1870; and after M. Bouley had made a long and very favourable critique on Mr. Fleming's work on hydrophobia, the session was adjourned.

* In the report of the meeting for the 30th September this author proposed the use of sulphide of arsenic to destroy the *Phylloxera*, and his name was then wrongly given "Louvet."

BOOKS RECEIVED.

ENGLISH.—On the Culture of the Observing Powers of Children (Youmans and Payne: (H. S. King and Co).—The English Elocutionist: C. Hartley (Groombridge).—Human Physiology: J. L. Nichols, M.D. (Trubner).

FOREIGN.—Die Sonne: Parts 2 and 3: P. A. Secchi.—Medizinische Jahrbücher: S. Stricker, 1872, Parts 2 and 3.—Bulletin de la Société Impériale des Naturalistes de Moscou, 1872, No. 1.—Bericht über die Senckenbergische Naturforschende Gesellschaft, 1871-1872.

DIARY

FRIDAY, NOVEMBER 1.

GEOLOGISTS' ASSOCIATION, at 8.—On the Influence of Geological Reasoning on other Branches of Knowledge: Dr. Hyde Clarke.

SUNDAY, NOVEMBER 3.

SUNDAY LECTURE SOCIETY, at 4.—On Ancient and Modern Egypt; the Pyramids and the Suez Canal: W. B. Carpenter, M.D., F.R.S.

MONDAY, NOVEMBER 4.

ANTHROPOLOGICAL INSTITUTE, at 8.—Man and Ape; and The Origin of Serpent Worship: C. Staniland Wake.

TUESDAY, NOVEMBER 5.

SOCIETY OF BIBLICAL ARCHÆOLOGY, at 8.30.—Adjourned Discussion upon Israel in Egypt: Rev. D. Haigh, M.A.—On an Assyrian Prayer: Henry Fox Talbot.—On the Religious Beliefs of the Assyrians, No. II.: Henry Fox Talbot.—On the Tomb of Jacob at Shechem: Prof. Donaldson.—A T Conjugation such as exists in Assyrian, shown to be a character of early Shemite speech by its vestiges found in the Hebrew, Phenician, Aramaic, and Arabic Languages: Richard Cull.

ZOOLOGICAL SOCIETY, at 8.30.—Report on additions to the Society's Menagerie: the Secretary.—On *Platypsyllidæ*, a new family of Coleoptera: Dr. G. L. Le Conte.—On Lepidoptera collected by Dr. Van Patten in Costa Rica: Messrs. A. G. Butler and H. Druce.

WEDNESDAY, NOVEMBER 6.

MICROSCOPICAL SOCIETY, at 8.—On the Structure of the Valves of *Eupodiscus Argus* and *Isthmia enervis*: H. J. Slack.—Proposal for a standard of comparison of the magnifying powers of Compound Microscopes: J. E. Ingpen.

THURSDAY, NOVEMBER 7.

LINNEAN SOCIETY, at 8.—On the "Piopio" of New Zealand (*Keropia crassirostris Gmel*): T. H. Potts.—On the buds developed on leaves of *Malaxis*: George Dickie, M.D.
